Refrigerators

Introduction

Citizens and households are responsible for a large share of global energy and electricity consumption and the related greenhouse gas emissions into the atmosphere. Residential energy demand is also rapidly increasing, due to a higher degree of basic comfort and level of amenities: larger homes, new services and new appliances and equipment (in particular information and communications technology, ICT), which is putting a strain on the economies and energy infrastructures of both developed and developing countries.

Energy efficiency improvements in *residential appliances, heating and cooling equipment, ICT equipment and lighting* can play a key role in achieving a sustainable energy future and socio-economic development, and at the same time mitigate climate change. Energy efficiency measures related to residential appliances, heating equipment and lighting are in most cases highly cost-effective CO_2 emission reduction actions, and offer good opportunity to increase the security and reliability of energy supply. In developing countries efficient residential appliances and lighting are vital to reduce household energy costs, to improve living conditions while reducing local pollution. In addition to technical progress on efficiency, large energy savings and carbon reduction can only be achieved with a paradigmatic change in consumer behaviour in the context of usage patterns of energy using products. These changes must be aided by “smart” product design providing automatic optimisation of energy and water resource usage for a given task and providing readily accessible feedback to the consumer to catalyse optimum usage patterns.

These themes are echoed in a growing number of *policy commitments* and in strategies calling for action at local, regional, national and global levels. The challenge, now, is to ensure market, policy, trade and information barriers do not impede the timely development, delivery and proper use of energy efficient residential equipment, resulting in a missed opportunity for climate change mitigation, security of energy supply and socio-economic development, particularly considering the present global economy. Last, but not least, the consumer must accept these changes and not misuse energy saving on one side by energy consumption for other purposes.

In addition, *smart appliances* and equipment, *smart meters* and communication protocols, allow households to be a key part of the *smart grids*, with storage, load flexibility and generation capabilities through renewable energies and *demand response and system energy savings*.

The international community of stakeholders dealing with residential appliances, equipment, metering and lighting (including manufacturers, retailers, consumers, governments, international organisations and agencies, academia and experts) have already gathered six times at the **International Conference on Energy Efficiency in Domestic Appliances and Lighting (EEDAL)** (Florence 1997, Naples 2000, Turin 2003, London 2006, Berlin 2009, Copenhagen 2011) to discuss the progress achieved in technologies, behavioural aspects and policies, and the strategies that need to be implemented to further progress this important work.

The previous EEDAL conferences have been very successful in attracting an international audience, representing a wide variety of stakeholders involved in policy implementation and development, as well as the manufacturing and promotion of energy efficient residential appliances and lighting. The EEDAL conference has established itself as an influential and recognised international event where participants can discuss the latest developments, establish synergies and build international partnerships among stakeholders.

Following the success of the previous EEDAL conferences, the University of Coimbra and the European Commission Joint Research Centre, in collaboration with the United Nations Development Programme, the International Energy Agency, and the Collaborative Labeling and Appliance Standards Program (CLASP), organised the 7th International Conference on Energy Efficiency in Domestic Appliances and Lighting – EEDAL'13, 11-13 September 2013, in Coimbra, Portugal

EEDAL'13 provided a unique forum to discuss and debate the latest developments in energy and environmental impact of residential appliances and lighting, heating and cooling equipment, ITC equipment, smart meters and smart grids, consumer behaviour, the policies and programmes adopted and planned, as well as the technical and commercial advances in the dissemination and penetration of technologies and solutions, particularly: energy efficient residential appliances, consumer electronics and ICT, heating and cooling equipment and lighting.

The three-day conference included plenary sessions where key representatives of governments and international organisations, manufacturers and academia presented their views and programmes to advance energy efficiency in residential appliances and lighting, for example, through international co-operation on product information and eco-design requirements. Parallel sessions on specific themes and topics allowed in-depth discussions among participants. The conference also hosted ad-hoc workshops to review and advance international collaboration and provided opportunities strengthen existing and promote new initiatives and partnerships.

Improving confidence of evaluation of energy savings through international standards[1]

Li Pengcheng, Liu Meng, Chen Haihong

China National Institute of Standardization

Abstract

Several regions and organizations have standardized the evaluation of energy savings with different objects and diverse technical perspective. In 2008, ISO (International Organization for Standardization) and IEA worked together to identify standardized methodologies for the calculation of energy savings. International standards were proposed to harmonize the framework, principles and methodologies of evaluation of energy savings. In 2010, ISO decided to establish a new Technical Committee (ISO/TC 257, Energy savings) to start the development of international standards for determining energy savings in three categories: regions, organizations and projects. This paper presents the working program and newest progress of the international standards in this new technical field. The impact of the standards on stakeholders including policy-makers, evaluators, ESCOs and energy-using organizations will be discussed. The implementation of international standards combined with validation mechanisms may enhance the adoption of these standards and the paper discusses ways to implement these standards. The authors will also discuss the key factors which may affect successful implementation of these standards.

Introduction

In recent years, concerns about rising energy demand and climate change have greatly affected global energy-related practices. Both suppliers and users of energy resources now have to work toward conservation and increasing efficiency. Energy savings and resulting improvement of energy efficiency are the most effective ways to restrain energy consumption and reduce greenhouse gas (GHG) emissions. Without energy savings and the progress made in energy efficiency since 1973, total energy consumption of OECD countries would have been 63% higher than at present. Further, IEA analysis shows that, for a group of 17 IEA countries (the IEA 17), total final energy consumption would have been 17% higher in 2006. According to this trend, it means IEA 17 has saved energy of 20 EJ in 2004.[1] More recently, the IEA and the IPCC 2007 Working Group III identified energy efficiency's significant potential to reduce GHG emissions over the next 20 to 30 years. [2]

IEA analysis shows many barriers to energy efficiency affect all economic sectors. These obstacles include uninformed investors with little familiarity with energy-efficient products and the difficulty of quantifying external benefits. As a result, it is important to coordinate policies in a way that addresses all of these barriers, across all sectors. As a cross-sector recommendation, it is recommended to develop measurement and verification protocols to ensure consistency in methodology, overcome uncertainties in quantifying the benefits of energy efficiency investments, and stimulate increased private-sector involvement. The total potential energy savings by sectors per year by 2030 may reach 82.1 EJ. (Fig. 1)

[1] Project 201210231 supported by Special Fund for Sector Research in the Public Interest.

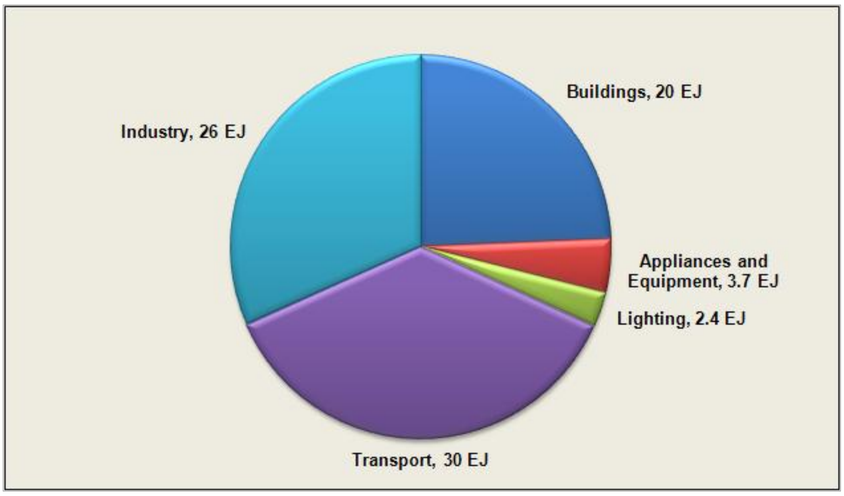

Figure 1 Potential energy savings from energy efficiency by sector per year by 2030[3]

Energy utilities play an important role in promoting energy efficiency. Utility activities to promote energy efficiency often combine a requirement to meet energy efficiency with the use of market-based instruments to enable utilities to trade savings obligations and to allow competition in the delivery of energy services towards savings targets. Through properly structured programs, utilities can recover costs and maintain revenues and profits by sharing the costs and benefits with the final consumer. This gives utilities a large incentive to ensure energy savings are delivered at least cost.[3] Energy savings and the resulting improved energy efficiency are the best ways to restrain energy consumption and reduce GHG emissions. The gains could be huge: total potential energy savings could reach 82.1 EJ by 2030, exceeding the annual electricity consumption in 2009 of China, Japan and the USA combined.

Measurement, calculation and verification have established themselves as the cornerstone to stimulate technologies and policies and encourage efficiency. According to the IEA, when determining energy savings it is important to ensure consistency in methodology; overcome uncertainties in quantifying the benefits of investments; and stimulate increased private-sector involvement.[4]

International standards are recognized as efficient tools to reduce uncertainty for all economic players. Technical consensus supports international trade and the development of new markets. Standards are also valuable in improving consumer understanding and confidence, which influences behaviour and choices. Technical standards to evaluate energy savings are not limited to the measurement of performance metrics; other standards in the field help in monitoring, identifying and verifying energy savings delivered via a range of programs. The adoption of these broader standards contributes to the development of more fungible and international energy efficiency markets, bringing us closer to the day when energy savings can be bought and sold as commodities in the same way electricity and gas are currently traded.

The standardization of energy savings is actually not an entirely new field, but has been carried out globally for two decades. As part of its national energy conservation plan, China has worked since the 1990s to develop and revise its national standards GB/T 13234, Method of calculating energy saved for enterprises (first published in 1991), and GB/T 13471s, Methods for calculating and evaluating the economic value of electricity saving measures (first published in 1992). The US Department of Energy (DOE) began working with industry in early 1994 to develop a consensus approach to measuring and verifying efficiency investments with the aim of overcoming existing barriers to efficiency. The North American Measurement and Verification Protocol (NEMVP) was published in 1996. The second version of the protocol renamed the International Performance Measurement and Verification Protocol (IPMVP), was published in 1997. A growing number of energy efficiency services companies are adopting the IPMVP, which is maintained by the Efficiency Valuation Organization (EVO) to measure and verify energy savings. In Europe, the European Union’s Energy End-use Efficiency and Energy Services Directive (2006/32/EC) calls for the development of harmonized measurement and verification methods for energy savings. South Africa has also taken steps toward development of a national standard for measurement and verification of energy savings. Internationally, the IEA has plans to evaluate energy savings policies worldwide.

Development of ISO standards

In 2007, ISO and the IEA recognized the need for an International Standard to promote energy efficiency and a shift to renewable sources. The two organizations agreed that the new standard should harmonize terminology and calculation methods for energy efficiency, consumption and savings, as well as methods and criteria to calculate energy yield of various primary energy sources.

In September 2010, the ISO Technical Management Board approved the creation of ISO technical committee ISO/TC 257, Energy savings, to develop the ISO standard. The scope of ISO/TC 257 is: Standardisation in the field of energy savings through general technical rules and specific methodologies for the calculation of energy savings in projects, organizations and regions, and guidance on measurement, verification, and assessment of data quality as it relates to these calculations. This TC is actively involved in developing the basic standards for determining energy savings in projects, organizations and regions; and providing effective tools, including quantitative methodologies, to enable stakeholders to better define, adopt, manage and improve technical and management measures to achieve energy savings and increase energy efficiency.

Working framework of ISO/TC 257

The main purpose of the new standards being developed by ISO/TC 257 is to facilitate the harmonization of national standards, specifications and requirements for determination of energy savings. Building on international practices and experiences, the upcoming ISO standards will target different levels, such as project level, enterprise level and regional level. The essential terminologies, technical rules, methodologies, tools and guidance for measurement, calculation and verification of energy savings may be addressed in different standards. The main work of these standards will include procedures, methodologies, principles, requirements and guidelines.

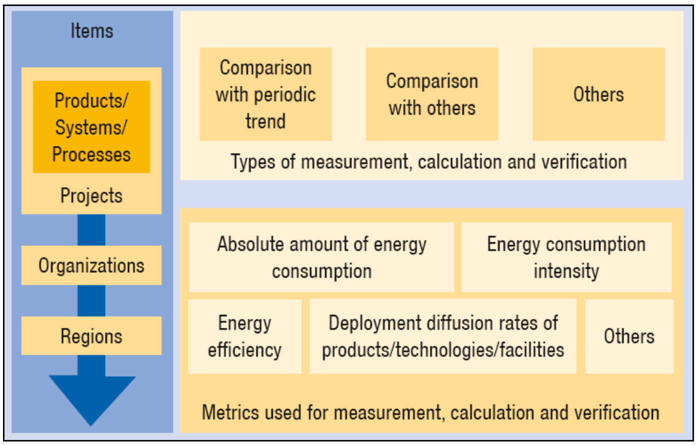

Figure 2 Working framework for measurement, calculation and verification of energy savings[5]

Figure 2 shows the working framework for measuring, calculating and verifying energy savings. According to the working scope, five categories are proposed to promote the development of standards in ISO/TC 257. These are:

- General technical rules
- Guidance on cross-cutting issues
- Methodology for regions

- Methodology for organizations
- Methodology for projects

ISO/TC 257 work programme

Energy savings amount to avoided energy consumption, which means that it cannot be directly measured in practice – a measured difference in energy consumption is often not a real energy savings because underlying conditions may have changed. It is usually necessary to calibrate inputs to determine real energy savings, and multiple methods (for example benchmarking) have been introduced to deal with this issue. Problems arise in evaluation of energy efficiency measures due to different methodologies in the calculation and evaluation methods used internationally. Many countries experience considerable difficulty in evaluating energy efficiency activities because of a lack of relevant International Standards. Transverse rules must be robust in relation to existing innovations in different countries and different fields if the new International Standards are to succeed.

Prior working items include general technical rules and some fundamental methodologies. These subjects will build the framework of principles and essential guidelines for developing special methodologies in different levels of items.

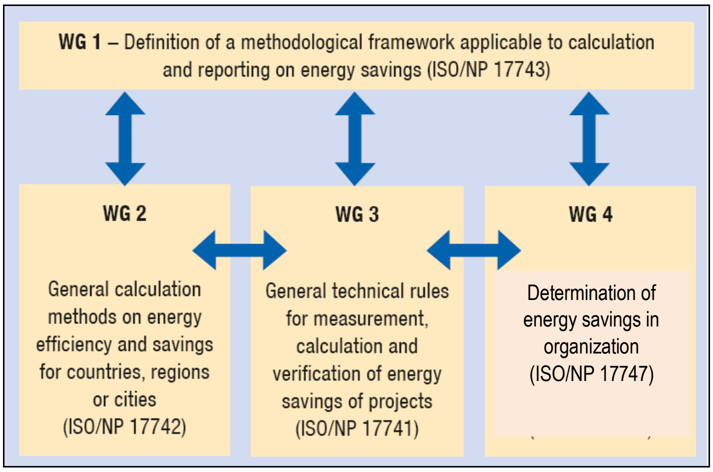

Figure 3 Working program of ISO/TC 257[6]

As shown in Figure 3, there are four standards have already been launched as new work in progress items and approved for registration within ISO/TC 257. The planed timeline for these projects is shown in table 1.

Table 1 planed timeline for ISO/TC 257's projects

Sequence number	Title	Current Stage	Planed published date
17741	General technical rules for measurement, calculation and verification of energy savings for projects	Working draft (WD)	April, 2015
17742	General calculation methods on energy efficiency and savings for countries, regions or cities	The 2nd versions of Committee draft	March, 2015
17743	Definition of a methodological framework applicable to calculation and reporting	The 2nd versions of Committee draft	April, 2015
17747	Determination of energy savings in organizations	Working draft (WD)	September, 2015

Note: Normally, the project of international standard in ISO will go through 5 key stages: New project (NP), Working Draft (WD), Committee Draft (CD), Draft International Standard (DIS) and Final Draft International Standard (FDIS).

More subjects could be developed as International Standards, or as a part of International Standards in ISO/TC 257, to enrich guidelines and tools to develop special methodologies in different levels. Potential additional subjects include: 1) framework and guidelines on measurement, calculation, verification and report of energy savings in energy efficiency services; 2) guidelines for selecting energy savings evaluators; 3) requirements of data quality for quantification of energy savings; 4) guidelines and procedures for analysis of energy savings potential; and 5) guidelines for evaluating and declaring energy savings in procurement of energy efficient products.

Implementation of ISO standards

Users of ISO standards

When used properly, these tools can provide significant advantages and benefits to users in the private and public sectors. As a solid technical foundation for energy savings quantification, ISO/TC 257's work products may create a flourishing market in energy efficiency improvements. For International Standards on this issue, target users may include:

- Organizations quantifying their tally in relation to energy saving projects, installing the equipment and implementing the programmes
- Investors evaluating projects and/or technologies
- Policy-makers evaluating and quantifying the energy savings of energy efficiency policies and programmes
- Stakeholders quantifying cuts in GHG emissions due to initiatives at project, organizational or regional level

Benefits of the ISO standards

Adopting ISO standards to determine energy savings – whether in projects, organizations or regions – can help to manage increased numbers of national, regional and private methodologies. ISO/TC 257's International Standards will provide the comprehensive tools to better understand and communicate scores at different levels, and to improve performance.

Because these standards cover both producers and users of energy resources, their beneficiaries will be highly diverse. The new standards will help avoid technical barriers to trade while stimulating the market for energy efficiency services providers, most of which are small- and medium-sized enterprises. The standards will make efficiency measures more reliable and competitive in energy management and public administration. They will also reduce technical barriers in energy savings trade and, hopefully, ignite a flourishing market.

When used properly, the standards can bring users significant advantages and benefits. These include:

- More opportunities to identify worthwhile investment in technologies/projects
- Enhanced clarity in understanding energy savings in projects/organizations/regions
- Greater confidence in the guaranteed/declared energy savings for projects
- Increased potential to use energy rationally and to minimize waste
- More consistent, scientific and effective policy instruments to promote efficiency or cut consumption

- Greater assurance for consumers of the validity of energy savings
- More firmly grounded assessments of GHG emission reductions linked to projects, organizations and programmes
- No technical barriers for energy efficiency services

These advantages and benefits contribute directly and indirectly to the interested parties' commitments to improved energy performance and sustainable development.

Key factors for success

A validation process by independent parties is the key factor in driving global acceptance of the ISO standards (such as certification of ISO 9000 series or ISO 14000 series standards). Similarly, the validation process is also an essential component of the GHG emissions reduction mechanism (liking Clean Development Mechanism, CDM). These standards also need a validation process that can be implemented by an independent party who will evaluate or verify the energy savings from projects, organization or regions. This will improve stakeholders' confidence in energy savings resulting from energy efficiency improvements. To establish a solid and practical validation process of energy savings according with these international standards, it is necessary to develop an integrated framework defining procedures for validating, requirements of validation bodies and competence of evaluator.

The new standards, combined with a validation progress, will give policy-makers greater confidence in making decisions based on potential energy savings from policy instrument liking energy efficiency programs. Furthermore, also as an important policy instrument, the energy savings trading systems (liking White Certification Scheme in Europe) built by authorities also show its big demand on standardization of procedures, methodologies, principles, requirements and guidelines for measurement and verification of energy savings in projects and organizations. The effective policy instrument will also push the governors, enterprise administrators or managers of energy efficiency projects to consider the energy savings results according to the international standards.

Capacity building is another key factor in the smooth implementation of standards. To help move the basic methods in the standards into real applications, it is necessary to have an abundance of competent personnel to apply these standards. It is important to develop a training and education program for the evaluators or verifiers of energy savings who will use the international standards. Efficiency Valuation Organization (EVO) has carried out a Certified Measurement & Verification Professionals (CMVP) program for persons determining energy savings of projects globally. It may provide best practices for future capacity building program for these international standards.

Conclusions

The effective measurement, calculation and verification of energy savings are the cornerstone of energy efficiency and sustainable development. In order to be successful, they require standardized tools, technologies and policies. Ongoing concerns about increasing energy demand and climate change have significantly affected global practices in recent years and both suppliers and users of energy resources have now to save energy and to improve energy efficiency. The work products of ISO/TC 257 – the basic standards for determination of energy savings in projects, organizations and regions and others – provide effective tools, including quantitative methodologies, for different stakeholders to better define, adopt, manage and improve the technical and management measures to achieve energy savings and increase energy efficiency. When used properly, these tools can provide significant advantages and benefits to users in both the private and public sectors. As a solid technical foundation for energy savings quantification, the ISO standards of energy savings may ignite a flourishing market of energy savings trade. Key factors include validation process, policy instrument and personnel competence will impact the wide use of these ISO standards.

Sustainability – Measuring Environmental Impacts

Sriram Gopal, Kevin Messner, Wayne Morris

Association of Home Appliance Manufacturers

Abstract

The term “Sustainability” is well on its way to being incorporated into the standard business lexicon as manufactured products are evaluated and designed to lessen their environmental impact. Defining and measuring sustainability has been more difficult. The appliance industry has taken the next steps to integrate sustainable practices throughout its value chain. Historically in the appliance industry, the environmental burden of products was measured through energy efficiency or water efficiency, in addition to non-environmental measures such as safety and performance. Now, multi-attribute measures have been implemented, so the industry must also look at the material composition and end-of-life disposition of products/packaging, as well as the overall operations of the facilities that manufacture these appliances and their supply chains. In 2010, the Association of Home Appliance Manufacturers (AHAM) embarked on a process to develop a series of technical sustainability standards. Their goal is to comprehensively measure, and then reduce, the overall environmental impact of home appliances. Another important goal is to establish one credible standard that avoids competing and confusing standards that may or may not be relevant or accurate. AHAM’s standard covering refrigeration products was published in June 2012, and 2013 will see the release of standards covering, clothes washers, dishwashers and clothes dryers. This paper describes the process AHAM is using to develop these standards, which starts with Life Cycle Assessment and includes pilot testing and collaborative input from key stakeholders in government, retail, academia, environmental advocacy, and others with expertise in sustainability.

Introduction

The Association of Home Appliance Manufacturers (AHAM) is a trade association that represents manufacturers of major, portable and floor care home appliances, and suppliers to the industry. AHAM’s membership includes over 150 companies located throughout the world. In the U.S., AHAM members employ tens of thousands of people and produce more than 95% of the household appliances shipped for sale. The factory shipment value of these products is more than $30 billion annually. The home appliance industry, through its products and innovation, is essential to U.S. consumer lifestyle, health, safety and convenience. Through its technology, employees and productivity, the industry contributes significantly to U.S. jobs and economic security. Home appliances also are a success story in terms of energy efficiency and environmental protection. New appliances often represent the most effective choice a consumer can make to reduce home energy use and costs.

AHAM is also a standards development organization, accredited by the American National Standards Institute (ANSI). The Association authors numerous appliance performance testing standards used by manufacturers, consumer organizations and governmental bodies to rate and compare appliances. AHAM’s consumer safety education program has educated millions of consumers on ways to properly and safely use appliances such as portable heaters, clothes dryers, and cooking products.

What Do We Mean By “Sustainability?”

There are many definitions of Sustainability or Sustainable Development. One definition was discussed when the World Commission on Environment and Development was convened in 1983 by the United

Nations. The commission was created to address growing concern "about the accelerating deterioration of the human environment and natural resources and the consequences of that deterioration for economic and social development." In establishing the commission, the UN General Assembly recognized that environmental problems were global in nature and determined that it was in the common interest of all nations to establish policies for sustainable development.

The Commission (also known as the Brundtland Commission in tribute to its Chair, Gro Harlem Brundtland) defined Sustainable Development in 1987 as a way of "development which meets the needs of the present generation without compromising the ability of future generations to meet their own needs." It contains within it two key concepts:

1. the concept of 'needs,' in particular the essential needs of the world's poor, to which overriding priority should be given; and
2. the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs.

In the U.S., the Environmental Protection Agency (EPA) has also embraced the concept of sustainability, stating that "[a] public policy perspective would define sustainability as the satisfaction of basic economic, social and security needs now and in the future without undermining the natural resource base and environmental quality on which life depends." This public policy recognizes "the need to support a growing economy while reducing the social and economic costs of economic growth."

The appliance sector has been advancing with technology continuously since it first appeared in the early 20th century. Today, technological advancements are occurring at an ever more rapid pace along with the size of many of the appliances. The main driver in the last 40 years has been to reduce the overall energy demands of the products and the achievements in this direction have been dramatic.

When the first life cycle analysis studies were performed on appliances in the latter 1990's, it clearly showed that energy during the use phase was the dominant driver on the environment. Today, while this is still a major contributor, it may not be the only major driver, and we need to be acutely aware of what those drivers may be. Through more advanced life cycle analysis approaches, we can better quantify the demands of these products on the environment.

Why Are We Measuring Sustainability?

Certainly we could be satisfied with just measuring the energy when the product is used, but as we continue to make improvements in this area, we need to be able to apply a life cycle study approach to the inter-relationship between energy and other environmental demand factors.

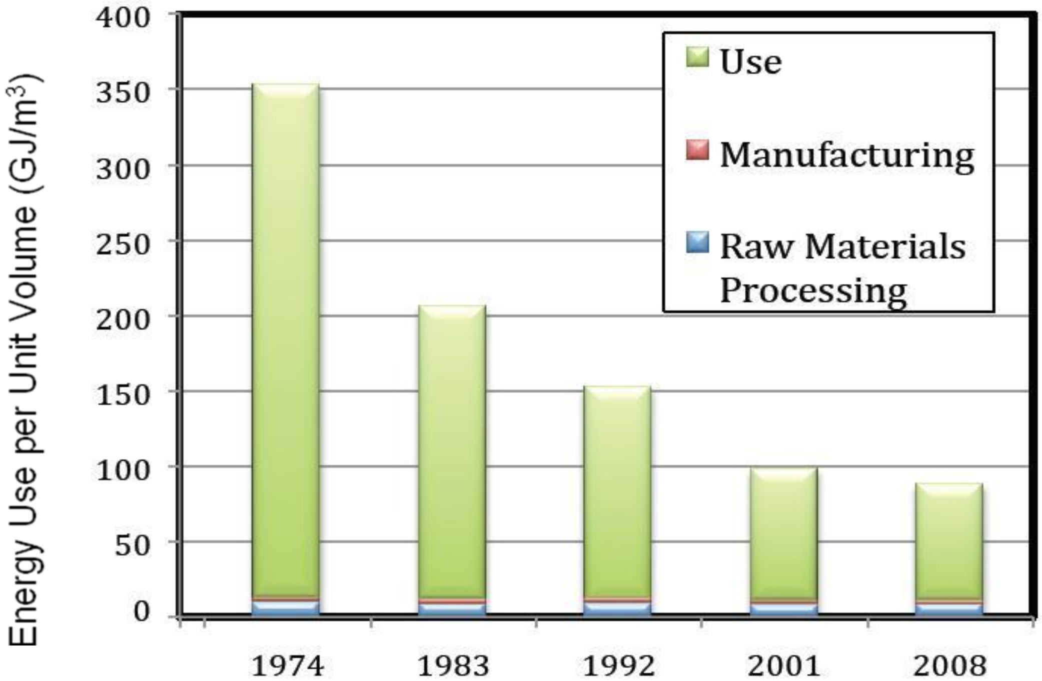

Figure 1: Appliance Remanufacturing and Energy Savings (Source: Boustani et al. (2010))

As home appliances become more energy efficient, relatively speaking, the proportion of energy impacts from other activities within the product life cycle are increasing (see Figure 1). While this shows energy being significant, when we measure the full life cycle of the product, energy is but one of several attributes we need to consider.

One key element beyond energy will be the design of products in such a way as to minimize their environmental impacts through the materials that are used and how they are handled at end-of-life. An integrated way to quantify the environmental impact of products and to assess different product elements will assist design engineers with a methodology and tool with which to judge different designs and look for ways to reduce the overall demand on the environment.

Many companies are already assessing the impact of their products on the environment. They focus on this in their advertising and consumers are becoming more aware of the impact of their purchasing decisions on the environment. Increasingly, retailers are beginning to be aware that their purchasing decisions of what products they carry within their portfolio can have a definite impact on the overall environment.

We currently see more than 350 marks, symbols or “ecologos” across a variety of product sectors (see Figure 2). Many of these represent certification programs. Some represent single-attribute programs and others look at more than one attribute. Certainly consumers could easily be confused with all these environmental marks if care is not taken to create programs based on sound principles of science. These programs must also be transparent and equitable.

Figure 2: Ecologos (Source: CSA Standards)

Standards

AHAM believes the development of open and transparent standards using expertise from standards development organizations, industry experts and consultation with sustainability experts will benefit its member companies. To this end, we have involved multiple organizations, including The Sustainability Consortium, several individual retailers, U.S. Environmental Protection Agency, Environment Canada and Consumers Union. We are meeting regularly with these groups to discuss the process and the standards throughout their development. We believe a set of measurement standards will allow companies to judge their own products against those of other companies, and within their own product portfolio, in order to make decisions about future designs. Consensus standards development will allow all parties to present technical information and to participate among their peers.

The AHAM standards development process is also committed to ensuring that the development of the standard follows the principles outlined in ISO 14020 on Environmental Labels and Declarations. These core principles, as applied to the sustainability standard for refrigeration appliances, are listed below:

1. The product sustainability standard shall be accurate, verifiable, relevant and not misleading.
2. Procedures and requirements for the product sustainability standard shall not create unnecessary obstacles to international trade.
3. The product sustainability standard shall be based on scientific methodology that is sufficiently thorough and comprehensive to support the claim and that produces results that are accurate and reproducible.

4. Information concerning the procedure, methodology, and any criteria used to support the product sustainability standard shall be available and provided upon request to all interested parties.
5. The development of the product sustainability standard shall take into consideration all relevant aspects of the life cycle of the product.
6. The product sustainability standard shall not inhibit innovation.
7. All organizations, regardless of size, should have equal opportunity to use the product sustainability standard.
8. The process of developing the product sustainability standard should include an open, participatory consultation with interested parties.
9. Information on the environmental aspects of products and services relevant to the product sustainability standard shall be available to purchasers and potential purchasers.
10. The focus of the product sustainability standard shall be on improving the sustainability performance of products designed today and in the future, rather than those designed in the past. We support the environmentally responsible disposal and recycling of appliances currently at end-of-life through existing initiatives such as the Appliance Recycling Information Center (ARIC) and North American Appliance Resource Management Alliance (NAARMA).
11. The product sustainability standard should lead to the differentiation of environmentally preferable products.
12. The requirements for the product sustainability standard should evolve with changes in the marketplace.
13. The requirements for the product sustainability standard should not set pricing or other commercial terms.

In addition, the standards are being drafted as to ensure conformity with the U.S. Federal Trade Commission's *Guides for the Use of Environmental Marketing Claims*, often simply called the FTC Green Guides.

Tools

The initial stages of the standard development process is built on an extensive review of the available life cycle literature for a given product category. While a number of life cycle analyses have been conducted, many focused on appliances distinctly different from those produced today, or in North America. In some cases, they also do not cover important environmental attributes. Therefore, in this standard development process, AHAM, CSA Standards Group, and UL Environment (ULE) partnered to produce more comprehensive life cycle analysis and "hot spot" analysis of many of these products for today's product designs. These life cycle analyses and hot-spot analysis will guide the development of the selection of the major attributes and help us derive the relative weighting of these attributes. Figure 3 is an example of the life cycle screening.

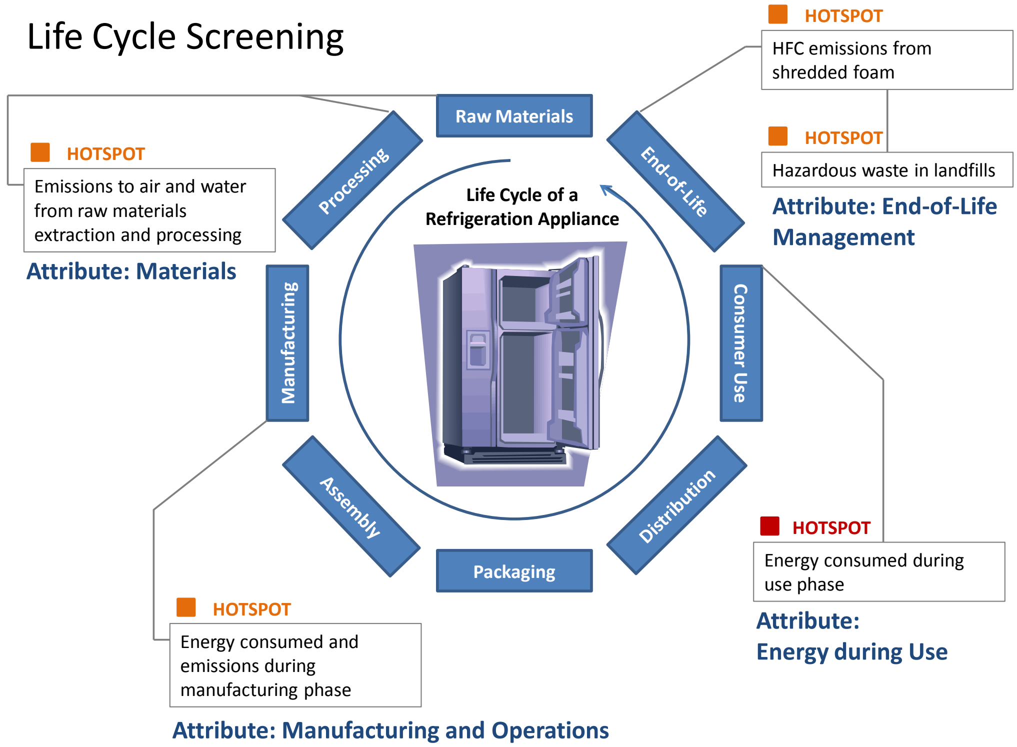

Figure 3: Life Cycle Screening

In all of the appliance categories AHAM has studied, there are several key attributes with impact on the overall environmental position of these appliances. These may include:

- Materials
- Energy During Use
- Manufacturing and Operations
- Performance
- End-of-Life Management
- Innovation

Nomenclature

We are utilizing the nomenclature of environmental effects as found in the ISO 14000 series of standards as in Figure 4.

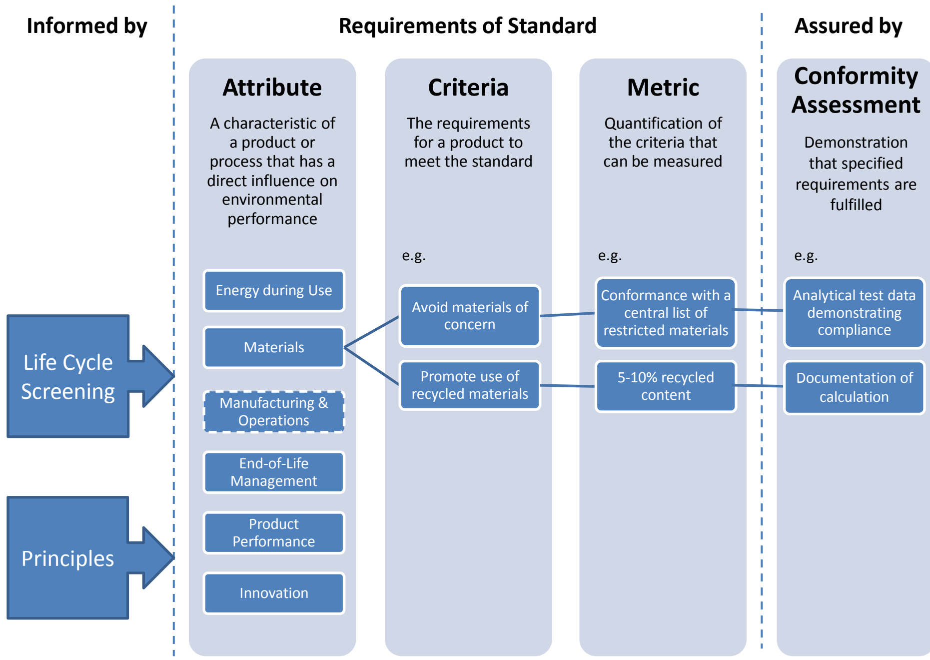

Figure 4: Standards Requirements

Development

The eventual goal for these standards is to develop consensus standards within the framework first of the American National Standards Institute (ANSI) and Standards Council of Canada (SCC) framework for North American standards. AHAM has joined together with three organizations to assist with these standards developments: CSA Standards, Underwriters Laboratories, and P.E./Five Winds International.

CSA Standards is a leading standards-based solutions organization serving industry, government, consumers and other interested parties in North America and the global marketplace. Focusing on standards and codes development, application products, training, advisory and personnel certification services, the organization aims to enhance public safety, improve quality of life, preserve the environment and facilitate trade. For more information, visit www.csa.ca.

The environmental group at Underwriters Laboratories (UL) supports the growth and development of sustainable products and services in the global marketplace through standards development and independent third-party assessment and certification. It is a wholly owned subsidiary of Underwriters Laboratories, a global leader in conformity assessment that has been testing products and writing standards for more than a century. UL currently offers Environmental Claims Validation (ECV), a service testing and verifying manufacturers' self-declared environmental claims, Sustainable Products Certification (SPC), a service testing and certifying products to accepted industry standards for environmental sustainability and Energy Efficiency Certification (EEC), a service testing and verifying product compliance with mandatory and voluntary energy efficiency regulations and programs. UL is developing additional environmental standards, as well as training and advisory services to support organizations in the sustainable products and services industry. For more information, visit www.ulenvironment.com.

Five Winds International, which recently merged with P.E. International, is an internationally recognized sustainability consulting firm, has been selected as a project manager for the AHAM project. Five Winds brings twelve years experience in improving the sustainability of companies and has been instrumental in helping to write international environmental standards.

These sustainability standards are being developed with a variety of uses in mind, and there is strong commitment from both member companies and retailers to employ the standards. Companies may simply use them for self-assessment in order to determine those areas in which they should concentrate their resources. They may also seek third-party certification using the standard to make a claim of sustainability on their products.

AHAM has made considerable progress in the three years since it first embarked upon this project. Hundreds of meetings, both virtual and face-to-face, took place between company representatives that were divided into Task Forces based on product category. AHAM facilitated these discussions, but it was AHAM members that took the lead in drafting the standards. ULE provided support in the LCA screening while CSA has taken the lead in the editorial process.

The sustainability standard for refrigeration products was published in 2012 and is currently in the ANSI accreditation process. Standards for clothes washers are nearing completion for release in 2013. The development process is also well underway for non-microwave kitchen cooking appliances, dishwashers, and clothes dryers with tentative publication dates in late 2013/early 2014. Sustainability standards on smaller appliances such as microwave ovens, room air conditioners and dehumidifiers will follow in 2014. At that point, it will also be time to re-visit the earlier standards in order to update them based on experience and changes in the regulatory environment.

Accreditation and Conformity Assessment

AHAM's standard development process is a hybrid, wherein most of the drafting is done by industry experts with input from AHAM, CSA, UL and Five Winds. Key Outside stakeholders are consulted regularly and are invited to comment on drafts of the standard. This approach aims to find a balance between transparency and expediency. However, once the AHAM-UL-CSA process is completed and the ANSI accreditation process begins, the amount of outside input also increases, thereby lengthening the timeline. On the other hand, it would be difficult to go straight to the accreditation process without first having a standard that companies can use to gain practical knowledge that will inform the ANSI process.

From the very outset, conformity assessment has not been included in the standards because they are designed to be strictly voluntary. Companies may use the standards simply to determine where to best allocate resources. However, should a company wish to certify a product using the standard, it is free to self-certify. The standards were never designed to make any certification, self or 3rd party, a requirement; however, they do contain provisions requiring a product to achieve a certain level of performance under the standard before allowing a company to make a claim of sustainability.

Lessons Learned

Now that AHAM has spent over three years in the sustainability arena, there have been a number of teaching moments that are applicable to not only future appliance standards, but to any other industry wishing to establish similar standards.

Consensus building is essential

AHAM's sustainability standards were developed through a collaborative effort with key stakeholders through a consensus process. Key steps in the process include identifying and recruiting committed individuals with the proper knowledge and skills to participate. Defining the goals of the effort is also important, as this establishes the boundaries of discussion. Recognizing that the companies involved are competitors in the marketplace, the process should encourage frank and substantive dialogue in which parties are given a number of options from which they can choose an appropriate compromise. However, compromise should never sacrifice the over-arching goal of these sustainability standards, which is to reduce the environmental impacts that result from the manufacture, use and disposal of home appliances.

Scoping is key

There are several aspects to scoping with respect to AHAM's sustainability standards. First, there is the scope of product categories that a standard will cover. The drafters of the standard must also determine the key attributes that the standard will address. The discussions covering the standard's scope should take place early on in the development process and must be well-documented. That said, there will be instances where circumstances will require that the scoping be modified, but those modifications should be well-considered.

Pay attention to the regulatory environment

The home appliance industry is heavily regulated and those regulations are constantly shifting. The standard development process has had to take new regulations into account. For example, the publication of the FTC Green Guides in October 2012 resulted in substantial changes to the standards that were being drafted at the time.

Conclusion

Through the combined efforts of our industry and other stakeholders, we believe that the AHAM-CSA-ULE sustainability standards will offer the appliance industry and others in this industry segment a set of objective standards for measuring product sustainability for future designs and for improvements to the environment. The appliance industry is pleased to continue our leadership in the area of environmental responsibility, and we look forward to the technical expertise provided by many stakeholders to produce strong, technical product sustainability standards that can help in the design of the next generation of appliances.

Economic analysis of the energy-efficient household appliances and the rebound effect

Abdessalem Tahar, Labidi Etidel
Laboratory of Economics and Industrial Management, Tunisia Polytechnic School.

Abstract

Energy efficiency improvement is one of the means to reduce energy consumption and carbon emissions. However, potential energy savings and carbon reductions resulting from technological improvements in energy consumption may be reduced by a rebound effect.

The rebound effect refers to the idea that some or all of the expected reductions in energy consumption, as a result of energy efficiency improvements, are offset by an increasing demand for energy services, arising from decrease of the effective price of energy services resulting from those improvements.

The present paper explores the rebound effects from an economist's viewpoint by applying a general equilibrium model in three sectors to measure these effects on the household side. Both, direct and indirect rebound effects expressed as efficiency elasticity and price elasticity are quantified and commented.

On the basis of our theoretical discussion and numerical simulation, we show that he size of direct and indirect rebound effects strongly depends on the elasticity of substitution between energy services.

1. Introduction

Energy efficiency improvement is one of the means to reduce energy consumption and carbon emissions. However, potential energy savings and carbon reductions resulting from technological improvements in energy consumption may be reduced by a rebound effect (Wigley, 1997).
The rebound effect appears when some or all of the expected reductions in energy consumption, as a result of energy-efficiency improvements, are offset by an increasing demand for energy services, arising from decrease of the effective price of energy services resulting from those improvements (Greening et al. 2000).

The first academic discussion of the rebound effect goes back to Jevons (1865) who observed that improvements in the efficiency of steam engines would lead to increasing rather than decreasing coal consumption. More recently, Khazzoom (1980) argued that improved efficiency reduces the effective price of energy and hence results in increasing demand. Following this pioneering study, a considerable work has been done on the rebound effect; these studies focused on theoretical and empirical aspects and are extremely diverse in terms of definitions, methodological approaches and data sources (Lovins, 1988; Henly et al., 1988; Brookes, 1990, 2000; Greene, 1992; Saunders, 1992, 2000; Herring, 1999, 2006; Berkhout et al., 2000; Reinhard et al., 2000; Roy, 2000; Birol et al., 2000; Jaccard et al., 2000; Sanne, 2000; Binswanger, 2001; Bentzen, 2004; Grepperud et al., 2004; Dimitropoulos, 2007; Sorrell et al., 2007; Brannlund et al., 2007; Sorrell, 2009; Sorrell et al., 2009; Jonas et al., 2009; Taoyuan, 2010; Jeroen, 2011).

Rebound effects may derive from energy efficiency improvements in production sectors and consumption household behavior. The literature distinguishes three types of rebound effect: direct, indirect and economy-wide (Greening et al. 2000).

- Direct rebound effect: increased energy efficiency for a particular energy service lowers the price of that service, and hence increases the consumption of it because of the substitution effect and the income effect.
- Indirect effects: the lower effective price of the energy service may lead to increased consumption of other goods, services and factors of production that also require energy.

- Economy-wide effects: a price reduction of the energy service may reduce the price of intermediate and final goods throughout the economy, leading to series of price and quantity adjustments in supply and demand in all sectors. An improvement in energy efficiency has an effect of reducing energy prices and leads to faster economic growth which eventually leads to an increase in energy demand (Barker et al. 2009). According to Sorrell (2009), the overall or economy-wide effects are the addition of direct and indirect effects.

This study is confined to direct and indirect rebound effects in household behavior.
Section 2 presents the general equilibrium model for three sectors in the economy (Energy and two types of appliance) where we:

- Model the behavior of households, energy suppliers and appliances suppliers.
- Determine and comment on the direct and indirect rebound effects expressed as efficiency elasticity and prices elasticity.
- Determine equilibrium prices and quantities which quantify the direct and indirect rebound effects.
- Give a numerical example to illustrate the results of the model.

Section 3 concludes the paper.

2. The rebound effect model

2.1. Consumer's behavior

Energy consumption in itself does not provide utility, but rather the services of the equipment that operate on energy. The consumer can thus be regarded as a producer of useful services, using energy as an input (Berkhout et al. 2000). For example, energy services represent the heating of a dwelling at a certain temperature, a certain number of kilometres travelled at a certain speed, comfort and reliability, etc. These services are assured by the consumption of energy goods such as air conditioners, cars, refrigerators, TV, etc (Quirion, 2005).

We consider two types of energy services, G and Q. Both have a price, respectively P_G and P_Q. The consumer maximizes the utility function $U(G,Q)$, under his budget constraint. In this model, a Constant Elasticity of Substitution (CES) utility function is used. The household maximization program is given by:

$$\max_{(G,Q)} U(G,Q) = [\theta G^{-\rho} + (1-\theta)Q^{-\rho}]^{-\frac{1}{\rho}} \quad (1)$$

$$s.t$$

$$P_G G + P_Q Q \leq R \quad (2)$$

Where ρ denotes the substitution parameter; the elasticity of substitution σ then equals $\frac{1}{1+\rho}$.

The energy service G (resp Q) is produced by the consumer, by combining equipment g (resp q) and energy E_g (resp E_q) in a Cobb-Douglas production function. Formally:

$$G = E_g^{\alpha} g^{1-\alpha} \quad (3)$$

$$Q = E_q^{\beta} q^{1-\beta} \quad (4)$$

where $\alpha, \beta \in (0,1)$.

Consumer purchases energy, appliance g and appliance q at the respective prices P_E, P_g and P_q. These goods cannot be consumed infinitely, since the consumer has a limited revenue R.

D_G denotes the energy service cost for appliance g.

$$D_G = P_G G \quad (5)$$

$$= P_E E_g + P_g g \quad (6)$$

Also, D_Q denotes the energy service cost for appliance q.

$$D_Q = P_Q Q \tag{7}$$

$$= P_E E_q + P_q q \tag{8}$$

Then, the budget constraint faced by the consumer may be rewritten as follows:

$$P_E E_g + P_g g + P_E E_q + P_q q \leq R \tag{9}$$

The household maximization program described above may be changed as follows:

$$\max_{(E_g, E_q, g, q)} U(G, Q) = [\theta(E_g^\alpha g^{1-\alpha})^{-\rho} + (1-\theta)(E_q^\beta q^{1-\beta})^{-\rho}]^{-\frac{1}{\rho}} \tag{10}$$

$$s.t$$

$$P_E E_g + P_g g + P_E E_q + P_q q \leq R$$

First-order conditions lead to energy and goods demands:

$$E_g = \left(\frac{R}{P_E}\right)\left(\frac{\alpha\beta A}{\alpha + \beta A}\right) \tag{11}$$

$$E_q = \left(\frac{R}{P_E}\right)\left(\frac{\alpha\beta}{\alpha + \beta A}\right) \tag{12}$$

$$g = \left(\frac{R}{P_g}\right)\left(\frac{(1-\alpha)\beta A}{\alpha + \beta A}\right) \tag{13}$$

$$q = \left(\frac{R}{P_q}\right)\left(\frac{(1-\beta)\alpha}{\alpha + \beta A}\right) \tag{14}$$

Where A is given by this expression:

$$A = \left[\frac{\alpha\theta}{\beta(1-\theta)}\right]^{\frac{1}{1+\rho}} \left[\frac{\left(\frac{1-\beta}{\beta}\frac{P_E}{P_q}\right)^{1-\beta}}{\left(\frac{1-\alpha}{\alpha}\frac{P_E}{P_g}\right)^{1-\alpha}}\right]^{\frac{\rho}{1+\rho}} \tag{15}$$

The total energy demand is:

$$E_d = (E_g + E_q)_d = \frac{R}{P_E}\left(\frac{\alpha\beta(A+1)}{\alpha + \beta A}\right) \tag{16}$$

Based on these demand functions, the two energy services can be calculated:

$$G = \left(\frac{R\alpha\beta A}{\alpha + \beta A}\right)\left(\frac{1}{P_E}\right)^\alpha \left(\frac{1}{P_g}\right)^{1-\alpha}\left(\frac{1-\alpha}{\alpha}\right)^{1-\alpha} \tag{17}$$

$$Q = \left(\frac{R\alpha\beta}{\alpha + \beta A}\right)\left(\frac{1}{P_E}\right)^\beta \left(\frac{1}{P_q}\right)^{1-\beta}\left(\frac{1-\beta}{\beta}\right)^{1-\beta} \tag{18}$$

The energy service cost D_G may be rewritten as follows:

$$D_G = \frac{R\beta A}{\alpha + \beta A} \tag{19}$$

Based on (17), we then know

$$D_G = \left(\frac{P_E}{\alpha}\right)^\alpha \left(\frac{P_g}{1-\alpha}\right)^{1-\alpha} G = P_G G \tag{20}$$

In a similar way, the energy service cost D_Q may be rewritten as follows:

$$D_Q = \frac{R\alpha}{\alpha + \beta A} \tag{21}$$

With (18), we get:

$$D_Q = \left(\frac{P_E}{\beta}\right)^{\beta}\left(\frac{P_q}{1-\beta}\right)^{1-\beta} Q = P_Q Q \qquad (22)$$

where P_G and P_Q represent the consumer price-index for the energy services which are given by the standard form for a Cobb-Douglas function:

$$P_G = \left(\frac{P_E}{\alpha}\right)^{\alpha}\left(\frac{P_g}{1-\alpha}\right)^{1-\alpha} \qquad (23)$$

$$P_Q = \left(\frac{P_E}{\beta}\right)^{\beta}\left(\frac{P_q}{1-\beta}\right)^{1-\beta} \qquad (24)$$

Energy efficiency coefficient defined as the ratio between the useful energy outputs and the energy inputs is given for each appliance g and q:

$$e_g = \frac{G}{E_g} = \left(\frac{P_E}{P_g}\right)^{1-\alpha}\left(\frac{1-\alpha}{\alpha}\right)^{1-\alpha} \qquad (25)$$

$$e_q = \frac{Q}{E_q} = \left(\frac{P_E}{P_q}\right)^{1-\beta}\left(\frac{1-\beta}{\beta}\right)^{1-\beta} \qquad (26)$$

Now substitute the energy efficiency coefficients from equation (25) and (26) into the expression (15) to obtain:

$$A = \left[\frac{\alpha\theta}{\beta(1-\theta)}\right]^{\frac{1}{1+\rho}}\left[\frac{e_q}{e_g}\right]^{\frac{\rho}{1+\rho}} \qquad (27)$$

Also, the energy service demands may be rewritten as a function of the energy efficiency coefficients:

$$G = \left(\frac{R}{P_E}\,\frac{\alpha\beta A}{\alpha+\beta A}\right) e_g \qquad (28)$$

$$Q = \left(\frac{R}{P_E}\,\frac{\alpha\beta}{\alpha+\beta A}\right) e_q \qquad (29)$$

Combining (23) and (25), the energy service price P_G may be rewritten as:

$$P_G = \frac{P_E}{\alpha e_g} \qquad (30)$$

Also, combining (24) and (26), the energy service price P_Q may be rewritten as:

$$P_Q = \frac{P_E}{\beta e_q} \qquad (31)$$

To analyze the impact of energy efficiency improvements on the households energy consumption, we suppose that G represents the energy services of the equipment which becomes more efficient. Thus, we assume that e_g increases and e_q remains constant. Then, we study its impact on the household energy demand.

The change in energy demand following a small change in energy efficiency may be measured by the efficiency elasticity of the energy demand:

$$\nu_{E_g}^{e_g} = -\left(\frac{\rho}{1+\rho}\right)\left(\frac{\alpha}{\alpha+\beta A}\right) \qquad (32)$$

$$\nu_{E_q}^{e_g} = \left(\frac{\rho}{1+\rho}\right)\left(\frac{\beta A}{\alpha+\beta A}\right) \qquad (33)$$

2.1.1. The measure of the direct rebound effect

a) The rebound effect as efficiency elasticity

In order to measure the direct rebound effect, we have to determine the efficiency elasticity of the demand for energy service G:

$$\nu_G^{e_g} = \left(\frac{1}{1+\rho}\right)\left(1 + \frac{A\beta\rho}{\alpha + \beta A}\right) \qquad (34)$$

Then, it can easily be shown that:

$$\nu_{E_g}^{e_g} = \nu_G^{e_g} - 1 \qquad (35)$$

We find analytically the expression used by Khazzoom, 1980; Greene et al.1999a; Berkhout et al., 2000; Binswanger, 2001; Sorrell et al., 2009; and Dimitropoulos, 2007a; to measure the direct rebound effect. Hence, the efficiency elasticity of energy demand $\nu_{E_g}^{e_g}$ is equal to the efficiency elasticity of the demand for energy service $\nu_G^{e_g}$ minus one.
Rebound due to energy efficiency improvements may be understood in terms of technical-engineering versus behavioral-economic phenomena. In fact, engineering models predict that an $x\%$ improvement in energy efficiency should lead to an $x\%$ reduction in energy consumption (i.e. $\nu_{E_g}^{e_g} = -1$). So, the engineering approach does not correctly quantify the impact of conservation measures on the demand for energy when it consider that $\nu_G^{e_g} = 0$.

Besides the engineering side, there is also an economic side which considers that a positive efficiency elasticity of the demand for energy service ($\nu_G^{e_g} \geq 0$) may be taken as a direct measure of the rebound effect (Berkhout et al. 2000). For example, if $\nu_G^{e_g} = 10\%$, then $\nu_{E_g}^{e_g} = 90\%$and the rebound effect is equal to 10% . This means that 10% of the potential energy savings are taken back as a result of the increased demand for energy services.

b) The rebound effect as price elasticity

In the following paragraph, we show that the rebound effect may be equal to one of two price elasticities, namely:
$\nu_G^{P_G}$: the elasticity of demand for energy services with respect to the energy cost of energy services(PG),
$\nu_E^{P_E}$: the elasticity of energy demand with respect to the price of energy.

First, the definition of the direct rebound effect may be based on the elasticity of the demand for a particular energy service, with respect to the energy cost of energy services. In fact, based on (35) we know:

$$\nu_{E_g}^{e_g} = \frac{\partial G}{\partial e_g}\frac{e_g}{G} - 1 \qquad (36)$$

$$= \frac{\partial G}{\partial P_G}\frac{\partial P_G}{\partial e_g}\frac{e_g}{P_G}\frac{P_G}{G} - 1 \qquad (37)$$

In this equation (40),$-\nu_G^{P_G}$ measures rebound in terms of energy cost elasticity where minus energy service price elasticity of useful service is used as a proxy for the efficiency elasticity of useful service $\nu_G^{e_g}$.

Secondly, the rebound may be captured by $\nu_{E_g}^{P_E}$ because $\nu_G^{P_G} = \nu_{E_g}^{P_E}$:

$$\nu_G^{P_G} = \frac{\partial G}{\partial P_G}\frac{P_G}{G} \qquad (41)$$

Or we have:

$$\begin{cases} G = e_g E_g \\ P_G = \frac{P_E}{\alpha e_g}. \end{cases} \Leftrightarrow \frac{P_G}{G} = \frac{1}{\alpha e_g^2}$$

Also:

$$\frac{\partial G}{\partial P_G} = \frac{\partial G}{\partial E_g}\frac{\partial E_g}{\partial P_G} \tag{42}$$
$$= \frac{\partial G}{\partial E_g}\frac{\partial E_g}{\partial P_E}\frac{\partial P_E}{\partial P_G}$$
$$= \alpha e_g^2 \frac{\partial P_E}{\partial P_G}$$

Now substitute into (41) to obtain:

$$\nu_G^{P_G} = \nu_{E_g}^{P_E}$$

So that,

$$\nu_{E_g}^{e_g} = -\nu_{E_g}^{P_E} - 1 \tag{43}$$

This expression shows that the rebound effect may be calculated by the price elasticity of energy demand for the relevant energy service.

c) Interpretation

Under this model, we showed and verified that the direct rebound effect (noted RE_{direct}) is given by:

$$RE_{direct} = \nu_G^{e_g} = -\nu_G^{P_G} = -\nu_{E_g}^{P_E} \tag{44}$$

This means that nearly $RE_{direct}\%$ of the engineer's estimate of the energy savings is lost because of the feedback from the engineering measures to the economy. In fact, consumers will react to changes in the energy efficiency of appliance (e_g). It is verified that the increase in energy efficiency appliances has an impact on the decrease in both energy service price and energy service cost which lead consumers to save an amount of money:

$$\nu_{P_G}^{e_g} = -1 \tag{45}$$

$$\nu_{D_G}^{e_g} = -\left(\frac{\rho}{1+\rho}\right)\left(\frac{\alpha}{\alpha+\beta A}\right) \tag{46}$$

For consumers, the direct effect of a price reduction may be decomposed into a substitution effect and an income effect.

- The substitution effect: if the price of the energy service P_G drops following an energy efficiency improvement (45), the energy service G becomes less expensive relative to other service Q. This may lead to an increased demand for the service G and therefore the efficiency appliance g.
- The income effect: energy efficiency improvements reduce the cost of energy service G (46) and leads to an amount of money being saved. So, consumers have an additional income which they may choose to spend on the same energy service G and get more of the same appliance g. For example, people may buy more air conditioners when it becomes more efficient, and heat more their homes than before.

2.1.2. The measure of the indirect rebound effect

In this model, the indirect rebound effect is measured by the efficiency elasticity of the demand for energy service Q:

$$\nu_Q^{e_g} = \left(\frac{\rho}{1+\rho}\right)\left(\frac{\beta A}{\alpha+\beta A}\right) \tag{47}$$

Recalling the equation (33), we notice that:

$$\nu_{E_q}^{e_g} = \nu_Q^{e_g} \tag{48}$$

Under the engineering side, if the increase in efficiency is implemented, the level of energy demand of appliance q will not be changed $\nu_{E_q}^{e_g} = 0$. However, under our economic analysis we show $\nu_{E_q}^{e_g} \geq 0$. This shows that an improvement of the efficiency of the equipment g may increase the energy consumption of the other equipment q. From this, the indirect rebound effect rises beyond the increase of energy service Q where the energy efficiency e_g is improved.

$$ER_{indirect} = \nu_{E_q}^{e_g} = \nu_Q^{e_g} \tag{49}$$

The prominent mechanism responsible for this type of rebound is believed to be secondary effect, which may also happen by way of income effect. In fact, energy efficiency improvements of appliance g reduce the price of energy service G and have no impact on the price of energy service Q, because:

$$\nu_{P_G}^{e_g} = -1$$

$$\nu_{P_Q}^{e_g} = 0 \tag{50}$$

As a result, an amount of money is saved. This leads to more expenditure on the energy service Q:

$$\nu_{D_Q}^{e_g} = \left(\frac{\rho}{1+\rho}\right)\left(\frac{\beta A}{\alpha + \beta A}\right) \tag{51}$$

So, the energy service Q increase, which leads to an increase in energy demand Eq. For example, the use of a more efficient air-conditioner may create more energy demand for lighting, cooking or driving.

2.2. Energy suppliers behavior

We define the energy suppliers production function as a Cobb-Douglas function which takes factor inputs K_E, L_E and converts them to energy output E:

$$E = b\, K_E^{\gamma}\, L_E^{1-\gamma} \tag{52}$$

Given the wage rate w and the capital rate of return r, the cost of the input bundle (K_E, L_E) is:

$$rK_E + wL_E \tag{53}$$

For given r, w and P_E, the suppliers profit-maximization behavior is:

$$\max_{(K_E, L_E)} \Pi_E = P_E b\, K_E^{\gamma}\, L_E^{1-\gamma} - (rK_E + wL_E) \tag{54}$$

First-order conditions are:

$$P_E b \gamma K_E^{\gamma-1} L_E^{1-\gamma} = r \tag{55}$$

$$P_E b(1-\gamma) K_E^{\gamma} L_E^{-\gamma} = w \tag{56}$$

They lead to the marginal rate of transformation:

$$\frac{\gamma}{1-\gamma}\frac{L_E}{K_E} = \frac{r}{w} \tag{57}$$

This can also be written as:

$$K_E = \frac{\gamma}{1-\gamma}\frac{w}{r} L_E \tag{58}$$

Or:

$$L_E = \frac{1-\gamma}{\gamma}\frac{r}{w} K_E \tag{59}$$

Now substitute K_E from equation (58) into (52) and (55) to obtain:

$$E = b\left(\frac{\gamma}{r}\right)^{\gamma}\left(\frac{1-\gamma}{w}\right)^{-\gamma} L_E \quad (60)$$

$$P_E = \frac{1}{b}\left(\frac{r}{\gamma}\right)^{\gamma}\left(\frac{\omega}{1-\gamma}\right)^{1-\gamma} \quad (61)$$

Also, substitute L_E from equation (59) into (52) to obtain:

$$E = b\left(\frac{\gamma}{r}\right)^{1-\gamma}\left(\frac{1-\gamma}{w}\right)^{1-\gamma} K_E \quad (62)$$

Then, based on (60) and (61) we get:

$$P_E E = \frac{\omega}{1-\gamma} L_E \quad (63)$$

and based on (62) and (61) we get:

$$P_E E = \frac{r}{\gamma} K_E \quad (64)$$

2.3. Appliance q producer's behavior

Under perfect competition, the suppliers of appliance q maximize q their profit and production under constant returns to scale. Then a Cobb-Douglas production function is:

$$q = a\, K_q^{\mu}\, L_q^{1-\mu} \quad (65)$$

Given r and w, the firm's cost is:

$$rK_q + wL_q \quad (66)$$

Then the firm's profit maximization problem is:

$$\max_{(K_q, L_q)} \Pi_q = P_q a\, K_q^{\mu}\, L_q^{1-\mu} - (rK_q + wL_q) \quad (67)$$

First-order conditions lead to

$$P_q = \frac{1}{a}\left(\frac{r}{\mu}\right)^{\mu}\left(\frac{\omega}{1-\mu}\right)^{1-\mu} \quad (68)$$

$$P_q q = \frac{1}{a}\frac{\omega}{1-\mu} L_q \quad (69)$$

$$P_q q = \frac{1}{a}\frac{r}{\mu} K_q \quad (70)$$

2.4. Appliance g producer's behavior

Producers of the appliance g have also a Cobb-Douglas production function:

$$g = c\, K_g^{\eta}\, L_g^{1-\eta} \quad (71)$$

and a total cost:

$$rK_g + wL_g \quad (72)$$

For given r, w, and P_g, profit-maximization firm's behavior is:

$$\max_{(K_g, L_g)} \Pi_g = P_g c\, K_g^{\eta}\, L_g^{1-\eta} - (rK_g + wL_g) \quad (73)$$

Based on the first-order conditions we get:

$$P_g = \frac{1}{c}\left(\frac{r}{\eta}\right)^{\eta}\left(\frac{\omega}{1-\eta}\right)^{1-\eta} \quad (74)$$

$$P_g g = \frac{\omega}{1-\eta} L_g \quad (75)$$

$$P_g g = \frac{r}{\eta} K_g \quad (76)$$

2.5. Market equilibrium

This model supposed only three goods: energy E, appliances g and q. Thus, after establishing consumer's and firm's equilibriums, we examine the general equilibrium. In order to simplify the notations, we normalize the number of firms and consumers to one. Market clearing for the three goods implies:

$$E_s = (E_g + E_q)_d \quad (77)$$

$$g_s = g_d \quad (78)$$

$$q_s = q_d \quad (79)$$

Firms are owned by the consumer and this taken into account in the budget constraints. Total income equals then the sum of returns to total capital and labor:

$$R = r(K_E + K_g + K_q) + w(L_E + L_g + L_q) \quad (80)$$

$$= P_E E + P_g g + P_q q$$

If capital supply (noted $\overline{K}$) and labor supply (noted $\overline{L}$) are exogenous, balanced capital and labor markets fulfill:

$$\overline{K} = K_E + K_g + K_q \quad (81)$$

$$\overline{L} = L_E + L_g + L_q \quad (82)$$

Then:

$$R = r\overline{K} + w\overline{L} \quad (83)$$

Now insert (64) and (16) into (77):

$$P_E E_s = P_E E_d \quad (84)$$

$$\frac{rK_E}{\gamma} = \left(\frac{\alpha\beta(A+1)}{\alpha+\beta A}\right) R \quad (85)$$

$$K_E = \left(\frac{\gamma}{r}\right)\left(\frac{\alpha\beta(A+1)}{\alpha+\beta A}\right) R \quad (86)$$

and with (76) and (13) into (78):

$$P_g g_s = P_g g_d \quad (87)$$

$$\frac{rK_g}{\eta} = \left(\frac{1-\alpha}{\alpha}\right)\left(\frac{\alpha\beta A}{\alpha+\beta A}\right) R \quad (88)$$

$$K_g = \left(\frac{\eta}{r}\right)\left(\frac{1-\alpha}{\alpha}\right)\left(\frac{\alpha\beta A}{\alpha+\beta A}\right) R \quad (89)$$

Also, insert (70) and (14) into (79):

$$P_q q_s = P_q q_d \quad (90)$$

$$\frac{rK_q}{\mu} = \left(\frac{1-\beta}{\beta}\right)\left(\frac{\alpha\beta}{\alpha+\beta A}\right) R \quad (91)$$

$$K_q = \left(\frac{\mu}{r}\right)\left(\frac{1-\beta}{\beta}\right)\left(\frac{\alpha\beta}{\alpha+\beta A}\right) R \quad (92)$$

At this step, recall that $\overline{K} = K_E + K_g + K_q$ and substitute (86), (89), and (92) to obtain:

$$\overline{K} = \frac{R}{r}\left(\frac{\alpha\beta}{\alpha+\beta A}\right)\left[\gamma(A+1)+\eta\frac{1-\alpha}{\alpha}A+\mu\frac{1-\beta}{\beta}\right] \qquad (93)$$

Then insert $R = r\overline{K} + w\overline{L}$ into (93):

$$\frac{\alpha\beta}{\alpha+\beta A} = \left(1+w\frac{\overline{L}}{\overline{K}}\right)\left[\gamma(A+1)+\eta\frac{1-\alpha}{\alpha}A+\mu\frac{1-\beta}{\beta}\right] \qquad (94)$$

Equation (94) can also be rearranged as:

$$A\quad\left(\gamma+\eta\frac{1-\alpha}{\alpha}-\frac{1}{\alpha}\right)+\frac{\overline{L}}{\overline{K}}wA\left(\gamma+\eta\frac{1-\alpha}{\alpha}\right)+\frac{\overline{L}}{\overline{K}}w\left(\gamma+\mu\frac{1-\beta}{\beta}\right)$$

$$+\quad\left(\gamma+\mu\frac{1-\beta}{\beta}-\frac{1}{\beta}\right)=0 \qquad (95)$$

By (61), (68), and (74) we can calculate the relative prices. As a result, the expression A mentioned above by (15) can be rewritten as function of labor and capital prices:

$$A=\left(\frac{\theta}{1-\theta}\frac{\alpha}{\beta}\right)^{\frac{1}{1+\rho}}\left[\frac{\left[r^{\gamma-\mu}\omega^{\mu-\gamma}\left(\frac{\mu^{\mu}(1-\mu)^{1-\mu}}{\gamma^{\gamma}(1-\gamma)^{1-\gamma}}\right)\left(\frac{1-\beta}{\beta}\right)\left(\frac{a}{b}\right)\right]^{1-\beta}}{\left[r^{\gamma-\eta}\omega^{\eta-\gamma}\left(\frac{\eta^{\eta}(1-\eta)^{1-\eta}}{\gamma^{\gamma}(1-\gamma)^{1-\gamma}}\right)\left(\frac{1-\alpha}{\alpha}\right)\left(\frac{c}{b}\right)\right]^{1-\alpha}}\right]^{\frac{\rho}{1+\rho}} \qquad (96)$$

If the return to capital r is normalized as unity, we obtain:

$$A = Dw^{\varepsilon} \qquad (97)$$

where

$$D=\left(\frac{\theta}{1-\theta}\frac{\alpha}{\beta}\right)^{\frac{1}{1+\rho}}\left[\frac{\left[\left(\frac{\mu^{\mu}(1-\mu)^{1-\mu}}{\gamma^{\gamma}(1-\gamma)^{1-\gamma}}\right)\left(\frac{1-\beta}{\beta}\right)\left(\frac{a}{b}\right)\right]^{1-\beta}}{\left[\left(\frac{\eta^{\eta}(1-\eta)^{1-\eta}}{\gamma^{\gamma}(1-\gamma)^{1-\gamma}}\right)\left(\frac{1-\alpha}{\alpha}\right)\left(\frac{c}{b}\right)\right]^{1-\alpha}}\right]^{\frac{\rho}{1+\rho}} \qquad (98)$$

and

$$\varepsilon=\left(\frac{\rho}{1+\rho}\right)\left[\mu(1-\beta)+\gamma(\alpha-\beta)+\eta(\alpha-1)\right] \qquad (99)$$

Applying (97) into (95), we get:

$$D\quad w^{\varepsilon}\left(\gamma+\eta\frac{1-\alpha}{\alpha}-\frac{1}{\alpha}\right)+\frac{\overline{L}}{\overline{K}}Dw^{\varepsilon+1}\left(\gamma+\eta\frac{1-\alpha}{\alpha}\right)+\frac{\overline{L}}{\overline{K}}w\left(\gamma+\mu\frac{1-\beta}{\beta}\right)$$

$$+\quad\left(\gamma+\mu\frac{1-\beta}{\beta}-\frac{1}{\beta}\right)=0 \qquad (100)$$

The equilibrium labor price w is the solution to (100).
This leads to equilibrium prices P_E^*, P_g^*, P_q^*, P_G^* and P_Q^* which are function of w^*, equilibrium quantities E_g^*, E_q^*, g^*, q^* and equilibrium energy services $G^*$and Q^*. Direct and indirect rebound effects are then calculated with P_E^*, P_g^*, P_q^* substituted in (34) and (47).

3. Numerical simulations

Numerically, for $\alpha = \beta = 0.5,\ \theta = 0.5,\ \gamma = \eta = \mu = 0.5,\ \rho = 0.5,\quad a=b=c=1$ equation (100) becomes:

$$2w\frac{\overline{L}}{\overline{K}}-2=0 \qquad (101)$$

Equilibrium prices are:

$$w^* = \left(\frac{\overline{K}}{\overline{L}}\right) \quad (102)$$

$$r^* = 1 \quad (103)$$

$$P_E^* = 2\left(\frac{\overline{K}}{\overline{L}}\right)^{0.5} \quad (104)$$

$$P_g^* = 2\left(\frac{\overline{K}}{\overline{L}}\right)^{0.5} \quad (105)$$

$$P_q^* = 2\left(\frac{\overline{K}}{\overline{L}}\right)^{0.5} \quad (106)$$

Equilibrium quantities of energy and appliances are:

$$g^* = 0.125(\overline{K}\,\overline{L})^{0.5} \quad (107)$$

$$q^* = 0.125(\overline{K}\,\overline{L})^{0.5} \quad (108)$$

$$E_g^* = 0.125(\overline{K}\,\overline{L})^{0.5} \quad (109)$$

$$E_q^* = 0.125(\overline{K}\,\overline{L})^{0.5} \quad (110)$$

Under these circumstances, the increase in the energy efficiency of the appliance g leads to an amount of energy savings generate by the use of this appliance, since

$$\nu_{E_g}^{e_g} = -\left(\frac{\rho}{1+\rho}\right)\left(\frac{\alpha}{\alpha+\beta A}\right) = -0.17 \quad (111)$$

This energy savings is offset by an increase in energy consumption of the appliance q:

$$\nu_{E_q}^{e_g} = \left(\frac{\rho}{1+\rho}\right)\left(\frac{\beta A}{\alpha+\beta A}\right) = 0.17 \quad (112)$$

Here, the energy efficiency improvement does not affect energy consumption. This is due to the direct and indirect rebound effects.
First, we have:

$$RE_{direct} = \nu_G^{e_g} = \left(\frac{1}{1+\rho}\right)\left(1+\frac{A\beta\rho}{\alpha+\beta A}\right) = 0.83 \quad (113)$$

This means that 83% of the potential energy savings generated by the use of efficiency appliance g are lost as a result of the increased demand for energy services G. As a consequence, an increase in energy efficiency of the appliance g leads to reduced energy consumption of this appliance at only by 17%.
Secondly, we have:

$$RE_{indirect} = \nu_Q^{e_g} = \left(\frac{\rho}{1+\rho}\right)\left(\frac{\beta A}{\alpha+\beta A}\right) = 0.17 \quad (114)$$

So an increase in energy efficiency of the appliance g leads to a rise in energy consumption of appliance q by 17%.

In addition we may calculate the total rebound effect as the sum of the direct and indirect rebound effect.

$$RE_{total} = RE_{direct} + RE_{indirect} \quad (115)$$

$$= 0.83 + 0.17 = 1$$

On the basis of our theoretical discussion, the magnitude of the direct and indirect rebound effects strongly depends on the elasticity of substitution σ (see Fig. 1). In order to assess the sensitivity of the rebound effect to the substitution elasticity, we vary the value of σ, keeping unchanged all other parameters.

- When the elasticity of substitution is assumed to equal zero ($\sigma = 0$) and ($\rho \longrightarrow \infty$), the CES function reduces to a Leontief utility function assuming strict complementarity between the energy services G and Q. In this case, total rebound effect is shared in two equal parts: 50% for direct rebound and 50% for indirect rebound.

- The next simulation is calculated with $0 < \sigma < 1$ and $\rho > 0$. The direct, indirect and total rebound effects may be calculated for different values of the elasticity of substitution as follows (see Table 1). Under a low elasticity of substitution, the direct rebound effect is increasing with the substitution elasticity. On the other hand, the indirect rebound effect is decreasing with σ. But, both direct and indirect rebounds are positive and their sum is always equal to one.
- In a next set of figures, the elasticity of substitution is equal to one ($\sigma = 1$) since ($\rho \longrightarrow 0$), and CES function reduces to a Cobb-Douglas function. In this case, the rebound effect is generated only through the service G because we have $RE_{direct} = 1$ and $RE_{indirect} = 0$.
- In the high elasticity case ($\sigma > 1$ when $-1 < \rho < 0$), the direct rebound effect is greater than one and the indirect rebound effect is negative ($RE_{direct} > 1$and $RE_{indirect} < 0$).
- When the energy services G and Q are perfect substitutes, with $\sigma \longrightarrow \infty$, since $\rho = -1$, the direct rebound effect becomes very important and the indirect rebound effect is negative and equal to the direct rebound.

Table 1: Variation of the rebound effects with substitution elasticity

elasticity of substitution (σ)	0.1	0.5	0.9
REdirect	0.55	0.75	0.95
REindirect	0.45	0.25	0.05
REtotal	1	1	1

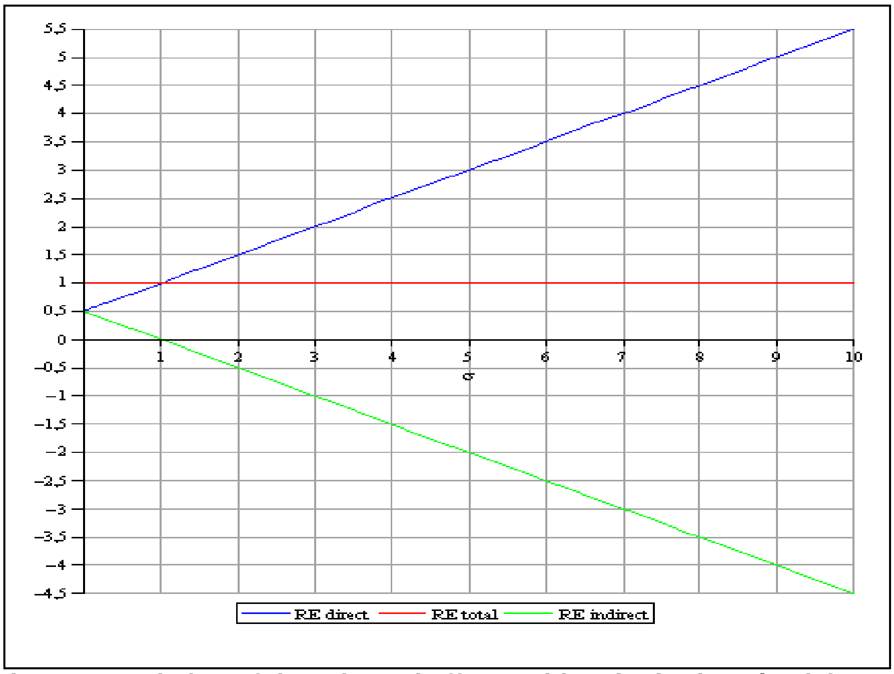

Figure 1: Variation of the rebound effects with substitution elasticity

4. Concluding remarks

The present paper explores the rebound effects from an economist's viewpoint by applying a general equilibrium modeling with three goods to quantify these effects on household energy consumption.
First, improvements in energy efficiency make energy services cheaper, and therefore encourage increased consumption of those services. This so-called direct rebound effect offsets the energy savings that may otherwise be achieved.

We determine an analytic measure of the direct rebound effect. Then, we show that this measure may be expressed as efficiency elasticity and price elasticity, which are used by Khazzoom (1980) and other various authors to capture empirically the direct rebound effect.
Second, an increase in energy efficiency of a one particular appliance leads to an increase in the energy consumption of the other appliances and goods. This is called the indirect rebound effect which may be measured through the efficiency elasticity of the demand for the other goods energy services.
Third, the price effects and income effects are the prominent mechanisms accounting for these direct and indirect rebound effects. Further, price effects due to reduced variable costs of energy services and income effects due to the redirection of saved money to other consumption have been expressed analytically and quantified.
Finally, on the basis of our theoretical discussion and numerical simulation, we show that the size of direct and indirect rebound strongly depends on the elasticity of substitution between energy services.

Towards an Evaluation Framework for Appliance Standards, Labeling, and Incentive Programs in China

John Romankiewicz, Nan Zhou, Edward Vine, Nina Zheng Khanna, David Fridley

Lawrence Berkeley National Laboratory

Abstract

China's standards and labeling programs have grown rapidly in recent years with mandatory minimum efficiency performance standards and mandatory labeling requirements for 45 products and 23 products, respectively. China has also implemented a number of incentive programs such as the Rural Area Household Appliance Subsidy and Highly Efficient Products Discount which both drove an increase in energy-efficient appliance sales. However, China lacks a framework to evaluate the savings of these standards, labeling, and incentive programs. Furthermore, China has not set aside a budget to perform such evaluations, even though they will likely play an increasingly critical role in China's energy efficiency policy making as energy intensity targets become increasingly difficult to hit and the government needs to understand which policies are most effective at increasing efficiency. In order to recommend evaluation methodologies for China, we have reviewed frameworks in the U.S. (federal and state level), E.U., and Australia and identified key methodologies and related data requirements. This paper provides an overview of ex-ante and ex-post evaluation types for standards and labeling, with discussion on baseline setting as well as correction factor and compliance rate adjustments. For incentives, gross savings and net savings approaches are addressed, including an explanation of free ridership. Finally, we look at China's data availability in order to select or adapt appropriate methodologies such that they can carry out an evaluation of the energy savings from various standards, labeling, and incentive programs.

1. Introduction

Governments around the world are undertaking energy efficiency program evaluations with similar motivations but varying levels of budget and data collection. While data are the foundation of evaluation, primary data collection can be costly, and many organizations rely on secondary sources for the majority of their data needs. As China ramps up its efforts in energy efficiency in the 12th Five Year Plan[1] and beyond, data availability for program evaluation is becoming an increasingly relevant question. In particular, China's programs for mandatory standards and categorical labeling have grown very rapidly to cover 45 products and 23 products, respectively, and a number of incentive programs (Energy-Efficient Products for the Benefit of the People, Rural Area Household Appliance Subsidy, and Highly Efficient Products Discount) have led to increased sales of energy-efficient appliances [1]. In this paper, we describe the methodologies and associated data inputs for the evaluation of standards, labeling, and incentive programs and perform an initial assessment of the availability and uncertainty of those data inputs in China.

Section 1 describes the relationship of evaluation goals, data uncertainty, and budget availability in order to provide some background for key decisions that China will make as it continues to improve its capabilities in program evaluation. Section 2 highlights key findings from Lawrence Berkeley National Laboratory's (LBNL) recent review of methodologies used in different countries around the world (U.S., E.U., and Australia) to evaluate the impact (energy savings) of standards, labeling, and incentives programs [2]. Section 3 provides the key data requirements for those methodologies, an

---

[1] Following on the success of the energy intensity target of the 11th Five Year Plan and in support of the 2020 target to reduce carbon intensity by 40-45% below 2005 levels, the State Council set forth new intensity targets for the 12th Five Year Plan (2011-2015). Under the new targets, energy intensity (energy consumption per unit of GDP) will be reduced by 16% and carbon intensity (carbon emissions per unit of GDP) will be reduced by 17% below 2010 levels by the end of 2015.

assessment of China's data availability, and three methodology options for China to consider in light of their data availability.

2. Data and uncertainty issues for program evaluation

There are strong relationships among the goals, data availability, uncertainty, and budget resources for any program evaluation process. As shown in Figure 1, the data inputs and algorithms used are usually determined by the goals and scope of the evaluation. Data inputs come from both primary and secondary sources collected from a wide range of literature and surveys of stakeholder groups, including consumers, manufacturers, and retailers. Each data source will carry with it an associated uncertainty, and each data input will have a relative sensitivity on the output of the evaluation algorithm. The organizations carrying out these studies should place an emphasis on measuring these levels of uncertainty and sensitivity in order to best serve the goals of the energy efficiency programs that they are implementing.

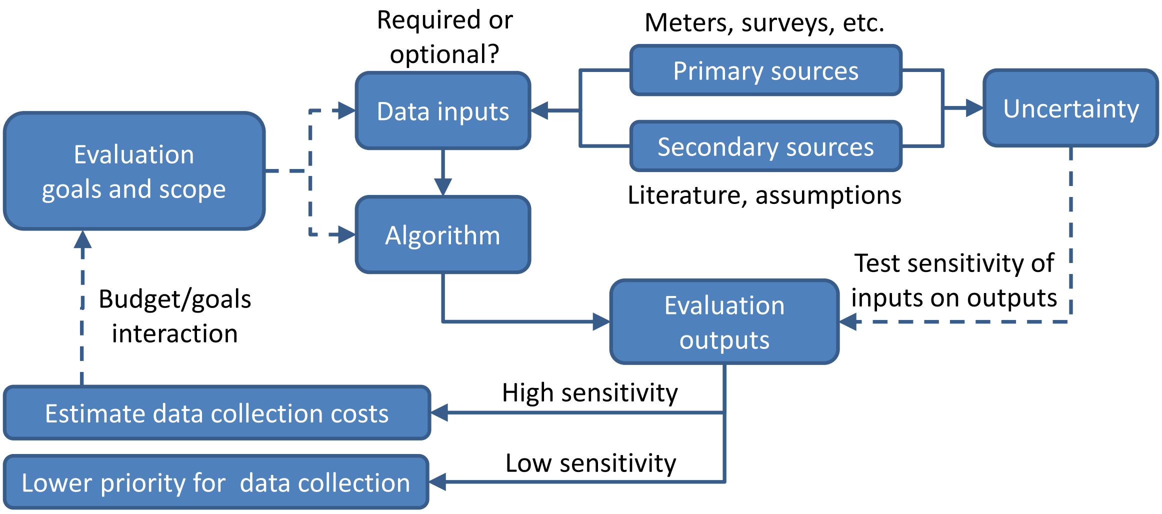

Figure 1: Interaction between goals, data, uncertainty, and budget for program evaluation

In the U.S., utilities are often seeking to determine energy savings, peak demand reductions, or market transformation of energy efficiency programs and, in turn, calculate the cost effectiveness of dollars spent on those programs. Cost-effectiveness mandates have driven evaluators to often spend additional money on data collection and evaluation in order to reduce uncertainty and improve estimates of energy savings. In China, program evaluation does not yet have these cost effectiveness mandates, but China's first demand-side management regulations were only set in place at the beginning of the 12th Five Year Plan (i.e., 2011). China's energy intensity and carbon intensity goals are providing an additional impetus for implementation and accurate impact evaluation of a growing number of energy efficiency programs.

In addition to determining the goals of any program evaluation, the scope of the process should also be outlined in terms of what measures (or products) were covered, what delivery strategy was used, and what impacts were expected in the design of the standard and program. For instance, determining the energy savings from a rebate program for compact fluorescent light (CFL) bulbs, the market transformation from a voluntary labeling program for refrigerators, or peak demand reduction for a retrofit program for commercial central air conditioning units are all viable scopes for program evaluation. Once the scope has been set, then the required data inputs and appropriate algorithms can be determined as shown in Figure 1. In evaluations, both primary and secondary data sources are used for collecting data: for example, reviewing engineering literature for estimating savings, or conducting surveys to collect hours of usage for a particular product.

All data sources, primary or secondary, will carry with them an associated degree of uncertainty. This uncertainty should be estimated. Additionally, the sensitivity of altering each input on the output should be tested using Monte Carlo simulation or some other estimation methodology. Together, the uncertainty and sensitivity of various data inputs can help determine where efforts and budget should be spent to improve data inputs and in turn improve the end accuracy of any evaluation or standards development. If energy efficiency goals are present, then this type of analysis enables the assessment of whether those goals were met or not.

In the U.S., risk analysis has been performed for utility-sponsored energy efficiency programs to identify which programs' energy savings estimates have the highest uncertainty [3]. The uncertainty of the savings for each program will depend on the uncertainty for each data input for that program's energy savings algorithm. For example, in this case, the following energy savings evaluation algorithm was used:

$$\Delta kWh_{lifetime,net,measure} = units \times \frac{\Delta kWh_{gross}}{unit} \times NTG \times EUL$$

- ΔkWh$_{\text{lifetime, net, measure}}$= Net energy savings
- ΔkWh$_{\text{gross}}$/unit = Gross energy savings per measure (unit savings)
- Units = number of measures (count)
- NTG = net to gross ratio[2]
- EUL = effective useful life[3]

Table 1: Primary and secondary data sources for standards development and program evaluation, adapted from [4]

	Primary data sources							Secondary data sources		
	Direct measurement (metering)	**Laboratory test data**	**Manufacturer surveys**	**Program participant surveys**	**Retailer surveys**	**National energy surveys**	**Government statistics**	**Energy/evaluation literature**	**Deemed values**	**Simulation and modeling**
Usage	X					X		X		
Unit energy consumption	X	X	X			X		X	X	X
Existing stock, saturation						X	X	X		
Lifetime	X		X	X		X		X		
Sales/shipments (real or forecasts)			X		X		X			
Site-to-source energy conversion factors							X	X		
Emission factors							X	X		
Free ridership				X				X	X	
Compliance		X								
Number of participants, non-participants				X				X		
Participant spillover				X				X		
Market effects				X				X		
Heating and cooling degree days							X	X		

[2] The net-to-gross (NTG) ratio determines the actual energy savings attributable to a particular program, as distinct from energy efficiency improvements that would have occurred without the program. The NTG ratio equals the program's net energy savings divided by the program's gross energy savings. Factors such as free ridership, participant spillover, and market effects contribute to NTG ratios according to varying definitions. More description is available in section 3.1.3.
[3] The effective useful life (EUL) of a measure (i.e., measure lifetime) is the period of time that the measure is expected to perform its intended function in a typical installation [19].

The number of measures (count), gross energy savings per measure (unit savings), and net-to-gross ratio all have uncertainty. In California, there is an impetus for the utilities to ensure that their energy savings are credible and reliable (not just estimated) given energy efficiency targets and cost-effectiveness mandates (getting the most efficiency with the least amount of money). In China, there are energy efficiency targets, but explicit cost-effectiveness mandates do not yet exist and estimated savings are acceptable. Given the limited budgets for evaluation in China, however, it is essential that only the most critical issues influencing the estimated savings be investigated – for example, the data issues that bring the most uncertainty (data sources, data types, program implementation methods, etc.). As energy efficiency targets become harder and harder to meet (with potentially the added pressure of tighter budgets), this type of risk and uncertainty analyses will help China focus on conducting accurate and credible evaluation studies, aiding future policy decisions and enabling cost-effective energy savings. If it is found that a certain data input has high uncertainty and sensitivity on the final output, then funds should be allocated for collecting additional primary data that would reduce that uncertainty. The impetus for that particular budget, however, must originate from the need for accurate and credible evaluations [4].

Table 1 outlines the common primary and secondary data sources used in program evaluation. While secondary sources largely consist of existing literature (including technical resource manuals) and simulations, primary sources involve metering and surveys of manufacturers, retailers, and consumers (participants). Additionally, some governments carry out national energy surveys, such as the Residential Energy Consumption Survey (RECS) that is used to gather socio-demographic data and energy usage in homes across the U.S.

3. International review of evaluation methodologies for standards, labeling, and incentives

This section provides a quick overview of impact evaluation methodologies and outlines key evaluation studies performed to date on appliance standards, labeling, and incentives in the U.S., E.U., and Australia.

3.1 Common methodologies in impact evaluation

The basic research question in impact evaluation is: What were the true effects produced by a program or intervention in terms of energy savings (as well as other impacts, such as changes in electricity demand and carbon emissions), separated out from what would have otherwise occurred absent the program or intervention? The recent international evaluation framework review prepared by LBNL referenced over 60 evaluation studies from the U.S., E.U., Australia, and other countries, and it examined 30 studies in depth for unique evaluation methodologies [2]. In general, evaluation of standards, labeling, and incentives follow a similar methodology, which is summarized in Figure 2 and can be broken down into three main parts: 1) stock model (steps 1-3), 2) baseline setting (step 1), and 3) *ex-post* evaluation options (steps 4-7).

3.1.1 Stock model

Ex-ante evaluation of appliance standard programs plays a large role in a number of countries' standards development process, whereby the impact on national energy demand can be estimated for different levels of proposed standards – essentially, different unit energy consumption (UEC) levels against the same baseline (step 1). The unit energy consumption (UEC_e) for the unit replacing or displacing the baseline unit can be gathered from engineering specification documents from the manufacturer. Subtracting UEC_e (energy use of the energy-efficient product) from UEC_b (energy use of the product in the baseline) under the correct usage conditions will give the per unit energy savings (step 2). The usage of the old and new products may vary in certain cases. Unit energy savings can be multiplied by the number of measures or units sold to calculate gross savings (step 3). Shipment projections are used to estimate the "number of measures," the number of products that will be sold under a new standard or labeling program. In the case of incentive programs, the "number of measures" typically mirrors the number of rebates given out for more efficient appliances.

These elements (UEC and number of measures) compose what is typically called an engineering-based model or a stock model in the literature. For the purposes of streamlining these calculations for large numbers of products and product groups, spreadsheet models are usually developed to track product vintage, efficiency, hours of use/lifetime, price, and other factors. Stock model methodologies do not vary widely for appliances. Typically, the model is simply an interaction between the existing stock, sales, and retirement of appliances, and their related energy consumption over time [5, 6].

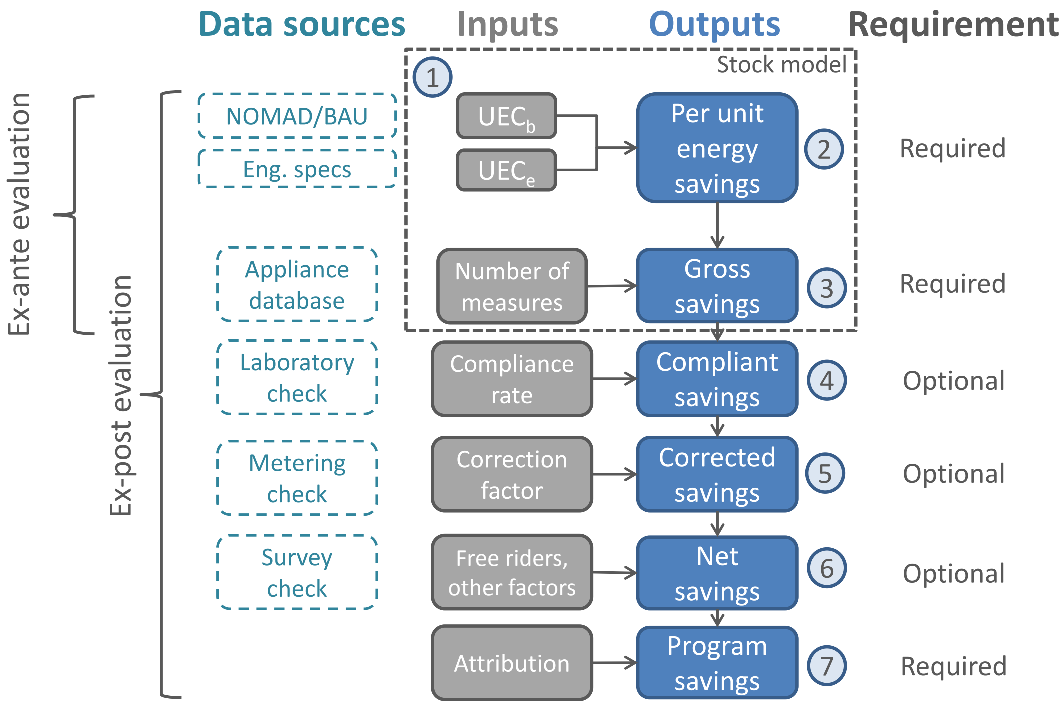

Figure 2: *Ex-ante* and *ex-post* evaluation frameworks for standards, labeling, and incentives

3.1.2 Setting the Baseline

Baselines can be set to estimate some initial level of market penetration for high efficiency products in the absence of standards or labeling. Setting the baseline against which energy savings are measured is one of the most important steps in program evaluation. Since standards, labeling, and incentive programs are all seeking to push more efficient appliances and products into the market, the questions regarding the baseline include the following:

- What is the efficiency of the products that they are replacing or displacing?
- What would have been purchased if the program had not been put in place?
- What would manufacturers have produced and retailers stocked without appliance standards?
- What type of refrigerator would a consumer have purchased without a rebate for a more energy-efficient model?

Setting baselines for standards evaluation is becoming more difficult. There is no longer much data on autonomous efficiency improvements over time in many countries, as standards and labeling (S&L) programs have increased in number. While the proliferation of these programs is good for energy efficiency, it does make setting baselines somewhat of a guessing game, although methodologies are improving. In general, standards evaluations have three baseline setting techniques to choose from:

1. Frozen baseline: the efficiency of new products remains constant in the base case
2. Improvement baseline: where historic UEC data exist, the efficiency of new products improves at a similar rate of historic autonomous efficiency improvement, declining into future
3. Market share baseline: where data on market share for models of different efficiencies exist, a baseline efficiency can be estimated for future years[4]

[4] An additional baseline setting methodology using Bass curves to describe market adoption is discussed in [1]

Frozen baselines have typically been used when there is a lack of data on market-driven improvements, as is typically seen in many developing countries. The China National Institute of Standardization (CNIS), the technical body responsible for developing standards and managing the mandatory energy labeling program, also uses frozen baselines in its annual white papers that have projections on the potential savings from new minimum energy performance standards (MEPS) on various products [1]. Improvement baselines have been used in a few cases; for example, they were used in the case of a recent, comprehensive evaluation of standards and labeling (S&L) programs for refrigerators in Australia [7], where high quality data on shipments were available. As shown in Figure 3, various S&L programs have had distinct impacts on the efficiency of refrigerators sold, including the first mandatory labeling implemented in 1986, updated labeling and MEPS implemented in 1999, and updated MEPS implemented in 2005. Finally, market share baselines have been used in the *ex-ante* evaluation of potential standards levels for U.S. federal standards. For example, given that ENERGY STAR now plays a significant role in the evolution of appliance energy efficiency, it is often taken into account when forming a baseline. Typically, the U.S. Department of Energy (DOE) will work with the U.S. Environmental Protection Agency (EPA) to come up with estimates of where the ENERGY STAR market share of a particular appliance is heading in the absence of standards [6].

3.1.3 Ex-ante and ex-post evaluations

Ex-ante evaluations are quite common for appliance standards, since they help prove the case for energy efficiency, in both reducing a country or state's energy demand and likely saving consumers money in the process. These evaluations take on many assumptions about appliance performance in the field, however, and there is a growing interest in correcting *ex-ante* evaluations with field data to achieve more accurate savings estimates through the use of correction factors. Finally, *ex-post* evaluation of incentives offers the option to include free ridership, reflecting the fact that some consumers would have purchased a more efficient appliance in the absence of an incentive, as well as program spillover, since some customers install additional energy efficiency measures, whether or not they participate in a program.

Appliance efficiency may vary widely in the field due to a number of factors. For example, the UEC_e that is used in *ex-ante* evaluation is often based on engineering specifications as claimed or declared by the manufacturer. In many countries, these specifications are verified by third-party laboratory testing, but not all countries have product testing, and non-compliant products may still exist even where testing is done. Verification testing can be done on a sample of products to get a representative compliance rate (step 4 in Figure 2), and test for how laboratory performance might differ from claimed performance (as shown in Figure 4). In fact, reliable data on compliance rates are not that widely available in many places around the world, so many program evaluations often skip this step. Alternatively, metering measurements could be taken on an appliance once it is installed in a home or commercial building, and then installed performance could be compared with claimed performance to get a representative correction factor (step 5). A recent study at LBNL explored this issue in depth [8].

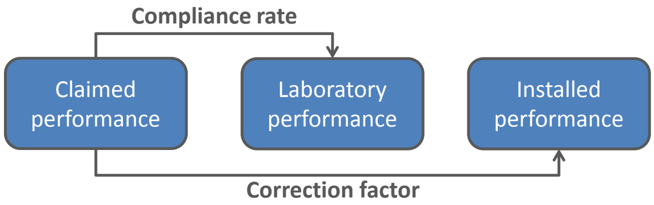

Figure 4: Relationships of compliance rates and correction factors to performance data

Net savings adjustments (step 6) are common for incentive evaluations and include combinations of estimates for free riders, participant spillover, and market effects. One of the most important concepts to understand within a technical measurement approach is that net savings is a behavior metric that adjusts gross savings to account for how a program influences the decision-making processes of the participants or people in the marketplace. In the case of free riders, the original baseline will account for the product being replaced or displaced, while the free rider proportion will account for those participants who would have gone ahead with purchasing a more efficient product even without the incentive that was offered. Participant spillover will account for additional energy saving actions that the participants may have made due to the incentive program. Market effects evaluations estimate a program's influence on encouraging future energy efficiency projects because of changes in the marketplace. The evaluation focuses on the changes in the structure or functioning of a market, or the behavior of participants in a market, that results from one of more program efforts [9, 10].

In the last step, a specific savings amount has to be attributed to a specific program (step 7). This is important when there are various programs that overlap in their influence on one sector's energy efficiency. It is common for labeling and incentive programs to have some overlap, for instance, since both programs are pushing the consumer to purchase an above average efficiency product. Like free riders, attribution factors are also calculated using some mixture of surveying and expert input.

Not depicted in Figure 2 are site-to-source energy conversion factors and emissions factors, which help to determine primary energy savings and emissions savings once secondary energy savings have been determined from the evaluation. Site-to-source energy conversion factors differentiate between primary and secondary energy use and efficiency, which the U.S. EPA has a standardized definition for: "When primary energy is consumed on site, the conversion to source energy must account for losses that are incurred in the storage, transport and delivery of fuel to the building. When secondary energy is consumed on site, the conversion must account for losses incurred in the production, transmission, and delivery to the site. The factors used to restate primary and secondary energy in terms of the total equivalent source energy units are called the source-site ratios" [11]. Once the quantity and type (coal, natural gas, oil, etc.) of primary energy or source energy units is known, then a carbon dioxide emissions factor can be used to find the associated carbon emission savings for the energy saved. Similar emissions factors could be used to determine the amount of emissions avoided for other common air pollutants including sulfur dioxide, nitrogen oxides, and ozone.

3.2 Review of international impact evaluation studies

3.2.1 United States – Federal level

LBNL has conducted a number of national impact assessments for standards for major residential and commercial appliances, using dynamic Business-as-Usual (BAUs) scenarios where assumptions were made on baseline efficiency improvements over time in the absence of new standards. The data for making these assumptions came from a mixture of sources including trade associations (e.g., the Association of Home Appliance Manufacturers) and U.S. DOE Technical Support Documentation (TSD) for related appliance standards development [6, 12, 13, 14]. Also at the federal level, the U.S. EPA carries out impact evaluations for its certification labeling system ENERGY STAR. Key indicators such as ENERGY STAR awareness and ENERGY STAR impact on purchasing decisions are quantified through annual surveys [15]. LBNL has also conducted impact studies on the resultant energy savings from the ENERGY STAR program [16].

3.2.2 California and other U.S. States

California is a leader in energy efficiency, and as such, has developed protocols and procedures for impact and process evaluation [17, 18, 19]. Particularly in the area of incentive programs for building, appliance, and lighting efficiency, these protocols have been very helpful for program evaluators.

Alongside the development of protocols, the evaluation community in California developed the Database for Energy Efficient Resources (DEER) that contains "deemed savings" values for efficiency measures that are commonly installed in the marketplace. California has also established codes and standards in product areas that are not covered by federal standards [20]. Additionally, they recently performed an impact evaluation of several state standards that they had implemented, which incorporated estimates for naturally occurring market adoption and compliance rates [21].

There have been a number of studies by experts at LBNL, EPA, and the American Council for an Energy Efficient Economy (ACEEE) looking at the wide range of evaluation practices found across the U.S. [9, 22, 23]. Other states have developed their own regional or state-based technical resource manuals (TRMs), similar to California's DEER database [24]. Amidst the diversity of existing methodologies given the U.S.'s diverse regulatory space for electricity and energy efficiency, there have been efforts to consolidate methodologies and potentially make a national impact evaluation protocol for various energy efficiency measures. The State and Local Energy Efficiency Action (SEEAction) Network wrote a scoping study to identify issues with developing such a protocol [25], while the National Renewable Energy Laboratory (NREL) is running the Uniform Methods Project, which has developed draft methodologies for specific efficiency measures in residential lighting, commercial HVAC, and other areas.[5]

3.2.3 Australia

Australia has had a number of efforts in the evaluation of appliance programs. In 2002, Australia created its first draft framework for the evaluation of the Australian Energy Efficiency S&L program. An additional program audit for labeling was performed in 2004/2005, with more comprehensive program audits for air conditioners and refrigerators performed as recently as 2010 [7, 26]. These studies are very helpful for their use of improving baselines and correction factors as well as their strong data collection techniques.

3.2.4 European Union

European evaluation efforts have been headlined by two recent large-scale projects in support of E.U. energy efficiency targets. The first project was the Evaluation and Monitoring for the E.U. Directive on Energy End-Use Efficiency and Energy Services (EMEEES), which focused on bottom-up methodologies for 20 different energy efficiency measures [27]. The second project was the European Energy Efficiency Database (ODYSSEE), which focused on top-down indicators for energy efficiency as a route to monitor energy efficiency trends and policy measures in Europe [27]. In addition to these two projects, a number of studies have been done to evaluate the savings from the E.U.'s categorical labeling program [29, 30].

The EMEEES methodologies covered all forms of common programs including regulation (MEPS), labeling and training measures, financial incentives, and voluntary agreements. In addition to creating bottom-up methodologies for 20 different measures, the EMEEES project also proposed a template for member states to establish National Energy Efficiency Action Plans (NEEAPs) and a methodology for the E.U. Commission to perform *ex-ante* assessments and *ex-post* evaluations of the NEEAPs. The summary report for the EU's EMEEES project argued that top-down methodologies are accurate enough for appliances and vehicles, if there were well defined statistical indicators of average specific energy consumption per unit, while bottom-up methodologies were difficult due to free rider and multiplier effects which can be very costly to quantify.[6] If the measure saved more than 40 million kWh in annual electricity savings, more than 100 million kWh in annual energy savings, or greater than 5% of any individual member state's Energy Services Directive target, bottom up methodologies were justified. If a member state had only limited data about the measure, they used EU default values. If a member state had very measure-specific data, then there were specific harmonized guidelines they could follow to calculate the savings [31].

For a full list of other countries and program evaluation studies reviewed, see [2].

---

[5] More information on NREL's Uniform Methods Project can be found at: http://www.nrel.gov/extranet/ump/about.html

[6] While bottom-up evaluation relies on surveys and quantification (of participants and specific measures) to inform inputs into engineering-based models, top-down evaluation uses aggregate consumption indicators (such as total energy consumption or per-capita energy consumption) as inputs to macro-economic demand models.

4. Program evaluation options for standards, labeling, and incentives

This section provides the key data requirements for the methodologies reviewed in section 3, an assessment of China's data availability, and three methodology options for China to consider in light of their data availability for standards and labeling evaluations as well as incentive evaluations.

For the three methodology options, the first is largely based on China's existing capabilities and data availability. The second option proposes a small budget increase to conduct some data collection that will improve results and reduce uncertainty for the related analysis, with the idea that this option could be implemented on a shorter time scale of one to three years. The third option is a long-term implementation (five to ten years) of a number of improved data collection methods to achieve the lowest uncertainty with an effective use of budget.

Whether or not the Chinese government seeks to move towards these options that involve increased data collection and may require additional funds depends on their goals in the energy efficiency space. For instance, additional budget for surveying and metering may yield more certainty in the energy savings estimates from incentive evaluations. A full assessment of China's data availability will certainly aid the Chinese government's efforts in energy efficiency planning as they continue to improve their rapidly expanding standards, labeling, and incentive programs.

4.1 Key data requirements and China data availability

Table 2 outlines the data types needed for evaluations of standards, labeling, and incentive programs. The bolded items indicate which data types that China is already collecting through surveys and other types of data collection [1]. The shaded items are those data types that are optional in some cases. For instance, in the evaluation of incentives, free ridership is not needed for a gross energy savings evaluation but is required for a net energy savings evaluation. The levels of uncertainty and sensitivity have been estimated for this preliminary study based on the authors' knowledge of evaluation literature and familiarity with Chinese data availability. These hypothesized levels can later be tested once formal program evaluations are underway in China.

Associated with each data type is an assigned sensitivity based on that data's impact on the evaluation algorithm. Previous ex-post evaluations have shown that number of measures, unit energy savings, and net-to-gross ratio have the highest impact on the end result [3]. As such, those options have all been flagged as high sensitivity in Table 2. Each data type also has an assigned uncertainty based on the currently used data source. For example, the annual UEC data currently collected by the China Energy Label Center (CELC) are a combination of the unit's efficiency (since energy labeling is now mandatory for many consumer products, these data must be reported by the manufacturers to CELC) multiplied by some assumption on usage. Although there is low uncertainty about the declared unit efficiencies, there could be higher uncertainty on the usage of the product (air conditioner usage varies widely, for instance).

Table 2: Data types required for standards, labeling, and incentives evaluation with China's current data sources and associated uncertainty and sensitivity

Data type	Standards, labeling, incentives? (S,L,I)	Data source	Sensitivity (high, medium, low)	Uncertainty (high, medium, low)
Annual energy savings per unit product	S, L, I	CELC white paper, assumptions	High	Medium
Existing stock	S, L	Calculation	Low	Low
Market saturation (ownership, market shares)	S, L	China Statistical Yearbook	Medium	Low
Lifetime or retirement function	S, L, I	Literature, assumptions	Medium	Medium
Future shipment forecasts	S, L	Assumptions, calculation	High	Medium
Usage adjustment factor (UAF)	S, L, I	Literature, assumptions	Medium	Medium

Naturally occurring market adoption	S, L	Estimation	Medium	Medium
Compliance rate	S, L, I	Literature, assumptions	Medium	Medium
Real shipments/sales	S, L	CELC white paper	High	Low
Site-to-source energy conversion factors	S, L, I	Literature, assumptions	Medium	Low
Emission factors	S, L, I	Literature, assumptions	Medium	Low
Number of measures	I	Ministry data (e.g. Ministry of Finance)	High	Low
Free ridership	I	Survey needed	High	High
Participant spillover	I	Survey needed	Medium	Medium
Market effects	I	Survey needed	Medium	Medium

Note: bolded data types are for data that China has already collected, shaded data types are optional in some cases.

As mentioned in section 2, once the sensitivity has been determined, this can assist in deciding priorities for enhanced data collection. Here, we add the uncertainty as an additional parameter to help determine data collection priorities. Table 3 outlines the high, medium, and low priorities for data collection based on sensitivity and uncertainty parameters. For instance, if an input has a high sensitivity on the evaluation algorithm but a very low uncertainty based on the current data source, then it is a low priority for improved data collection methods. Table 2 shows that real sales for products have a high sensitivity for standards and labeling evaluation but a low uncertainty. Sales has perhaps the largest impact on the evaluation algorithm (thus the high sensitivity), but China has had data collection in place for about three years now via a retail sales survey company, so this would be a relatively low priority for any new or improved data collection. As another example, lifetimes of products can help in projecting sales or in determining useful life of a product and thus carry a medium sensitivity. The data are currently estimated based on international literature giving them a medium uncertainty since product lifetimes within China may vary from those in the U.S. or E.U.

Table 3: Relationship of sensitivity and uncertainty of data inputs to data collection priority

Uncertainty / Sensitivity	High	Medium	Low
High	High priority	High priority	Low priority
Medium	Medium priority	Medium priority	Low priority
Low	Medium priority	Low priority	Low priority

4.2 Identifying evaluation options for China

Identifying where China current collects data will aid in recommending options for China for evaluations that it can currently carry out with little or no additional data collection. Assigning sensitivity and uncertainty to all other data types will aid in recommending options for evaluation that it can carry out in the short-term (1-3 years) and long-term (5-10 years) based on expanded and improved data collection. In this section, we identify evaluation options for China for standards and labeling as well as incentive programs. We outline three options based on: 1) current capabilities, 2) increased but limited data collection over the next few years, and 3) a more expansive increased data collection over the next five to ten years.

4.2.1 Standards and labeling options

The three options for standards and labeling evaluation are as follows:

1. Ex-ante or simple ex-post evaluation based on existing capabilities (to implement now)
2. Ex-post evaluation with improved data on product usage, compliance, and site-to-source factors (to implement on a 1-3 year time scale)
3. Full ex-post evaluation with expanded surveying, testing, and/or metering (to implement on a 5-10 year time scale)

Within each option (outlined in Table 4), there is a specific direction for each data source:

1. Literature: Pull data from domestic or international literature
2. Existing data: Use data sources that China has already collected, including the China Energy Label Center's annual white paper
3. Datasets: Use a dataset that China should have at a future date (e.g. emissions factors)
4. Survey/metering: Employ new survey, laboratory testing, or on-site metering to gather new and improved data

Table 4: Data sources for standards and labeling evaluation options

Data type	**Implement now**	**Short-term (1-3 years)**	**Long-term (5-10 years)**
Annual energy savings per unit product	Existing data	Survey/metering	Survey/metering
Market saturation	Existing data	Existing data	Existing data
Lifetime	Literature	Literature	Survey/metering
Usage adjustment factor (UAF)	Exclude	Exclude	Survey/metering
NOMAD or other baseline	Exclude	Exclude	Datasets
Compliance rate	Exclude	Datasets	Survey/metering
Real shipments/sales (or forecasts if *ex-ante*)	Existing data	Existing data	Existing data
Site-to-source energy conversion factors	Literature	Datasets	Datasets
Emission factors	Literature	Datasets	Datasets

Note: Exclude means that data point is not needed for the specified analysis in this option.

Option 1 is roughly based on China's current evaluation capabilities and data availability and, therefore, does not involve any expanded surveys. Unit savings, market saturation, and sales can be taken from CELC's existing databases and retail surveys. All ex-post evaluation adjustments (such as usage adjustment factor and compliance rates) are excluded. Site-to-source energy conversion factors and emission factors can be estimated with existing domestic literature, such as project design documents reported under the Clean Development Mechanism.

Option 2 makes two major changes from Option 1. First, there would be a set amount of surveying or on-site metering to determine hours of usage for various products (e.g. lighting, televisions, air conditioners, etc.). This would help decrease the uncertainty surrounding the high sensitivity data point on unit energy savings but would also carry an associated need for budget to finance that surveying or metering. Second, new estimates could be made on compliance rate and emission factors based on expanded datasets that China is likely to have in one to three years. For example, China is currently expanding its product verification testing (within CNIS's Energy Efficiency Laboratory Division) and may have an expanded dataset on product compliance in the coming years. Additionally, with China's expanding reporting for carbon intensity targets and growing carbon market programs, data on emission factors will likely improve over the coming years.

Option 3 suggests a full set of evaluation capabilities, the extent of which is even beyond current evaluation scopes in the U.S., E.U., and elsewhere. The main difference in going from option 2 to option 3 is in using more sophisticated ex-post evaluation adjustment factors, including usage adjustment factors, compliance rates, and baselines. Through a mixture of laboratory testing and on-site metering, China can get a more accurate energy savings estimate by comparing how products perform in the field versus how they are declared to perform by manufacturers. It should be noted, however, that extensive testing like this is not yet regularly performed for ex-post evaluation in major developed countries due to the high budget required. There will always be a balance between budget and certainty, and China should make appropriate decisions based on their evaluation goals. For baselines, China will have enough data to perform a more sophisticated baseline analysis given that it will have collected 10-15 years of retail sales data broken down by energy efficiency labeling level.

4.2.2 Incentives options

Unique data points for an incentives evaluation (as compared to a standards or labeling evaluation) are highlighted in Table 5. The options for evaluation follow a similar categorization.

1. Simple ex-post gross savings evaluation based on existing capabilities (to implement now)
2. Ex-post net savings evaluation with improved data on free ridership and unit energy savings (to implement on a 1-3 year time scale)
3. Full ex-post net savings evaluation with expanded surveying on free ridership, participant spillover, and market effects (to implement on a 5-10 year time scale)

Table 5: Data sources for incentives evaluation options

Data type	Implement now	Short-term (1-3 years)	Long-term (5-10 years)
Annual energy savings per unit product	Existing data	Survey/metering	Survey/metering
Number of measures	Existing data	Existing data	Existing data
Free ridership	Exclude	Survey/metering	Survey/metering
Participant spillover	Exclude	Exclude	Survey/metering
Market effects	Exclude	Exclude	Survey/metering

Note: 'Exclude' means that data point is not needed for the specified analysis in this option.

China has implemented a number of rebate programs for energy efficient products in the past few years including Rural Area Household Appliance Subsidy Program (also known as "Appliances to the countryside") and Energy Efficient Products Discount Program (also known as "Huimin gongcheng") [1]. Evaluations for gross energy savings can be performed on these programs by simply multiplying the number of rebates by the unit energy savings and expected useful life of the product. This assumes, however, that all of the measures or efficient products were successfully installed which may not be the case. Inspections and surveying could be performed on a selection of sites to determine the proportion of measures installed to rebates granted. For a net energy savings evaluation, a survey will be needed to evaluate the amount of free ridership. Further down the line, a more sophisticated survey can be administered to estimate other values including participant spillover and market effects. The degree to which these values are used in estimating net-to-gross ratios in ex-post evaluation varies widely in the U.S. Additionally, there is a concern that with a proliferation of energy efficiency policies (standards, labeling, incentives, other awareness campaigns) impacting any one consumer's purchase, it may become increasingly difficult to attribute the savings from an energy-efficient product to any one incentive program [9].

5. Conclusion

As China ramps up its efforts in energy efficiency in the 12th Five Year Plan and beyond, data availability for standards development and program evaluation is becoming an increasingly relevant question. In this study, we have surveyed international evaluation methodologies and recommended options for China to improve its capabilities in program evaluation. In order to establish the foundation of these recommendations, we first outlined the relationships between program goals and budget, choice of algorithm and methodology, data gathering, and data sensitivity and uncertainty. Improvement to data inputs should be prioritized based on how much those inputs impact the end result of the analysis (sensitivity) and an assessment of data quality and collection method (uncertainty). Given the scope of China's appliance standards, labeling, and incentive programs and the scale of energy consumption growth in this sector, improvements to practices in development and evaluation should continue to be recommended. We found that data types with high sensitivity and high or medium uncertainty should be prioritized for increased or improved data collection in the medium term (1-3 years). Both annual energy savings per unit and free ridership fit this description, and China can plan increased surveying and metering to reduce the uncertainty of these values. Any increased data collection will need extra budget and human resources, which may be difficult for CNIS to manage. A small-scale surveying and metering pilot program could be introduced as a near-term, low budget option for China to test out how China might improve its evaluations and decrease the uncertainty of energy savings achieved by its expansive standards, labeling, and incentive programs.

Acknowledgments

We would like to express our deep appreciation to the China Sustainable Energy Program of the Energy Foundation and the Collaborative Labeling and Appliance Standard Program (CLASP) for providing funding for this project. We would especially like to thank Kevin Mo and Steven Zeng. This work was supported by the China Sustainable Energy Program of the Energy Foundation and the

Collaborative Labeling and Appliance Standard Program (CLASP) through the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

An econometric model to assess residential electricity savings in the EU

Paolo Bertoldi, European Commission Joint Research Centre

Bettina Hirl, University of Lugano

Abstract:

For policy makers at the European and national level it is important to know how effective energy policies and measures are and how much energy has been saved, in particular towards the 2020 energy saving target. Alongside the evaluation of the energy savings, it is also necessary to collect as much information and knowledge as possible about energy consumption trends and factors influencing energy consumption. Moreover, for policy makers it is crucial that a monitoring and evaluation method is giving good and reliable results on the one hand and is relatively easy and straightforward to use in practice on the other hand. In the paper a new methodology for quantifying the energy savings produced by energy efficiency measures and policies is described. The methodology is based on a relatively simple econometric model that is used to estimate consumption and, based on that model, to forecast energy consumption. The forecasted consumption is then compared with the actual consumption. The differences between the forecasted and the actual consumption can be interpreted as the estimated energy savings.

We present a general energy demand model which is used to evaluate energy savings due to energy efficiency policies. The general model can be applied to different sectors (e.g. residential, tertiary) and different fuels (e.g. electricity, gas). In this paper the model is applied to the residential electricity sector.

Based on the econometric model, the energy savings are estimated for six Member States. The results show that energy efficiency policies are already starting to be successful and their impact on energy consumption is already visible in the analyzed MSs, which achieved important savings in consumption.

1. Introduction

Energy efficiency has become one of the main policy goals in the European Union. Many important directives and regulations to promote energy efficiency have been implemented or are in the planning phase just before implementation. Furthermore a lot of EU Member States have been very active in the area of energy efficiency on the national level, having implemented many important policies and measures. For the policy maker at the European and national level it is therefore important to know how effective these measures are, where the different countries stand in terms of energy efficiency, and how they compare to each other. A monitoring and evaluation system is needed. Alongside the evaluation of these policies, it is also necessary to collect as much information and knowledge as possible about energy consumption trends and factors influencing energy consumption. In this project we build a methodology to evaluate energy efficiency improvements of a country by quantifying the energy savings produced by energy efficiency measures and programmes. For policy makers it is crucial that a monitoring and evaluation method is giving good and reliable results on the one hand and is relatively easy and straightforward to use in practice on the other hand. The methodology we are using in this project is a relatively basic econometric model that is used to estimate actual consumption and based on that model to forecast energy consumption.

The general economic model used to estimate energy demand usually includes energy prices, an indicator for the economic situation (e.g. GDP), a variable for weather/climatic conditions (e.g. heating degree days), and the population size. To this variables we add the stock of electric appliances (i.e. refrigerators). Energy demand is then estimated as a function of these factors. Based on the model, we also forecast energy demand for a pre-specified period (2 and 4 years).

The forecasted consumption is then compared with the actual consumption. The differences between the forecasted and the actual consumption are the achieved (estimated) can be interpreted as energy savings (the interpretation of this difference will be discussed in more detail in chapters 3.2. and 3.3..)
In this project we present a general model[1] that can be applied to different sectors (residential and tertiary sector) and different markets (electricity and gas) under different conditions and specifications.

2 Design of the Database

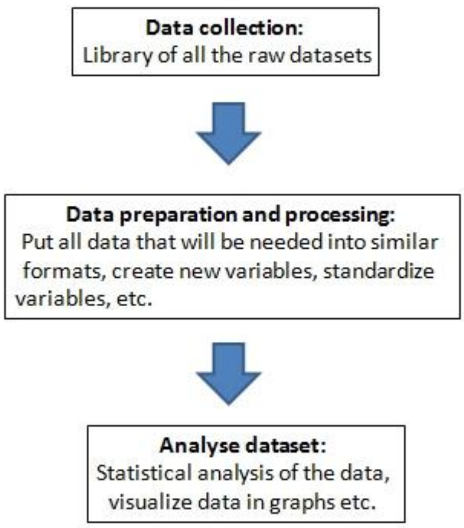
2.1 Methodology

The database is created for the econometric analysis with a statistical software programme. In this project Eviews is used but any other statistical software can be used as well. The structure of the database consists of multiple levels. The first level consists of the raw datasets (Excel files) taken from various data sources. On a second level, the relevant data needed for the model is transformed, processed and formatted for use in Eviews.[2]

The formatted data can then be analysed (statistical analysis, graphs etc.) as a preparation for the econometric analysis. The creation of the database is a crucial step in the project process as the quality of the models depends to a large extent on the data used. The statistical analysis can be found in chapter 3 as a part of the research design/methodology.

The methodology for the database design and data analysis is as follows:

Fig. 1: Database methodology



2.2 Outline of the Database

The database consists of all collected raw datasets. From these raw datasets we produced two individual excel sheets with the data needed for the econometric analysis, one for each of the two econometric models.

The following table gives an overview of the database with the collected datasets/variables that could be used for the econometric model and also for further analysis related to the project. The database is as inclusive as possible to give an overview of all relevant data. Not all datasets / variables included in the database will actually be used in the modelling process.

---

[1] The models are based on the National Consumption Metrics Models developed by Marvin Horowitz.
[2] Note: The econometric analysis as described in this report is done in Eviews and hence the database is formatted for use in Eviews. However, the available, collected datasets can be used in any other statistical software.

While the geographic dimension of the dataset all EU-27 countries are included in the database, for the econometric analysis not all EU-27 Member States have been included but only certain group of countries. The Member States that have been included in the analysis depends on data availability, the choice of the regression model and the grouping of countries. The time dimension of the database is: 1990 to 2010 (2010 being the latest available year on Eurostat at the time of the project). The economic sectors coverage is the residential sector

Tab. 1: Overview of available datasets

Data Source	Dataset/ Variables
All Sectors	
Eurostat	Actual heating degree days
	Real GDP per capita
	Population
	Value added by economic sectors
	GDP deflator
Odyssee Database	Energy efficiency index
	Final energy intensity
Residential Sector	
Eurostat	Final energy consumption
	Final electricity consumption
	Final gas consumption
	Gas prices
	Electricity prices
	Number of households (per country)
	Average people per household
Odyssee Database	Stock of appliances

2.3 Data availability and quality

In general, the datasets are available for the full timeframe of the analysis from 1990 to 2010. Only the population dataset and the energy consumption datasets are complete for all Member States. The heating degree dataset is complete from 1990 until 2009 but ends at 2009, there is no data on actual heating degree days for 2010 on Eurostat at the time of the project. All other datasets are incomplete with missing observations for at least one Member State but usually for several Member States and over several periods. For data on households like the number of households per country, average people per household and average size of dwelling in square meters the datasets are very incomplete and cover only a few countries and short time periods.

The countries that are being analyzed in this project were partly also selected because of the high availability and quality of their corresponding datasets. This is true for the four bigger countries, namely France, Germany, Italy, and the United Kingdom. However, also for these countries we have incomplete datasets and/or differences in the quality of the available data. For Italy, for instance, the electricity prices for the residential sector are missing for three periods.

There are several ways to deal with missing data. One way to deal with missing data would be to pool countries together to a group and then do a panel analysis. Another way is to estimate the missing data points or extrapolate them. For some Member States there might exist a similar dataset without the missing observations in another database, e.g. a national database. However, this is only true for some countries and the different languages in the EU make it difficult to collect those data.

The quality of the available data can differ to a great extent and is closely related to the methodology of data collection. Methodologies may change over time which can cause a disturbance of the dataset. These disturbances can have significant impacts on the econometric models' results.. Apart from a change in data collection methodology, other factors can influence the quality of the data. These factors are seldom known and are difficult to detect in the data. One possibility to understand more about the quality of the data is to look at the graphs of the different datasets. If there are important outliers or very unusual trend patterns it is very likely that the quality of the data is not very high. Data quality was another determinant in order to select countries for our econometric analysis. The quality of the datasets of France, Germany, Italy, and the United Kingdom is in general relatively high compared to other countries also because these countries have a long tradition in data collection.

3 Design of the econometric models

3.1 General research outline

The aim of this project was to build a methodology that produces good and reliable energy efficiency (energy savings) estimates to evaluate if policies designed to reduce energy consumption in the EU have already been successful. Furthermore, the models have to be relatively simple to be of use in the daily practice of the policy maker for policy evaluation and further development of policies. The project presents a general model that can be applied to different sectors (residential and tertiary sector) and different markets (electricity and gas) under different conditions and specifications.

We have used two different estimation approaches to estimate the models. The first approach is to estimate individual time series models with OLS. The second approach is to estimate a panel model with country fixed effects (LSDV) including either all 27 EU Member States or, alternatively, a sub-group of countries.

The individual time series models generally deliver more precise results and smaller forecast erros whereas the panel models have more observations and hence deliver more stable coefficients less affected by multicollinearity and outliers.

We estimate different models for each of the six countries selected, by changing the cut-off period, the explanatory variables, and also the estimation method (panel and individual time series models) We then compare models according to forecast results, forecast percentage errors, goodness of fit of the estimated regression, and significance level of the regression coefficients.
The general aggregate energy demand function our models are build on can be written as follows:

$$Y_{it} = f(RP_{it}, HDD_{it}\ , RGDP_{it}, POP_{it}, ST_{it}, t)$$

Where Y_{it} is the aggregated energy demand (electricity or gas), RP_{it} is the real price, HDD_{it} are the actual heating degree days, $RGDP_{it}$ is the real GDP, POP_{it} is population, ST_{it} is the stock of appliances, and t is the year.

Our general econometric model consists of a dependent variable and multiple explanatory variables. In this project the dependent variable is defined as the energy consumption of a single fuel (electricity or gas) divided by population (or employees in some cases). Based on the economic theory of energy demand, the following main factors were identified to influence energy consumption: energy prices, economic situation/development, and weather conditions. These factors are included as explanatory variables in all the models presented in this project. For some models, a time trend variable is added, which represents the change in equipment stock and/or other societal trends. The model is in log-log form (dependent and explanatory variables are expressed in logarithms) so that the coefficients can be directly interpreted as elasticities.

Energy prices are delivered for fuel categories on a half-yearly basis by Eurostat. From these half-yearly prices, annual average prices are calculated. Energy prices are transformed into real prices by correcting them with the individual GDP deflators for each country and period. In the case of Italy, electricity prices are missing for three consecutive years. However, prices including taxes are delivered for these years by Eurostat. The missing values are extrapolated by taking the average amount of taxes that add to the price of electricity and subtracting this value from the prices with taxes. Energy consumption is closely linked to the weather. The reason for this lies mainly in the fact that heating is the biggest part of residential gas consumption. In many countries, electrical heating is getting more popular compared to other heating methods. In that sense, cooler temperatures than normal also have an influence on electricity consumption. It is also very likely that people spend more time in the house using electric appliances in cold years and cooler climates. This also increases electricity consumption. The model accounts for climatic and weather conditions by including annual actual heating degree days for each country into the regression equation. Degree days are available for the period 1990 until 2009. The average value for 1980 until 2009 is then used for the year 2010.

Another important influencing factor of energy consumption is the economic situation. A general positive relation between economic growth and energy consumption can be observed although this correlation decreased slightly during the last years due to a more efficient and less energy intense economy. Nevertheless, the models show that the influence of economic growth on energy consumption is positive and statistically significant in most cases. The models account for economic growth and the economic situation by including GDP per capita or an industrial production index into the equation. The GDP is provided by Eurostat as real GDP per capita.

In line with our analysis of the available data and of the factors influencing energy consumption, we specify the following general econometric model:

$$\frac{\ln Y_{ijt}}{N_{ijt}} = \alpha_{ijt} + \beta_{HDD} lnHDD_{jt} + \beta_{RP} \ln RP_{ijt} + \beta_{RGDPPC} \ln RGDPPC_{ijt} + \beta_{ST} \ln ST_{ijt} + \beta_{DT} DT_{jt} + \varepsilon_{ijt}$$

where Y_{ijt} is aggregated energy consumption, N_{ijt} is population or number of employees, HDD_{jt} are the actual heating degree days, RP_{ijt} is the real price per kWh for electricity or per Gj for gas respectively, $RGDPPC_{ijt}$ is the real GDP per capita, ST_{ijt} is the stock of electrical appliances (e.g. refrigerators) DT_{jt} is a series of time dummy variables and ε_{ijt} is the disturbance term all for country j, year t and fuel market i[3]. As energy consumption and the regressors are in logarithms, the coefficients are directly interpretable as demand elasticity.

The general model is valid for all countries, sectors, single fuels and estimation methods. We estimate panel data models (with all 27 EU Member States and with only a small group of countries) and individual time series models. For the panel data models, we include fixed effects (FE) time and cross section dummy variables, whereas the cross section dummies are the individual intercepts, α_{ijt} and the time dummy variables are represented by DT_{jt} in the model specified above. For the individual time series models, one individual intercept and no time dummy variables are included in the model, as the time dummy variables capture the unobserved heterogeneity of individual countries.

Since the data availability is best for the residential electricity consumption models, we estimated a panel-27 model, two sub-panel models (one with four countries (DE, FR, IT, UK) and one with two countries (BG, RO), and individual time series models for Germany, France, Italy, and the United Kingdom. The reason why we estimated different models is to try out under which setting the model works best and we get the most precise saving estimates.

	Residential electricity

Sub-panel (BG, RO)	x
Individual time series (3 variables)	x
Individual time series (4 variables, incl. fridge)	x

The energy demand models we estimated were then used as the basis for the energy consumption forecasts in order to determine the energy savings occurred in a specific country. We forecast for two cut-off periods (2006 and 2008), meaning the forecasting periods are two and four years respectively. The forecast consumption levels were then compared to the actual consumption levels, the difference between the two can be interpreted as the achieved energy savings under suitable assumptions. Generally the difference between actual consumption and forecasted consumption is the part that is not explained by our econometric model (the residual). In a regression the residual is usually the result of a combination of omitted variables, measurement error, misspecification of the model, and other random events. By including all relevant variables, choosing the correct function form (e.g. log-log as in our case), and minimizing measurement error by understanding the data, we are reducing the part of the difference/residual which is not due to a omitted variable. The variable which is missing (hence the omitted variable in our model) is clearly the level of energy efficiency policies in a given country. Hence, by controlling as good as possible for the other factors that make part of the residual, we can expect that the omitted variable, energy efficiency policy, takes up a large part of it. A significant part of the difference between actual and forecasted consumption can thus be attributed to the impact of energy efficiency policies. We cannot tell how large the part of the difference that is due to the energy efficiency policy variable is in terms of percentages but it can be shown that our models deliver good results and have a good overall fit. Nevertheless, we suggest to interpret the estimated savings as a general trend in savings rather than very precise estimations of actual savings.

3.2Estimation results

This chapter summarizes estimation outputs and results of the models estimated.[4]

The overall goal of the project is to quantify savings resulting from energy efficiency measures and policies. Important for our analysis is therefore the performance of the models in terms of forecasting preciseness, measured by the percentage forecast error[5]. This is a slightly different approach than usually undertaken in econometric studies, where the primary attention lies on the estimation outputs, i.e. sign and significance level of the coefficients and the goodness-of-fit measure (e.g. R^2). For the evaluation of the different models, we focus primarily on the preciseness of the forecasts. As we are interested in forecasting energy demand rather than explaining and interpreting the impact of each individual variable on energy demand, we place less focus on the individual coefficients of the regression estimation and place more emphasis on the preciseness of the forecasts.

Our analysis shows that the individual time series models produce – in most cases- better forecasting results than the panel models (by panel models we mean the panel-27 model with all 27 EU Member States and the smaller sub-panel models with 2-4 countries). The results from the individual time series models are generally more precise and more reliable than from the panel models. In some cases, however, panel models provide superior results for some countries. For instance, some sub-

[4]All estimation output tables, consumption forecast graphs, and savings' estimates and precision levels' tables can be found in the annex of the full report. The most relevant tables and graphs can be found at the end of this chapter.

[5] The percentage forecast error is calculated by dividing the standard error of the forecast by the forecasted consumption

panel models for a group of four countries (DE, FR, IT, UK) produce better results for some countries. In all models estimated some coefficients are statistically significant and carry the expected sign. [6]
As expected, the number of significant coefficients is generally a bit higher in the panel models. The differences in significance levels between panel models and individual time series models is most likely due to the number of observations. For the panel models, the number of observations is substantially higher than for the individual time series models.

In general, the estimation outputs are in line with our expectations concerning the sign of parameter coefficients. The results show that the price has a negative influence on consumption, although the price elasticity of energy demand is relatively inelastic. In some models, the values of the coefficient for the real price are also in the expected range, mostly close to -0.30 which is in line with usual estimates of price elasticity of electricity demand.

Actual heating degree days are significant and carry a positive sign in some cases, showing there is a positive correlation between heating degree days and energy consumption. However, our models also show that sometimes the influence of heating degree data is not as clear and important as may be expected, some of the coefficients are not significant and carry a negative sign. The coefficient for real GDP per capita is usually positive, showing that an increase in GDP will also increase energy consumption.

Apart from the three main explanatory variables (real price, real GDP per capita, and actual heating degree days) included in all models estimated, some models also include the stock of refrigerators. The coefficients for the stock of refrigerators, which is only included in the residential electricity consumption models, have the expected positive sign and are statistically significant in some cases (see Appendix), which indicates that the stock of refrigerators is important to be included in the models as time trend for the rate of use/change of appliances in households. Furthermore, it might be desirable to include a comparable variable also for gas consumption models.

Tab. 2: Comparison of regression coefficients of selected models for residential electricity consumption: Panel-27 LSDV (fixed effects) model vs individual time series models (OLS)

Although the significance level of estimation outputs of our models is worth noting, the primary goal of the project is to produce precise forecasts of energy consumption and energy savings, therefore the

[6] The R^2 is generally in the expected range for the individual time series models. For the panel data models, the reported R^2 is not the correct one. To obtain the correct R^2 for a panel model, one has to calculate the within R^2 which adjusts for the fixed effects.

main focus should be on the forecasting results rather than on significance levels of individual coefficients. There exists a trade-off between estimation outputs that are statistically significant and the preciseness of the forecasts. Whereas the panel models generally produce a higher number of statistically significant coefficients, the individual time series models generally deliver more precise forecasts. The first result is – as already mentioned- due to the increased number of observations; the second result is due to the differences between countries. Although our panel models account for heterogeneity (observed and unobserved) between countries not all differences can be captured in the models. Therefore, individual models deliver more precise results for the specific countries. A prerequisite for estimating individual time series models is a sufficient number of observations. For France, Germany, Italy, and the United Kingdom the number of observations was sufficient to produce good forecasts whereas for Bulgaria and Romania we do not have enough observations and hence have to rely on the panel model estimates for these two countries.

3.3 Energy savings

For policy makers it is of crucial interest to know if the policies they implemented are delivering the desired results, in our case energy savings. During the last years, energy efficiency has become one of the main policy goals in energy policy in the EU. A series of EU-wide, national and also regional policies have been implemented. The models we estimated were built to forecast energy consumption and hence show the accumulated energy savings of the last years as a result of the policies implemented. Our results show that we can already see an impact of energy efficiency policies on energy consumption. The impact varies between sectors and fuels. The most significant effect of policies can be seen in the residential electricity sector where our models estimated energy savings for the majority of countries analysed. As explained in chapter 3.2, energy savings are calculated as the difference of actual and forecasted consumption. The difference between actual and forecasted consumption is largely driven by the omitted variable, energy efficiency policy, in our model. Although we cannot say how large the difference due to energy policy and how large the part of other factors influencing the residual is (as mentioned above the difference could in theory also be caused by measurement error, a wrong function form or temporary random events), we can show that our models have a general good fit, and deliver precise results with small forecasts errors. Hence, it is very likely that the difference between actual and forecasted consumption is mainly due to energy efficiency policies. The forecasts are produced based on the energy consumption models estimated. Since we estimated a series of different models (individual time series models and panel models) with different specifications (i.e. varying explanatory variables) our results in terms of estimated energy savings for the same countries differ between the models.

Our results show that the highest energy savings have been realized in residential electricity consumption showing that energy efficiency policies have already been successful there.
In line with our expectations, we find that for the four bigger EU countries (France, Germany, Italy, United Kingdom) our models estimated higher energy savings as for the two newer EU Member States, Bulgaria and Romania. This can be explained by the different implementation times of energy efficiency policies in the two groups of countries. Germany, France, Italy, and the United Kingdom started to implement policies to reduce energy consumption since the early 1990s whereas Bulgaria and Romania implemented most policies during recent years. Hence, results of these policies are not yet as visible as in the other four countries.

In the panel model for residential electricity consumption with all 27 EU Member States almost no energy savings are visible. The general observation is that actual consumption lies above forecasted consumption for the countries analysed only Italy and Germany achieved savings in this model. Contrary to that, the sub-panel models and individual time-series models show significant savings for most countries and periods analysed. The individual time series models estimated for France, Germany, Italy and the United Kingdom show savings in residential electricity consumption for all countries and periods except for France in the year 2010. Savings lie between 0.42% and 11.34% per year in these models. The graphs (Fig.2) show that actual consumption is flattening for the four countries whereas forecasted consumption follows a rising curve.

The most precise results are gained from the residential electricity consumption models, whereas the gas consumption models deliver less precise forecasts. This is to a great extent caused by an overall lower quality of the data for this sector compared to the data for residential electricity consumption. Furthermore, some variables included in the residential electricity consumption models (i.e. stock of electricity consuming appliances) are not are available for gas consumption such as the stock of energy consumption appliances.

The percentage errors of the forecast for the individual time series models are generally lower than for the panel models. Percentage errors for the individual time series models for residential electricity consumption with four regressors are between 0.63% and 4.61%. For residential gas consumption, our models delivered comparatively low forecasting errors lying between 2.56% and 6.91

In summary, we can say that policies are starting to have a visible effect on energy consumption, especially in the residential electricity sector, where our models show important energy savings for some countries. Furthermore, in Bulgaria and Romania, important energy efficiency potential could be realised. Until today, our models show no significant energy savings for these two countries. Concerning the preciseness of the forecasts, it can be said that individual time series models generally delivered better and more reliable results than panel models although there are some individual exceptions. Furthermore, it is important to note that the availability and quality of the datasets has a great influence on the models. Models generally produced better results where more data and data of better quality was available (as was the case for residential electricity consumption). Finally, we can say that our models perform generally well when being used for modelling electricity consumption and less well for modelling gas consumption.

Tab. 3: Forecasted consumption, energy savings, and percentage error of forecasts for the individual time series models for residential electricity consumption (regressors: RP, RGDPPC, HDD, ST), for DE, FR, IT, UK

Forecasted consumption & Energy savings		Cut-off period 2006			Cut-off period 2008

4 Conclusions

Energy efficiency has become one of the main policy goals in energy policy in the European Union. In order to develop and implement new policies, it is of crucial importance for the policy maker to evaluate the impact of the policies. In this project we applied a general energy demand model to the residential sector to analyse electricity and gas consumption savings. Based on the econometric model, we estimated the respective energy savings for six selected countries. Our results show that energy efficiency policies are already starting to be successful and their impact on energy consumption is already visible in some sectors, as for instance in residential electricity consumption, where the majority of the analysed countries achieved important savings in consumption.
The project also showed that generally individual time series models deliver better forecasting results than panel models whereas panel models have a higher number of statistically significant coefficients.

This project has to been seen in the context of an ongoing study of energy consumption in the European Union. It builds a valuable basis for future research and points out opportunities and also difficulties for future research. The project shows that the models that have been used can deliver important and reliable results of energy savings estimates. However, it became also clear during the project work that the quality of the models' results depends to a large extent also on the quality and availability of the database. For future research projects, it will be of great importance to expand the now existing database with datasets that are not yet available now but will be maybe in the future. The datasets, estimation outputs, graphs and tables delivered by this project are a good basis for future research work.

Measuring Success in Mid-stream Programs: Design and Evaluation Recommendations from a TV Program

Marti Frank, Ph.D., Jane Peters, Ph.D., Joe Van Clock, and Alex Dunn, Ph.D.

Research Into Action, Inc., USA

Abstract

"Mid-stream" energy efficiency programs are gaining popularity in the United States because of the efficiency with which they can target a product's supply chain. These programs typically entail the formation of partnerships between major retail chains and program administrators, enabling them to reach a large proportion of the consumer market while maintaining just a few relationships.

Although funders and implementers have lauded the success of these programs in increasing adoption of efficient televisions, evaluations have not supported this perspective. Previous evaluations found that programs had little measurable influence on the complex and fast-changing television market. If an approach to evaluation cannot be found, major funders may withdraw their support, putting the future of mid-stream consumer electronics programs in the U.S. at risk.

Evaluators and program designers must meet three key challenges in order for mid-stream programs to continue, and succeed: 1) Create an evaluation approach for retailers and manufacturer participants; 2) Identify relevant, observable metrics for measuring a mid-stream program's success and establish an appropriate standard of proof for assessment of market influence; and 3) Agree on an approach to determine the market baseline, in other words, what would have happened, absent the program.

This paper proposes approaches to each of these challenges based on the authors' experience evaluating one of the largest and longest-running consumer electronics efficiency programs in the U.S. and discusses opportunities to employ the methodology from this study in evaluating energy efficiency policy and codes and standards efforts.

Introduction

"Mid-stream" energy efficiency programs take their name from the point, in a product's supply chain, they seek to influence – a middle ground between the product's manufacturers and component suppliers (the "upstream" players) and the end user. In the U.S., this middle ground is dominated by a handful of retailers. For example, four retailers together account for two-thirds of refrigerator sales (Sears, Lowe's, Home Depot, and Best Buy) and two retailers account for more than half of television sales (Best Buy and Wal-mart) [2, 3].

Mid-stream energy efficiency programs are gaining popularity in the United States because of the efficiency with which they can target a product's supply chain. Consolidation in the retail sector makes mid-stream programs particularly attractive because of their potential for operational efficiency, and with it a positive benefit/cost ratio. In these programs, administrators typically form partnerships with major retail chains, enabling them to reach a broad swath of the consumer market while maintaining just a few relationships. In addition, mid-stream programs facilitate access to top corporate decision-makers, direct influence over product assortment, and access to product sales data, impacts that end-user-focused programs may not as easily obtain.

These are a few of the advantages of mid-stream programs, to which there is also an important drawback: mid-stream programs are difficult to evaluate and in the U.S. there are few evaluation precedents. Below, we describe the evaluation of a TV energy efficiency program operated by the Northwest Energy Efficiency Alliance (NEEA), from 2009 to the present, in the Pacific Northwest region of the U.S. (the states of Oregon, Washington, Idaho, and Montana) [1].[1] The study can serve as an example to other evaluators of mid-stream programs, or energy policy or regulation, in how to meet three key challenges in evaluating these programs: 1) Creating a qualitative evaluation approach for retailers and manufacturer participants; 2) Identifying relevant, observable metrics for measuring a mid-stream program's success and establishing an appropriate standard of proof for qualitative assessment of market influence; and 3) Agreeing on an approach to determining the market baseline (what would have happened, absent the program) suitable to mid-stream programs. The evaluation described in this paper adds to the scant midstream program evaluation literature. Previous evaluations include a theory white paper and a baseline study conducted in advance of the launch of one of the first large midstream programs [4, 5]; an evaluation of NEEA's 2010 television program [3]; and a program "review" of a similar program in California in 2011 [8].

NEEA's TV Program

The Northwest Energy Efficiency Alliance (NEEA) is a non-profit organization that works to accelerate the innovation and adoption of energy-efficient products, services, and practices in the Pacific Northwest region of the U.S. In 2009, NEEA launched the Consumer Electronics Television Initiative (the program) with the goal of increasing the availability of energy efficient televisions at retail stores in its four-state region. As a mid-stream program, NEEA's TV program pays incentives to the retailers who sell the products, rather than the end users who buy them. The program theory stipulates payment of an incentive for each qualified product sale will lead to several outcomes, most important of which is that retailers will bring more qualified products into their TV assortments than they would absent the program.

The program's other activities include sustained engagement with retailers' corporate sustainability staff and in some cases TV buyers; the delivery of timely, detailed information about the program's energy specification to help retailers identify qualified models when making their assortment decisions; employment of retail store "detailers" who visit each participating store three to ten times per year to place point-of-purchase (POP) marketing materials on qualified televisions; the coordination of social media-driven marketing campaigns; and participation in the ENERGY STAR television specification development process to encourage the strictest possible energy consumption limits.

NEEA expected these activities to result in several outcomes of varying importance to the program's success. The most significant expected outcome, described above, was a shift in retailers' TV assortments to include a higher proportion of program-qualified products. Other expected outcomes included retailers taking actions to accelerate the sales of program-qualified TVs; retailers increasing their demand on TV manufacturers for program-qualified TVs; improvement in consumers and retail sales associates' ability to identify program-qualified TVs; and increasing stringency of the ENERGY STAR TV specification.

Although the program's other expected outcomes were given less emphasis by program managers and not considered by NEEA as critical to the program's success, the evaluation team found them useful in guiding the design of a study that would have enough breadth to uncover program influence, should it exist.

Evaluation Questions, Challenges, and the Study Design

The study design for the evaluation of NEEA's 2011 TV program was driven by NEEA's explicit research questions and the evaluation team's hypotheses about where the program's influence might be both material and observable. NEEA's several research questions fell into four key areas of inquiry, three of which provided evaluators with methodological challenges: What was the program's influence on television retailers, television manufacturers, and on increasing sales of qualified televisions?

---

[1] The full study includes detailed findings and all data collection instruments. The study is the source of all data and quotes used in this paper, unless noted otherwise.

The study that resulted was multi-modal and included five distinct data collection activities, qualitative and quantitative analytical methods. Table 1 shows the evaluation activities, data sources, sample size, and the research areas addressed. Below we discuss the three biggest challenges to evaluating NEEA's TV program, and mid-stream programs in general.

Table 1. Data Collection Activities

Activity	Source of Data	Research Topics
Program Data Review	Salesforce.com database	Influence of program on retailer behavior Influence of program on ENERGY STAR specifications Characteristics of participating stores
	Reports submitted by store detailers	
	Public comments on proposed ENERGY STAR specifications	
	Comparison of findings with raw data from the previous evaluation	
In-depth Interviews	Program Staff	Influence of program on retailer behavior, including assortment decisions Influence of program on product design Influence of program on ENERGY STAR specifications
	Other TV Program Managers	
	EPA ENERGY STAR Staff	
	Retailer Corporate Staff	
	Manufacturers	
Store/Department Manager Surveys	Retail store and TV department managers	Influence of program at store level Store-level awareness of program
Retail Store Visits	"Mystery shopping" visits to participating stores	Store-level awareness and attitudes toward efficiency TV promotional activities
Sales Data Analysis	TV sales data submitted to online program incentives database	Characteristics of Northwest U.S. TV market Program influence on sales of qualified TVs

Challenge #1: Creating an evaluation approach for the supply chain

Although data collection needs vary based on the program design and research questions, efficiency programs targeting retailers and manufacturers will likely be attempting to influence both product assortment (the products on a retailers' shelves) and/or product design. As the NEEA evaluation showed, evaluating influence on supply chain partners like these is different, and more difficult, than measuring influence on end-users.

Retailers are the participants in the NEEA program and the program's ability to influence retailers' assortment decisions was perhaps the key factor in its success. More research questions focused on the program's expected impact on retailers than any other area. For example: How did retailer behavior change as a result of the program? How has NEEA's relationship with retailers changed as a result of the program? How have retailer attitudes toward efficiency changed at the corporate level and store management levels, as a result of the program?

In residential programs targeting end users, the decisions at the core of the evaluation are made by the product's purchaser, typically the one or two decision-makers in a household. In order to receive the incentive, participants usually provide the program with their names and contact information. Participants typically share a language and time zone with evaluators. In energy efficiency programs, participants rarely have any extenuating factors that make them unwilling to discuss their decision-making process (for example, privacy concerns are more common in medical studies). Even though some end-user participants may be unreachable or unwilling to speak to evaluators, there are usually a sufficient number of participants to constitute a representative sample, such that evaluators can apply both qualitative *and* quantitative evaluation methods to the data.

None of the characteristics of end user participants apply to the retailers and manufacturers who are the participants in mid-stream (or even up-stream) programs.

Evaluators may have limited access to the decision-makers. In mid-stream programs, the contacts with whom the program staff interact may not be the ultimate decision-makers who the program seeks to influence, and may be unavailable to evaluators. In the NEEA TV program, TV buyers were the ultimate assortment decision-makers but were usually unwilling to speak with evaluators, as were product managers and design decision-makers at major manufacturers. Among retailers, evaluators were only allowed to speak with buyers at one retail organization, even after repeated requests to different individuals. Questions submitted by email went unanswered. Further, most manufacturers' design staff are located in Asia; may not feel comfortable conversing in English, and were unwilling to respond to questions.

The decision-making process is a team effort. Unlike end-user purchase decisions made by householders, many people contribute to decisions made by organizations. In the NEEA TV evaluation, the number of individuals and corporate "teams" complicated the effort to understanding the program's influence.

The decision-making process is confidential. Retailers' assortment selection and manufacturers' product design processes are considered proprietary. As areas of competitive intelligence, interviewees were willing to speak only in generalities about their organization's processes and considerations. No one was willing to share evidence that would have allowed the evaluators to quantify or even just verify program influence, for example, a product selection algorithm or product matrix. As one retailer interviewee commented about his company's television selection algorithm, "Pursuit of confirmation of what that algorithm is would be futile. I work [there], and they won't even tell me. . . It's like asking for the secret combination for how to make Coca-Cola. They're just not going to tell you."

The small number of participants does not support quantitative evaluation methods. In a typical mid-stream program the participants, measured as business entities, will usually number in the single digits. If participants are taken as the unit of analysis, quantitative approaches to measuring influence are eliminated, leaving only qualitative or anecdotal methods.

Strategies for measuring influence on supply chain partners

The strategies the evaluators used to get around these barriers in evaluating NEEA's TV program may be useful to other evaluators. The team took the following steps:

Employ a multi-modal study design with consistency in research questions across modes. The study was designed for triangulation, and included several data sources *in addition* to in-depth interviews with the participants. This allowed for multiple data points on each research question and provided a balanced picture of the changes taking place in the market as a result of the program. As a result of a previous evaluation of the TV program, the evaluation team knew their go-to data collection activity for deeply qualitative information, the in-depth interview, would need to be supplemented by additional data sources. Interviews with retail store managers, “mystery shopping” visits to participating stores, a quantitative analysis of sales data, and a thorough review of program data all contributed to answering NEEA’s research objectives.

Use multiple informants at each organization. Business decisions may ultimately be made by a single individual, but many people contribute to them. Even though evaluators were not able to speak to the ultimate decision-makers, they did succeed in reaching multiple informants in varying positions within each retail organization, all of whom attempted to influence the TV buyers’ decisions. For example, at one major retailer, evaluators interviewed the sustainability lead, the utility coordinator, and a senior director focused on energy management. Evaluators had several conversations with the interviewees, some of which occurred in person at industry events.

Use program documentation to fill in the gaps. The implementer of the NEEA TV program used Salesforce.com to track email correspondence with the participants. Evaluators conducted a thorough review of this database and created a chronology of the program’s interactions with each participant organization.

Ask indirect questions and capture the nuance. In addition to asking a direct question like, “Do you have a sense of how often the fact that a TV is qualified for this program weighs into your decision to buy it?” evaluators also asked many indirect questions like, “What, if anything, would you have to stop doing if this program ended?” Another example of this approach was in the series of questions about the implementer and the information they provided. Evaluators chose not to use typical satisfaction questions and instead asked both about respondents’ familiarity (“Would you say that you feel well-informed about upcoming changes to the program’s specifications?”), usefulness (“How do you use the information from the program in your conversations with manufacturers?”) and suggestions for improvement (The implementer told us that they check in with you throughout the year. Is there anything they could do to better support you?”).

Hypothesize about what might have happened if the program achieved its desired influence, and test these hypotheses. This tactic influenced nearly every aspect of the data collection process, from interview questions to the inclusion of entire collection methods. Mystery shopping visits to participating stores and interviews with store managers, for example, were only included in the study in order to test these hypotheses but resulted in findings that were some of the most helpful to program managers in improving the program. For example, evaluators speculated that if the program influenced buying decisions, retail buyers would: demonstrate familiarity with the qualifying product criteria, have received them well in advance of their decision-making, and have discussed the specifications with manufacturers. Evaluators sought to document whether this was the case in their questions to retailers and manufacturers and close examination of the content and chronology of the program implementer’s correspondence. In another example, evaluators also theorized that if the program influenced retailers to work to increase sales of qualified products, corporate executives (the program’s primary contacts within the retail organizations) might have taken several possible actions, including: communicating program details to store managers and/or sales associates; providing incentives to store managers and/or sales associates for increased sales of qualified products; and acting to increase promotion of qualified products. Evaluators interviewed store managers and conducted “mystery shopping” visits to participating stores to document whether influence of this type was observable.

Challenge #2: Identifying observable, measurable metrics

Relevant success metrics are important for all social programs. For programs working with retailers and manufacturers, ensuring that the chosen metrics can be measured, given the realistic constraints of most evaluations, is an important selection criterion. In evaluating NEEA’s TV program we encountered four types of problems in the way the program documented its projected outputs (the program’s own work products) and outcomes (expected changes in the market). Below, we summarize the problems and recommendations for avoiding them. Table 2 provides metrics from the NEEA TV program that illustrate each of these problems and the evaluators’ recommended changes.

Outdated Metrics

Outdated program metrics prevent evaluators from gauging the true success of a program because they focus attention on factors that are no longer relevant. The key metric for the TV program’s interaction with its retailer participants was measuring the combined market share of participating retailers. This was an important metric during the program's first year or two, when the goal was to engage retailers in the program. But by the time of this evaluation the program had already achieved its goal of gaining 80% market share and that metric was no longer useful.

Recommendations

Evaluate the appropriateness of metrics annually. Revise outdated metrics to reflect the program's achievements and current goals. For example, a metric that gauges the extent of retailers' commitment to the program may be more relevant.

Imprecise Metrics

Imprecise metrics do harm to both the program and its evaluation. Precise metrics allow implementers to design activities that will incentivize their participants toward the program's own goals, and further allow implementers to make knowledgeable, thoughtful decisions about which activities to pursue and with what degree of effort. A key objective for the TV program was to influence retailers to "stock" and "promote" energy efficient TVs. Evaluators and program staff struggled to define precisely what was meant by "stocking" and how it should be measured. The retail industry uses "stock" to mean the number of units of a given model that are available for sale at a particular store and a specific time. The program used the word "stock" in the same way that the retail industry uses "assortment," meaning the variety of product models carried by each store. So what was to be evaluated? Stocking or assortment? In another example, program staff felt their program design de-emphasized the promotion metric and argued that they did not expect their activities to result in retailers' increased promotion of efficient TVs. Program documentation however gave equal weight to the program's influence on stocking and promotion.

Recommendations

Evaluate each metric to assess whether it is in fact a goal of the program, and of equal weight with other goals. Review the program logic model and/or other documentation for accuracy. Write a description of the activities that can be used to measure the metric, include what data need to be obtained and potential sources. Check with participants and/or industry literature to sure that the terminology used complies with typical industry conventions.

Un-measurable Metrics

Program staff and evaluators accustomed to end-user-focused programs may be surprised to find that some of the more straightforward elements in these evaluations are much harder to determine in a mid-stream program evaluation. Quantitative influence on retail assortment and manufacturer product design are examples of un-measurable metrics. In the NEEA TV evaluation, evaluators could not determine a way to quantify the program´s influence on either. Participants themselves were unable to render an estimate when asked directly in in-depth interviews and were not willing to give evaluators access to data that would allow quantitative assessment based on inputs to their decision-making process (or, may not have even possessed such data). Further, the data evaluators needed to measure changes to assortment or product design, which were difficult if not impossible to obtain. For example, lists of all TV models produced by every manufacturer in each model year and all of their features, energy use data, and the manufacturer's suggested retail price (MSRP).

Recommendation

Plan for evaluation during program design so that all metrics have an evaluation plan in place. Change or eliminate any metric for which an evaluation plan cannot be specified. Obtain access to data required for evaluation at program outset, or ideally when contracting with participants.

Inappropriate Metrics

It is possible for a program's success metrics to be up-to-date, precise, and measurable (i.e. meeting the criteria described above), but still not provide an accurate assessment of the program's progress. In cases like these we describe the metric as "inappropriate," but "irrelevant" or "misleading" may also be accurate. NEEA's metric, "Increase in the number of TVs that meet current ENERGY STAR specifications," is an excellent example. This metric is both precise and measurable, but irrelevant to measuring the program's influence as it is affected by changes to the ENERGY STAR TV specification and in TV technology.

Recommendation

Select metrics that are observable and verifiable. Ask whether a program's influence is likely to result in or lead to changes in the metric. If so, can the evaluation can distinguish the influence of the program from all other plausible causes that could influence this metric? If other potential drivers exist, program evaluators need to capture additional data in order to control for these alternatives.

Table 2. Example before/after comparison of success metrics for NEEA's TV program

Program Metric	Problem	Recommended Revision	Explanation
Market share of participating retailers exceeds 80% of NW TV sales	Outdated	Retailers and manufacturers contacted at correct times to influence decisions; ongoing needs addressed	Participation rate is an output of recruitment, and at this point is an assumption because it has already been completed. The recommended language reflects the output of the implementer's current activities.
TVs that consume less energy	Imprecise	Year-over-year decrease in annual TV unit energy consumption (UEC) at all sizes and price points	This is not an output of the program and cannot be measured with program data. Recommended wording increases clarity.
Retailers commit to stocking and promoting the most energy-efficient TVs	Imprecise and un-measurable	Retailers increase the proportion of qualified TVs in their assortment, and promote these TVs	This outcome is one of the most important in the program theory. However, the Initiative does not require retailers to make any explicit commitments, so as-worded it is not accurate and not measurable. "Stocking" refers to the number of units kept onsite at a retail store, an activity the Initiative is not aiming to influence. And the outcome should specify "qualified" TVs.
Increase in the number of TVs that meet current ENERGY STAR specifications	Inappropriate	Market data are sufficient to track initiative progress, support spec development and inform retailer discussions	This outcome is not a good indicator of Initiative progress and could indicate an overly lax ENERGY STAR specification or an increase in the total number of TV models produced. The desired outcome it reflects (decreasing TV UEC) is covered by "Year-over-year decrease in annual TV UEC at all sizes and price points"

Contextualizing program goals using market data

Once there are appropriate metrics for a mid-stream program, how does one define success? How much does the program need to increase sales? How much influence does the program need to have on decision-makers to be judged successful? While the answers will vary by program and metric, one rule that can be generalized to nearly all is to rely on the specific market context when setting the bar. The use of the market context in setting the program goals will provide program staff, funders, and policy-makers realistic expectations for potential program outcomes and guide evaluators in portraying the program's achievements as success or something less.

There have been two evaluations of NEEA's TV program, by two different evaluation firms. The first evaluator to study NEEA's TV program concluded the program had succeeded in establishing strong relationships with retailers but had not influenced their assortment decisions in any substantial way. The evaluator pointed to the fact that decision-makers stated the program was not one of the primary influences on their assortment decisions and were unable to quantify the influence of the program over their TV assortments. In support of these points, the evaluator paraphrased one major retailer interviewee as referring to the program generally as "a tie-breaker when deciding between two very similar models." Because retailers were unable to quantify how often the program served as a tie-breaking factor in their assortment decisions, this information could not be used to measure the program's impact.

We, the authors of the second and more recent evaluation of NEEA's TV program, reached a very different conclusion based on much the same evidence from retailers, but with one major difference: we contextualized the findings based on what we had learned about the retailer's *milieu*. Like the first evaluation, decision makers told us the fact that although they did consider whether a particular television model qualified for a program incentive, this was never the primary factor in their decision to include the product in their assortment. But when we asked retailers to explain the broader context of the assortment decision, we learned why energy efficiency and NEEA's TV program were not of the utmost consideration. Other product characteristics, including supply chain security, product features, value to the customer, and negotiations with manufacturers take priority. One interviewee said balancing all of the considerations is like putting together a jigsaw puzzle with "ten or twelve really big pieces." In this context, it becomes obvious that energy efficiency will never trump factors like supply chain security and retailers' need to minimize the potential for disruptions to product availability. Nor will retailers bring products into the assortment if doing so jeopardizes their relationship with manufacturers, who provide retailers with "market development funds" as an incentive for retailers to assort particular models or a particular number of models, or promote their products in certain ways.

As a result of contextualizing the program goal of influencing retail assortment decision-making within the retailers' operating environment, we came to the conclusion that the Initiative had succeeded in influencing retailers to consider its qualification criteria during their assortment decision-making. A no small task considering the number of influences with which the program was competing. We further judged that because the assortment decision-making process is complex and critically important to the retailers' financial success, the program's potential for impact on this area of decision-making was extremely limited.

Challenge #3: Setting the baseline

In the U.S., energy efficiency programs use a variety of methods for calculating a program's impact on energy savings. The method used by market transformation programs and most mid-stream programs may be described as a "baseline" method because it attempts to determine what would have happened absent the program. Baselines are commonly set in one of two ways.

A *hypothetical baseline* is created by evaluators or program staff based on a series of assumptions about the market, ideally grounded in market data. NEEA uses the hypothetical baseline approach to establish energy savings for its programs. Key inputs include the estimated "take-off" year of the incented product, absent the program, and the number of years required to reach full market penetration potential.

A *measured baseline* is composed of data on program metrics from non-program areas. In the last few years, "non-program areas" have been defined as geographic areas outside the program's service territory. The evaluation of NEEA's TV program took a similarly quantitative, but very different approach to creating a measured baseline. The evaluation applied a quasi-experimental design methodology to estimate program impact on TV sales. The method compares findings from treatment and control groups and is similar to quantitative approaches used in research projects in psychology or the medical sciences. The use of statistical analysis, following a quasi-experimental design approach, bears much potential for energy efficiency program evaluation and may be especially fruitful when program interventions can be designed in cooperation with evaluators, thus allowing an even broader range of analysis.

Using sales data to set a measured baseline for mid-stream programs

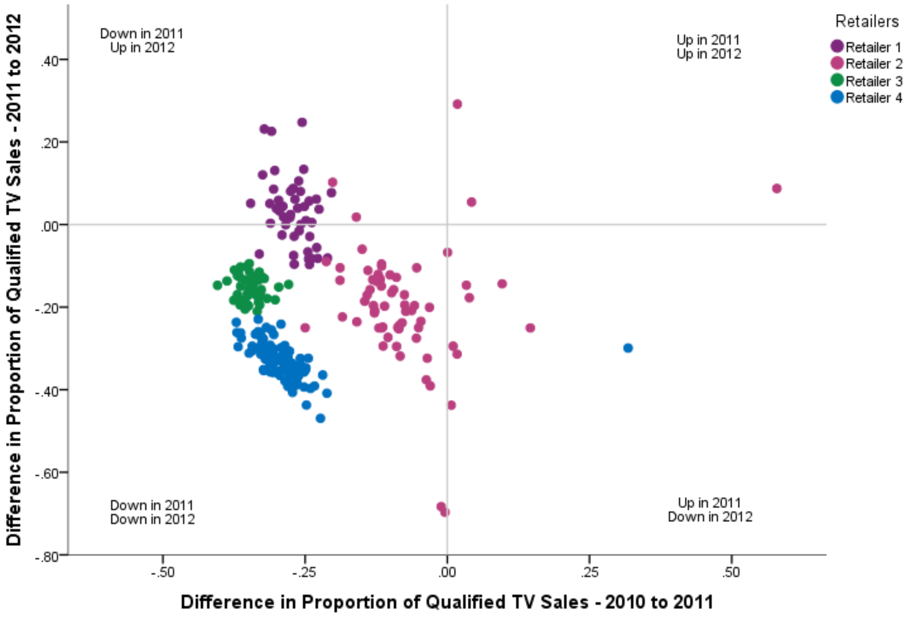
One benefit of mid-stream programs is access to detailed unit sales data provided by the participating retailers. These data can be obtained in other ways, for example purchased from a third-party like NPD or GfK, or tabulated based on submitted rebates (in an end-user focused program). Retailer-sourced data has several advantages, however. Retailer data includes identifying information for each unit sold, like retail chain and store, that is absent from aggregated third-party data and necessary for statistical analysis of program influence. Retailer-sourced data may also include fields of use to program managers and evaluators, like the presence or absence of efficiency features. And retailer-sourced data, unlike unit sales data derived from end users' rebate submissions, has the potential to include "full category" data, meaning all unit sales and not merely qualified unit sales.

There were several challenges in using sales data to evaluate the impact of this mid-stream program, and which other evaluators will likely encounter:

National retailers centralized decision-making and consistent store-level execution, combined with only limited regional program activities, resulted in the lack of an adequate control group. NEEA's TV program focused on building relationships with national retail chains and conducted limited regional activities, other than field staff visits to stores to place program point-of-purchase materials. Because retail chains determine product assortment nationally, with little regional variation, the program's influence on assortment affected the energy efficiency of televisions available nationally, not just in NEEA territory. This spillover effect benefits consumers but was detrimental to evaluators' ability to measure impact. In addition, the evaluation provided new evidence of the consistency in execution among stores in retail chains, further supporting the importance of regional, store-level activities to the quantitative evaluation effort. Sales data showed the proportion of qualified televisions sold by same-chain stores changed in similar ways, either increasing or decreasing from year to year, from 2010 to 2012. Figure 1 provides a visual representation of these changes, with each point representing a single store and the color denoting the store's chain. Points of the same color cluster together with few outliers, showing that chain stores perform similarly to one another and thus that execution is consistent within a chain. There is almost no overlap among the color/chain clusters, showing that the four major chains perform differently from one another. Results show that the majority of stores decreased sales of qualified televisions from 2010 to 2011 (all stores in the left two quadrants in

Figure 1). The high proportion of qualified televisions sold in 2010 (81%) partially explains the decrease in sales for the bulk of stores in these two quadrants. As the specifications became more stringent in 2011 and 2012, sales of qualified televisions decreased. In contrast to the other three retailers, most of Retailer 1 stores increased sales of qualified televisions in 2012. The clustering of same-chain stores suggests good store-level execution of a chain's planogram. This, in turn, reinforces that the program influences national retailer behavior, limiting the measurability of program impact regionally without region-specific activities.

Figure 1: Differences in the Proportion of Qualified Television Sales by Retailer, 2010-2012



Insufficient data to define a control group. In order to create a control group, the team required two types of information: sales data from non-participating stores in areas without TV energy efficiency programs, and detailed store characteristics for all stores, to support the use of propensity score analysis (a statistical technique for making comparisons between treatment and control groups). None of the retailer participants supplied store characteristics and only retailer supplied sales data from non-participating stores. Although the retailer did provide full category data, they were at the year and state levels (for example, total 2011 sales in Florida), limiting the potential for statistical analysis to a simple comparison of the average proportion of qualified televisions sold annually. This comparison lacked face validity because evaluators could not control for previous impact factors on sales, such as: regional promotional activities, seasonal differences, and store-level characteristics.

Varying levels of data quality, with two of the biggest retailers providing low-quality data. Evaluators needed full category sales data in daily or at least weekly intervals. Out of the four biggest retailers, only two provided quality data. One retailer provided only qualified product sales, preventing the team from including this retailer in any of their analysis. A second retailer provided data in monthly rather than daily increments.

These challenges and findings, from the qualitative portion of the evaluation, led the team to execute only one of its four intended approaches. All of them have the potential to be employed to evaluate other mid-stream programs, should the program design and data collection support them. They are:

Compare periods before and after a change in program criteria. Evaluators hypothesized that if the program was influencing retailers to boost sales of qualified TV models, the proportion of sales of qualified units would be visible around periods in which the program criteria changed. For example, a decrease in sales of televisions that no longer qualified for an incentive. Two factors curtailed this approach. First, the program's sales data lacked information on non-energy related television features like unit sale price that could confound this analysis. Interviews revealed a second confounding factor: retailers assort low-priced televisions specifically for the holiday period, the same period in which the program criteria changed. Further, field staff data and store manager interviews showed store-level staff lacked direction from corporate, awareness of the program and its qualification criteria, and did not conduct the type of promotion necessary to support the underlying hypothesis.

Compare similar participating and non-participating stores. This approach requires detailed characteristics for all stores in order to match participating and non-participating stores. The approach also requires sales data from non-participating stores at the same level of detail as those received from participating stores. As noted above, the data required to make this comparison were lacking, as were the program design elements required to show variation.

Compare major national chains and small chain and non-chain stores. The small data sample size and the lack of sales dates prevented this analysis. Although some minor and non-chain stores provided full category data, many provided only partial year data for 2011, disqualifying many potential statistical comparisons. Additionally, buying groups typically provided the sales data for minor and non-chain stores, rather than the stores themselves. Thus the date-of-sale included with each unit was the date when unit shipped from the buying group to the store; not the date-of-sale to the customer. Lacking a probable estimate for the length of turnover for these units, evaluators could not accurately compare sales between major chain and non-major chain stores.

Quantitatively assess influence of promotional activities. This approach holds perhaps the greatest potential for quantitatively evaluating mid-stream program impact. It requires implementing program activities following an experimental or quasi-experimental design approach. It demands either cooperation between program staff and evaluators or, as was the case in the NEEA evaluation, a spot of luck. One of the participating retailers aired a 15-second promotional video on in-store video walls at one of the major retailers. The data were sufficient to support analysis because the retailer provided high-quality data and the video aired in a one-month-on, one-month-off pattern throughout nearly the entire calendar year, providing treatment and control periods.

Case study: Findings from the statistical analysis of the NEEA TV program's sales data

The NEEA TV program expected to increase sales of TVs meeting the program qualifications in NEEA territory. In two cases, statistical analysis showed an increase in sales of qualified televisions resulting from the program's activities. A program-produced video, aired at all stores in one major chain, increased sales of top-tier televisions (televisions qualified at the highest energy efficiency level incented by the program). Across all retailers, an increase in the proportion of qualified televisions in a retailers' assortment increased the proportion of sales of qualified televisions.

Statistical analysis showed evidence that a promotional effort Initiative increased sales of top-tier televisions[2]. One participating retailer played an Initiative-produced video on in-store video walls in its stores during alternating months of 2011 (February, April, June, August, October, and November). Top-tier TV sales increased 3% in months when the video played, compared to months when it did not (11% of total sales compared to 8%)[3].

A second program impact demonstrated, by analysis of sales data, there is direct relationship between television assortment and sales, with a 1% increase in assortment leading to a 1.3% increase in sales of qualified products[4].

Conclusions and Recommendations for Designing and Evaluating Mid-stream Programs

The study yielded many recommendations specific to NEEA's TV program, but with broad applicability to other mid-stream programs.

Mid-stream programs are most effective when a set of shared program requirements are incented in cooperation by several funders. Mid-stream interviewees agreed that achieving a critical mass of program sponsors is key to earning their attention and participation. When evaluating a program with several sponsors, evaluators need to balance the role of their client with the impact of the sponsorship

---

[2] Top-tier TVs in 2011 were ENERGY STAR 5 + 20% televisions.

[3] A repeated measures t-test ($t(49)=-8.1$, $p<.0001$) was used to compare the averaged proportion of sales of top-tier TVs, by store, in months when the video did and did not play. Sales in November and December were excluded because the video played in both months and did not follow the alternating-month pattern found during the rest of the year.

[4] A random effects model showed a significant effect of assortment on the proportion of qualified TVs sold.

group as a whole. Local or regional activities, discussed below, can help identify the impacts of a single funders' efforts.

Participants' contracts should specify, and incentive structures should support, the activities or goals the program desires. The way in which a program contracts with its mid-stream partners, significantly impacts program results. Programs have many options in structuring incentive payments (for example, paying per-unit vs. for meeting sales targets) and as the study showed, programs would be wise to make explicit the expected commitments from its partners.

Programs need to plan ahead at least as far as their supply chain partners. Retailers and manufacturers plan much further ahead than typical efficiency programs, and the design-sales cycle times vary greatly depending on the product. The market timing should be taken into account when programs plan releases of and updates to qualification criteria, plan promotional campaigns, and enter into contracts.

Regional or local activities are important to support impact evaluation, if designed following an experimental or quasi-experimental design approach. Even though mid-stream programs recognize operational efficiencies by focusing on retailers' corporate-level staff, activities at the store level are necessary to further increase product sales and support quantitative evaluation. Even with today's national markets, evaluators can still measure what happens locally, when data collection and intervention design are sufficient.

Evaluators need to look at the entire supply chain, even if the program's activities are more limited. In this study, actionable findings resulted from looking at all levels of the TV supply chain, from manufacturers to sales associates, even though the program's activities focused on interacting with retailers' corporate staff.

Data collection is an important part of mid-stream programs. Sales data collection is key, especially for tracking program impact. Sales data should be "full category" and include all product characteristics, including sales price or MSRP, and sale data, including store and date. Store characteristics are also important, including store location, format, size, sales area, age, number of local competitors, proximity to local competition, volume code, shrink, and surrounding demographics. Field staff, too, should track multiple data points during each store visit, including identifying store data, visit date, time in store, version of POP materials, number of qualified products on display, number of qualified products found unlabeled and incorrectly labeled, number of sales associates trained, and any positive or negative feedback received from store staff or customers. It is also important for program managers to track their correspondence with mid-stream participants. Salesforce.com served as an effective tool for the NEEA TV program, although it is incumbent on the program staff to be conscientious in uploading contact records, and for evaluators to provide program staff several reminders to make those uploads before beginning their evaluation.

Like all energy efficiency programs, a detailed logic model and up-to-date progress indicators are vital to evaluation. Program managers know more about the markets in which they're acting and the characteristics of their mid-stream partners than evaluators. Program documentation provides evaluators a roadmap to the program's current state of knowledge and helps focus the evaluation, resulting in study findings that will be relevant and actionable. Accurate documentation is also a guide for program managers, who can use it to prioritize their "asks" when negotiating with retailers.

THE SUPPLY SIDE MATTERS: ESTIMATING THE IMPACT OF A RESIDENTIAL LIGHTING PROGRAM USING SALES DATA

Iris M. Sulyma and K.H. Tiedemann

BC Hydro

Abstract

Compact fluorescent lamps and light emitting diodes use about one-quarter as much energy as incandescent lamps with similar lumen outputs. Although they have higher initial costs than do incandescent lamps, compact fluorescent lamps and light emitting diodes last from ten to twenty times longer than incandescent lamps. This report provides an evaluation of the energy and peak impacts of the BC Hydro Energy Star Lighting Program, which is a multi-year energy acquisition and market transformation initiative that encourages its customers to use energy-efficient lighting, with a focus on compact fluorescent lamps (CFLs), light emitting diodes (LEDs), Energy Star fixtures and LED fixtures. The BC Hydro Energy Star Lighting Program has been successful in increasing product availability, product awareness, product affordability and product acceptability for energy efficient lighting. A significant degree of market transformation has occurred with respect to replacement of traditional incandescent lamps with spiral CFLs. The program reported energy savings for F2012 of 16.2 GWh per year compared to evaluated savings of 28.7 GWh per year. The difference between the evaluated and the reported savings is primarily due to the evaluated impact of spillover.

Introduction

Compact fluorescent lamps (CFLs) and light emitting diodes (LEDs) use about one-quarter as much energy as incandescent lamps with similar lumen outputs. Although they have higher initial costs than do incandescent lamps, compact fluorescent lamps and light emitting diodes last from ten to twenty times longer than incandescent lamps. To earn the Energy Star label, manufacturers must certify that the product meets the energy efficiency criteria jointly set by Natural Resources Canada, the US Environmental Protection Agency, and the US Department of Energy. When products are certified to meet these energy efficiency standards, the manufacturers may place the Energy Star label on their lighting products. As technology advances and more energy-efficient lighting products are available in the marketplace, Energy Star reviews the guidelines for the lighting category and strengthens them as necessary to ensure that generally only the top 25% of lighting products in terms of energy efficiency can earn the Energy Star label.

The BC Hydro Energy Star Lighting Program is a multi-year energy acquisition and market transformation initiative that encourages its customers to use energy-efficient lighting, with a focus on CFLs, LEDs, Energy Star fixtures and LED fixtures. The objectives of the program include: (1) sustain and increase a greater market share in advance of regulations for more efficient lighting; (2) promote efficient lighting products not covered by regulations and newer products such as LEDs; (3) promote and increase awareness and drive customers to retailers to purchase efficient products; and (4) provide residents province-wide with an accessible and simple lighting program.

This report provides an evaluation of the impacts and effects of BC Hydro’s Energy Star Lighting Program. A quasi-experiment involving non-equivalent group comparisons was employed to assess supply and demand side impacts, and to estimate energy and peak savings. A number of methods have been proposed to estimate free riders and spillover including purchaser self-report surveys, trade ally surveys, quasi-experimental designs with a comparison group, and discrete choice modelling.

Literature Review

In many jurisdictions, residential lighting programs represent a significant share of electricity demand side management (DSM) savings. To date, most of these savings have come from the promotion of purchase and installation of standard twister or spiral CFLs. As a significant degree of market transformation has been achieved with standard CFLs replacing incandescent lamps, a number of utilities and other DSM implementing agencies have reduced or eliminated incentives for standard CFLs, and they have instead provided support for purchase and installation of “specialty” CFLs including reflectors, A-lamps, globes and dimmable lamps; Energy Star lighting fixtures; and LEDs. Residential lighting programs have emphasized four main mechanisms.

(1) Upstream Buy-Down. Upstream buy-downs involve retail price reductions where incentives are provided to manufactures which then provide a mark down to the retailer, who provides a reduced price to the consumer at the time of purchase.

(2) Direct Installation. Direct installation typically involves the installation of CFLs at the time of a residential audit.

(3) Downstream Buy-Down. Downstream buy-downs typically involve point-of-sale or mail-in coupons for consumers to obtain the product at a discounted price.

(4) Give Away. Give away typically involves provision of free CFLs at promotional events or through the mail.

A large number of studies have evaluated the impacts of residential lighting programs on energy consumption. Almost all studies use some form of the following algorithms to estimate energy savings and, less frequently, peak demand savings. Key parameters in these algorithms are the difference in average watts between the base and the efficient technology (delta watts, ΔW), annual hours of use, the peak coincidence rate, the installation rate net of replacements which is often called the in-service rate (“Install”), the free rider rate (FR), the spillover rate (SO), the cross effects rate (CE) which is often called the cooling and heating interactive effect, and the number of rebated measures. For first-year energy savings, the basic algorithm is:

$\Delta kWh = \Delta W \cdot Hours \cdot Install \cdot (1 - FR + SO) \cdot (1 - CE) \cdot$ no. of measures.

For peak demand savings, the basic algorithm is:

$\Delta MW = \Delta W \cdot Coincidence \cdot Install \cdot (1 - FR + SO) \cdot (1 - CE) \cdot$ no. of measures.

An extensive literature review was undertaken to understand the values of these various parameters calculated in recent studies. The data bases examined included the Social Science Research Network, the Consortium for Energy Efficiency, California Measurement Advisory Council (CALMAC) International Energy Program Evaluation Conference (IEPEC) Proceedings and Scopus. In a number of cases, only some of the parameters were provided, but the others could be derived from available information.

Some observations on these studies include the following.

Delta Watts. Delta watts refers to the difference between the (average) wattage of the efficient lighting measure and the (average) wattage of the baseline measure. The delta watts vary from 33.3 watts (PG&E, CFL globes) to 53.3 watts (Focus on Energy Wisconsin, CFL). Recent studies have used a variety of approaches to estimate delta watts. The self-report method uses customer survey information to determine the wattage that was used before and after the lamp or fixture change out. The in-home inspection approach uses program implementation contractors to determine the pre-efficient measure wattage in similar fixtures. The multiplier approach assumes that the baseline wattage is an assumed multiple (between three and four) of the efficient wattage. The manufacturer rating approach uses replacement wattage information on the lamp packaging.

Daily Hours of Use. Daily hours of use refers to the estimated hours of use of the efficient lighting product. The hours of use vary from 1.30 hours per day (SDG&E, CFL globes) to 3.20 hours per day (NYSERDA, CFL). Hours of use is affected by a number of factors including demographics, attitudes towards energy use and energy efficiency, dwelling type and age, saturation rate of lamps and fixtures, location and application of the lamps, electricity prices and hours of sunshine. Hours of use is estimated from on-site metered data, with some key considerations for the metering protocols including the type of loggers used (current sensing vs. light sensing), the length of the metering period (short periods with statistical modelling versus twelve months to produce annual load shapes), additional data collected on site (such as a full socket inventory) and data integrity.

Peak Coincidence. Peak coincidence refers to the share of lamps which are on during the peak demand period. The peak coincidence vary from 0.032 (SDG&E, reflector) to 0.22 (Markdown and Buydown, New England). Peak coincidence is also affected by a number of factors including demographics, attitudes towards energy use and energy efficiency, dwelling type and age, saturation rate of lamps and fixtures, location and application of the lamps, electricity prices and hours of sunshine. Again, peak coincidence is estimated from on-site metered data, with some key considerations for the metering protocols including the type of loggers used (current sensing or light sensing), the length of the metering period, additional data collected on site.

Installation Rate. The installation rate or in-service rate represents the percentage of incented lighting products which are ultimately installed by the program participant. The installation rates vary from 0.67 (PG&E, CFL globes) to 0.83 (New Jersey Clean Energy, CFL). Installation rates are affected by a number of factors including whether the efficient technology is replacing an inefficient technology, whether the customer is responsible for purchase and/or installation, whether products are purchased in multi-packs, the type of lamp and especially the length of life of the lamp being replaced, and the discounted price.

One – Free Riders + Cross Effects. Free riders refer to customers who received an incentive to purchase an energy efficient lamp or fixture, but would have purchased the energy efficient product at the same time without the incentive. Spillover refers to customers who purchased an additional energy efficient lamp or fixture without an incentive, but would not have done so at the same time in the absence of the program.The one minus free rider plus cross effects vary from 0.36 (NYSERDA, CFL) to 1.00 (Markdown and Buydown, New England and New Hampshire Home Performance, CFL). A number of methods have been proposed to estimate free riders and spillover including purchaser self-report surveys, trade ally surveys, quasi-experimental designs with a comparison group, and discrete choice modelling.

One – Cross Effects. Cross effects or interactive effects refer to the waste heat given off by lamps which affects heating, cooling and ventilation energy requirements. Only one utility, EmPOWER Maryland, reported a one minus cross effects value which was 1.06. For the non-reporting utilities, it was assumed that the one minus cross effects value was 1.0. Cross effects are affected by a number of factors including space conditioning mode, climate zone, dwelling characteristics, electricity and natural gas prices and attitudes towards energy use and energy conservation.

Method

The basic design of this evaluation study was a quasi-experiment with a non-equivalent comparison group. For the evaluation, there were five main activities: (1) conduct a program review; (2) undertake a supply-side assessment; (3) undertake a demand-side assessment; (4) measure hours of use and peak demand; and (5) estimate energy and peak savings. This study used multiple lines of evidence, which are summarized as follows:

Program Review. To undertake the program review, we reviewed program documents, interviewed BC Hydro staff, and built a program logic model.

Supply-side Assessment. To conduct the supply-side assessment, we tabulated and examined results of annual in-store surveys of lighting stocking behaviour at representative samples of retail establishments. The surveys have about 40 participants per year.

Demand-side Assessment. To conduct the demand-side assessment, we tabulated and examined results of the 2011 residential lighting surveys. The treatment group survey (British Columbia survey) had 601 respondents and the comparison group survey (North and South Dakota) also had 601 respondents. We also used information from the Residential End Use Surveys conducted since 1997 to build econometric demand models for energy efficient lamps. We also received, aggregated and analyzed limited sales data for the time frames before, during and after the marketing campaign.

Hours of Use and Peak Coincidence. To measure hours of use and peak coincident demand, we conducted in-home monitoring of 333 lighting fixtures in some 50 single family dwellings, with each fixture monitored for a minimum of twelve months.

Energy and Peak Savings. To estimate energy and peak impacts, we used detailed engineering algorithms which were informed by the data from the supply-side assessment.

Results

Program Review. From a program logic perspective, there were three main program activities: retailer education, product rebates and consumer education.

(1) BC Hydro Power Smart has provided retailer education for the residential lighting market since the inception of the program. Retailer education is a key component of the current Energy Star Lighting program, and retailer education has both on-site and on-line components.

(2) Product rebates are aimed at creating customer interest in energy efficient lighting and reducing first costs. The Lighting Campaign Spring 2011 included in store instant discounts on selected lighting products from March 1 to April 30, 2011, while the Lighting Campaign Fall 2011 included in store instant discounts on selected lighting products from October 1 to November 30, 2011.

(3) Consumer education is aimed at creating customer awareness, knowledge and purchase intent for energy efficiency lighting products, and the lighting campaigns included radio, print, television and point of purchase materials.

A key aspect of a program review is an assessment of the program rationale, in other words, does the program make sense? Program rationale can be assessed in a variety of ways, but the most straight forward way is to build a program logic model. A program logic model divides a program into its main activities, and then examines the logic chain of inputs, outputs, purpose and goal for each activity. The following table provides a program logic model and describes key assumptions which must be met for the program to be effective. The program rationale was examined using this program logic model, which was developed from interviews with staff, a documents review and a literature review. This review and analysis confirmed that the basic program logic was valid. There were strong linkages among inputs, outputs, purposes and goal statements. Indicators for key components of the logic model were clear, well defined and measurable.

Table 1. Program Logic Model

	Retailer education	**Product rebates**	**Consumer education**	**Assumptions**
Inputs	Retailer staff training conducted	Power Smart and manufacturer rebates in place	Advertising, promotions and point of purchase material provided	Suitable inventory available in stores
Outputs	Increased sales person knowledge of energy efficiency	Reduce first cost of energy efficient lighting products	Increased customer knowledge and awareness of energy efficiency	Energy efficient lighting meets customers' lighting requirements
Purpose	Increased sales of energy efficient lamps by 679,000 units and energy efficient fixtures by 186,000 units by fiscal 2014			Rebound is negligible
Goal	Save 41 GWh of energy per year by fiscal 2014 at program cost of 414.9 million			-

Supply-side Assessment. The main supply side analysis was an examination of trends over the most recent three years using shelf stock information. Table 2 shows trends in shelf stock shares for standard base lamps. For the three years for which we have data, the shelf stock shares by lamp type are constant, with the share of energy efficient lamps (CFLs and LEDs) at 28%. Note that halogen share was available only for the 2011 survey, so it was assumed that this share was constant, which is consistent with evidence from recent Residential End Use Surveys on installed lamp shares.[1]

Table 2. Shelf Stock Shares by Product

Product	2009	2010	2011
		Lamps	
Incandescent lamps	61	61	60
CFL	23	24	24
LED	4	3	4
Halogen	12	12	12
		Fixtures	
Energy Star fixtures	6	8	7
Other fixtures	94	92	93

Table 3 shows trends in prices for lamps. From 2009 to 2010, incandescent lamps have fallen in price, and most types of CFLs have increased in price. There is not yet enough information to make a conclusion about LED lamp or halogen lamp price trends.

Table 3. Prices for Selected Products (dollars)

Product	2009	2010	2011
		Lamps	
Incandescent 40 W	1.14	0.80	0.91
Incandescent 60W	1.20	0.85	1.10
Spiral CFL	4.21	4.29	4.58
Globe CFL	7.42	7.53	8.55
A19 LED	-	24.63	24.34
PAR LED	-	27.27	29.13
		Fixtures	
ES ceiling fan	118.78	118.51	155.73
ES ceiling fixture	33.47	32.44	39.66
ES floor lamp	73.51	55.69	50.79
ES table lamps	37.70	22.96	22.36

Demand-side Assessment. Survey respondents were asked about whether or not they were aware of various lighting products, and Table 4 shows the survey results for lighting product awareness. Differences which are significant at the 10%, 5% or 1% level are indicated by one, two or three asterisks respectively. BC survey respondents show a higher level of awareness than Dakota survey respondents for all four lamp categories, and these differences are statistically significant for every lamp product category except incandescent lamps. Dakota survey respondents show a higher level of awareness than BC survey respondents for both fixture categories, and these differences are both statistically significant.

[1] Note, as of January 2011 British Columbia prohibits retailers from ordering 100 and 75 watt incandescent lamps. These actions do not affect the data in this report, but will be apparent in the next round of data collection.

Table 4. Product Awareness (%)

	BC	Dakotas	Difference	Z-test
Incandescent	97.4	97.0	0.4	0.35
CFL	94.5	91.8	2.7*	1.83
LED	71.7	63.7	8.0***	2.96
Halogen	84.3	77.7	6.6***	2.94
Energy Star fixture	28.8	35.6	-6.8***	-2.53
LED fixture	43.4	50.6	-7.2***	-2.48

One, two and three asterisks mean that the coefficient is statistically significant at the 10%, 5% or 1% level respectively.

Survey respondents were asked whether or not they had purchased various lighting products, and Table 5 shows the survey results for lighting product purchases. BC survey respondents show a higher level of purchase than Dakota survey respondents for three of the six product categories, and these differences are statistically significant. Dakota survey respondents show a higher level of purchase than BC survey respondents for basic CFLs and specialty CFLs, but neither difference is statistically significant. Those who purchased at least one of these lighting products were asked how many they purchased, and this information was used to calculate the average purchase rate.

Table 5. Purchased at Least One (%)

	BC	Dakotas	Difference	Z-test
Incandescent	44.4	52.6	-8.2***	-2.82
Basic CFL	39.6	41.2	-1.6	-0.59
Specialty CFL	10.4	10.8	-0.4	-0.09
LED	12.3	7.7	4.6***	2.69
Halogen	24.7	15.4	9.3***	3.96
Any fixture	21.7	16.6	5.1***	2.20

One, two and three asterisks mean that the coefficient is statistically significant at the 10%, 5% or 1% level respectively.

Survey respondents were asked whether or not they had installed various types of lighting products, and Table 6 shows the survey results for lighting product installation. BC survey respondents show a higher level of product installation than Dakota survey respondents for five of the six product categories, and these differences are statistically significant for three of them. Dakota survey respondents show a higher level of product installation than BC survey respondents for incandescent lamps.

Table 6. Installed at Least One (%)

	BC	Dakotas	Difference	Z-test
Incandescent	60.3	65.5	-5.2**	-1.91
Basic CFL	55.7	54.9	0.8	0.29
Specialty CFL	15.3	13.9	1.3	0.65
LED	13.5	8.3	5.2***	2.87
Halogen	29.9	19.9	10.0***	4.00
Any fixture	21.7	17.0	4.7***	2.05

One, two and three asterisks mean that the coefficient is statistically significant at the 10%, 5% or 1% level respectively.

Survey respondents were asked how influential program activity was in their decision to purchase energy efficient lighting products, and attribution rates were calculated by weighting the responses and finding a weighted average. If spillover is ignored, the attribution rate is equal to one minus the free rider rate, the larger the attribution rate the more influential a program is, and the larger the proportion of reported energy savings attributed to the program. Table 7 shows the attribution rates calculated from customer survey data for specialty CFL lamps and for Energy Star fixtures. The attribution rate for specialty CFLs is 0.81, and the attribution rate for Energy Star fixtures is 0.73.

Table 7. CFL Lamp and Energy Star Attribution (survey based)

Specialty CFL	**Very influential**	**Somewhat influential**	**Not too influential**	**Not at all influential**	**Attribution (1 – free rider)**
Share	0.43	0.57	0.00	0.00	
Weight	1.00	0.67	0.33	0.00	
Weighted share	0.43	0.38	0.00	0.00	0.81
Energy Star Fixture	**Very influential**	**Somewhat influential**	**Not too influential**	**Not at all influential**	**Attribution (1 –free rider)**
Share	0.46	0.30	0.18	0.06	
Weight	1.00	0.67	0.33	0.00	
Weighted share	0.46	0.21	0.06	0.00	0.73

Table 8 provides an attribution analysis for LED lamps and LED fixtures based on reported sales data. Program management was able to obtain sales data for the eight weeks of the fall lighting campaign as well as four weeks before and four weeks after the fall campaign for companies representing some 80% of the market, and this sales information was inflated to represent the whole market. Since out of campaign sales represent base sales levels, one minus (ratio of out of campaign sales to in campaign sales) is the attribution rate. The attribution rate for LED lamps is 0.89, and the attribution rate for LED fixtures is 0.84.

Table 8. LED Lamp and LED Fixture Attribution (sales based)

	Out of campaign sales (8 weeks)	**In campaign sales (8 weeks)**	**Out of campaign/in campaign**	**Attribution (1 – free rider rate)**
LED	5,924	55,474	0.11	0.89
LED fixtures	610	3,797	0.16	0.84

To understand the longer-term impact of the program we build an econometric demand model using annual estimates of residential saturation of energy efficient lamps and prices of energy efficient lamps, as well as awareness of energy efficient lamps and a dummy variable for the Energy Star program period. Data for the period from 1997 through 2008 was used. Both ordinary least squares (OLS) and maximum likelihood (ML) models were estimated. The regression results are shown in Table 9. The estimated models perform well with very high adjusted R-squared and minimal auto-correlation.

Table 9. Demand for Energy Efficient Lamps (log of average installed)

	OLS		**ML**	
	Coefficient	St. dev.	Coefficient	St. dev.
Constant	3.12***	-0.66	3.19***	0.63
Log of price	-1.52***	0.29	-1.55***	0.27
Log of awareness	1.57*	0.72	1.55**	0.67
Program dummy	1.04***	0.29	1.10***	0.28
Adjusted R-sq.	0.99	-	0.99	-
Durbin-Watson	1.89	0.05	2.11	-0.05

One, two and three asterisks mean that the coefficient is statistically significant at the 10%, 5% or 1% level respectively.

Because the regression models are in double log form, the regression coefficients are elasticities, except for the program period dummy variable which needs to be rescaled. Table 10 shows the elasticities based on the demand regression models. These elasticities say that a 1% increase in price reduces saturation of energy efficient lamps by 1.52% to 1.55%, a 1% increase in customer awareness of energy efficient lamps increases saturation of energy efficient lamps by 1.57% to 1.55%, and the presence of the Energy Star Lighting program increase saturation of energy efficient lamps by 175% to 183%.

Table 10. Elasticities (%)

	OLS	ML
Price	-1.52	-1.55
Awareness	1.57	1.55
Program	183.0	175.0

Note. For price and awareness the elasticity is the percentage change due to a one percent change in the forcing variable, but for program the elasticity the elasticity is the percentage change due to the presence of the Energy Star Lighting program.

Hours of Use and Peak Coincidence. The purpose of the hours of use and peak coincidence analysis was to determine annual, seasonal and daily operating hours of use for light fixtures located in different areas of the home. Information collected through the Residential Load Monitoring Study was used to estimate annual hours of use and peak coincidence with sample drawn from BC Hydro's 2008 Residential End Use Survey participants. Lighting end uses (n = 333) were monitored using time of use loggers between June 2010 and July 2011, so that at least 12 months of data was collected for each monitored lamp. Information on location of lamps and fixtures by room was used to weight the monitored hours of use by room to calculate weighted hours of use and peak for lamps and for fixtures. The results of these calculations are shown in Table 11.

Table 11. Hours of Use and Peak Coincidence

	Average hours of use	Peak coincidence
Lamps	2.56	0.31
Fixtures	3.18	0.39

Energy and Peak Savings. The purpose of the impact analysis was to estimate the program impact on energy and peak demand savings for CFLs, LEDs, Energy Star fixtures and LED fixtures and determine the extent of spillover, if any. Key parameters are the difference in watts between the base and the efficient technology, annual hours of use, the peak coincidence rate, the installation rate net of replacements, the free rider, the spillover rate, the electricity cross effects adjustment, and the number of rebated units. For first-year energy savings, the basic algorithm is:

$$\Delta GWh = \Delta W \cdot Hours \cdot Install \cdot (1 - FR + SO) \cdot (1 - CE) \cdot Units.$$

For peak demand savings, the basic algorithm is:

$$\Delta MW = \Delta W \cdot Peak\ Coincidence \cdot Install \cdot (1 - FR + SO) \cdot (1 - CE) \cdot Units.$$

Table 12 shows gross unit savings for lamps and lighting fixtures without spillover. The delta watts estimates were provided by the program based on internal analysis, and the annual hours and peak coincidence estimates came from the Residential Load Monitoring Study. At first glance the smaller level of delta watts for LEDs than for CFLs may seem surprising since LEDs are more efficient than CFLs, but this is due to the fact that LEDs have typically been replacements for lower wattage standard efficiency lamps than has been the case for CFLs.

Table 12. Gross Unit Savings

	Δ watts	Annual hours	Peak coincidence	Unit energy savings (kWh/y)	Unit peak demand (W)
CFL	53	934	0.31	49.5	16.4
LED	44	934	0.31	41.1	13.6
LED fixtures	53	1,161	0.39	61.5	20.7
Energy Star fixtures	110	1,161	0.39	127.7	42.9

Table 13 shows net unit savings for lamps and lighting fixtures without spillover. The estimates of unit energy demand, unit peak demand, the installation rate and one minus the free rider rate are explained above, while the estimate of one minus cross effects comes from a recent internal study by Power Smart engineering staff. For net unit energy savings, the algorithm is:

(5) kWh = ∆kWh · Install · (1 – FR) · (1 – CE).

For peak savings, the basic algorithm is:

(6) kW = ∆W · Install · (1 – FR) · (1 – CE).

Table 13. Net Unit Savings

	Unit energy (kWh/y)	Unit demand (W)	Install rate	1 - FR	1 - CE	Net unit energy (kWh/y)	Net unit demand (W)
CFL	49.5	16.4	0.94	0.81	0.95	35.8	11.9
LED	41.1	13.6	0.82	0.89	0.94	28.2	9.3
LED fixtures	61.5	20.7	1.00	0.84	0.94	48.6	16.3
Energy Star fixtures	127.7	42.9	1.00	0.79	0.98	98.9	33.2

Table 14 shows net energy and demand savings including spillover. Net unit energy and net unit demand come from the previous table, while the number of program incented units was provided by the program. For net unit energy savings, the basic algorithm is:

(7) GWh = Net unit energy savings · Program incented units.

For net peak savings, the algorithm is:

(8) MW = Net unit demand savings · Program incented units.

The evaluated savings were 28.7 GWh and 9.5 MW. This is substantially above the program reported savings of 15.5 GWh and 5.5 MW. The difference between the evaluated and the reported savings is primarily due to the evaluated impact of spillover.

Table 14. Net Total Savings

	Net unit energy (kWh)	Net unit demand (kW)	Units	Net energy savings (GWh)	Net demand savings (MW)
CFL	35.8	11.9	236.532	8.5	2.8
LED	28.2	9.3	140,402	4.0	1.3
LED spillover	28.2	9.3	411,164	11.6	3.8
LED fixtures	48.6	16.3	12,322	0.6	0.2
Energy Star fixtures	98.9	33.2	40,567	4.0	1.4
total				28.7	9.5

Conclusions

Program Design and Implementation. The BC Hydro Energy Star Lighting Program has been successful in increasing product availability, product awareness, product affordability and product acceptability for energy efficient lighting. A significant degree of market transformation has occurred with respect to replacement of traditional incandescent lamps with spiral CFLs. The Energy Star Lighting Program has continued to evolve and now successfully features a wide range of energy efficient lighting products including specialty CFLs, LEDs, Energy Star fixtures, and LED fixtures.

Program Energy, Peak and Price Impacts. Engineering algorithms informed by BC Hydro customer survey, North and South Dakota customer survey data, on-site metering data and a series of shelf stock studies were used to estimate direct program impacts. The program reported energy savings for F2012 of 16.2 GWh per year compared to evaluated savings of 28.7 GWh per year. The difference between the evaluated and the reported savings is primarily due to the evaluated impact of spillover.

Evaluation Methods. Most evaluations of residential lighting programs focus on information based primarily on demand-side or purchaser analysis and in-home metering of hours of use. This study argues that a richer and more persuasive evaluation can be undertaken by supplementing the study with supply –side information collected through shelf stock surveys and interviews with trade allies to collect detailed sales information.

Systematic market monitoring: a pilot project on TVs demonstrates the value for policy design

Sophie Attali, Anette Michel, Eric Bush

Topten International Services, Switzerland

Abstract

The Ecodesign and Energy Labelling regulations, covering a long list of energy using products, can have a strong influence on the market towards higher efficiency. But several decisions on minimum requirements and labelling scales have been taken based on weak and outdated market data. Some of the regulations are assumed to have been missing their targeted energy savings because the policy instruments had not been appropriately designed. A systematic monitoring of the market evolution based on quality data - which does exist – would allow evaluating the effects of policies and serve as a basis for future policy design.

Using GfK market data and in collaboration with WWF Switzerland, Topten has undertaken a monitoring of the TV market in Europe. Market data from 2007 to 2012, covering the entire EU and at the country-level for six countries, has been analysed regarding developments in sales, screen size, price and On mode power. For the 2012 data also the crucial information on the energy efficiency class is included. The results show the market trends towards larger screen size and higher energy efficiency and how the Label and Ecodesign implementing measures (in combination with the new measurement standard) have influenced the TV market.

The results of the TV market monitoring provide a sound basis for decisions in the framework of the Ecodesign regulation for TVs' revision. In addition the project' results demonstrate the value of a systematic market monitoring, when it is based on sound data.

Introduction

Decisions on product policies: systematic market monitoring needed

Based on the Ecodesign Directive from 2005 [1], its recast [2] and the recast of the Energy Labelling Directive from 2010 [3] the European Commission has introduced Ecodesign requirements for 16 product groups and new or updated Energy Labels for 9 product groups since 2005. These implementing measures are estimated to lead to Energy Savings of about 430 TWh annually by 2020 [4]. In 2013 some 15 new implementing measures will be adopted, saving another 360 TWh annually by 2020 [4], and more are to come in the near future. In general, the Ecodesign and Energy Labelling process is a success.

In many cases however, higher energy savings could have been achieved with policy instruments better aligned to the market and technical development. Several of the new Energy Labels need to be revised shortly after their introduction to the market: many products are already in the top-A+++-classes of the new Labels for washing machines [5], dishwashers [6], and tumble driers [7]. In the case of TVs, the Ecodesign regulation is thought to have been of only little impact, because 'the requirements are at a lower level than many products already on the market' [8]. As a key reason for not setting adequately ambitious requirements, the Ecodesign evaluation study [8] identifies 'the absence of up-to-date information on market developments'.

Today, market data is gathered by the authors of the preparatory study, based on which a Working Document is drafted, which is discussed by the Consultation Forum, before a draft regulation is voted. The whole process takes up to 7 years (in the case of the recently adopted Ecodesign and Labelling regulations for boilers and water heaters), and by the time of the application of a measure, the data the decision was based on was out-dated in many cases. Another problem is the quality of the market data: as the budget for the preparatory study does not cover expenses to buy quality market data, the authors have to rely on publicly available data –usually data provided directly by the industry. The data is often only a sample, not sales-weighted and quickly outdated, and is not comparable to data assessed at a later stage for evaluation reasons. The time-consuming task of data gathering is not cost-effective, because it has to be repeated each time a market overview is of interest (preparatory study, impact assessment, evaluation of measures, revision of measures…), while the results are not comparable because different sources and methods have been used. In order to improve the availability of market data to adequately decide on Labels and requirements, Topten International suggests a systematic market monitoring activity in Europe, based on quality sales data. Sound sales data showing the market development in recent years can be bought from market research companies (e.g. GfK) [9]. If in the future a mandatory product registration database is set up, sales data could be linked to this and an annual report on (aggregated) sales development could be produced using the database. It would be more cost-effective to observe the market with a regular (e.g. annual) monitoring, based on sound data that is comparable over time and between countries, than to undertake isolated data gathering tasks whenever the state of the market is of interest. A regular market monitoring for all product categories with an Energy Label allows to react in time and start a revision of the Label before all models are in the top class, and to design new Ecodesign requirements and Energy Labels appropriately so that these instruments, the introduction of which goes hand in hand with high administrative costs before and during their implementation[1], have a maximum effect on the market towards higher energy efficiency. An example of how simple an effective market analysis regarding energy efficiency can be is shown in a recent publication covering Swiss appliances sales data [10 and11].

With the present paper, Topten demonstrates the value of a systematic market monitoring, through the example of a market monitoring on TVs. The study on TVs was realized based on GfK data, and thanks to the support of WWF Switzerland [12] and the European Climate Foundation [13],

The Ecodesign regulation on TVs [14] is the first Ecodesign implementing measure to be revised. The revision process started in 2012 with the publication of a discussion paper [15] and a Consultation Forum. The adoption of the revised Ecodesign and Labelling regulations is planned for the fourth quarter of 2013 [4]. The TV sales data analysed in the present study allows to draw conclusions on the effectiveness of the requirements on On mode power introduced by the 2009 Ecodesign regulation [14] and of the Energy Label adopted in 2010 [16]. At the same time the availability of sound market data will help to support decisions on appropriate minimum efficiency requirements for the revised regulations.

TVs: market development, standards and product policies

The preparatory study on TVs was started in early 2006. At the same time, the measurement standard was revised to introduce a different methodology to measure the TVs On mode power. The Ecodesign regulation on TVs was adopted in July 2009, the Energy Labelling regulation in September 2010. During these years and up to now the market changed dramatically: the formerly dominating Cathode Ray Tube (CRT) TVs completely disappeared from the market and were replaced by flat panel TVs – mainly by Liquid Crystal Display (LCD) TVs. This development was to a large extent drawn by the change from analogue to digital TV broadcasting, the trend to high resolution (HD) displays, and went hand in hand with a trend to larger screens [17]. In 2012 Light Emitting Diode (LED)-backlit LCD-TVs are dominating the market, and current driving forces to market development are trends towards internet connectivity, 3D or ultra high definition TVs [14]. It is expected that in the mid-term Organic Light Emitting Diode (OLED)-TVs will start the next fundamental market change. The most important steps in TV standardization and policy making since 2007 are briefly presented below.

a) August 2007: preparatory study finalised

Started in early 2006, the preparatory study on TVs was finalised in August 2007. Sales data used in the study was from 2003 and 2004, when CRT TVs were still clearly dominating the market. The authors of the preparatory study stated that a fast development was happening at the time of research and that it was ‘difficult to give a precise evaluation of the mid to long term situation’ [17]. LCD and Plasma TVs had newly entered the market and started to replace CRT TVs.

b) October 2008: Publication of IEC 62087:2008 standard

---

[1] According to the Evaluation of the Ecodesign Directive [8], 12.5 million Euros were spent between 2006 and 2011 by the European Commission for preparatory studies and a similar amount on staff and other costs.

Already since 2004 experts from major TV manufacturers and independent international experts were involved in the development of the new IEC dynamic test signal methodology [18]. IEC 63087:2008 [19], published in October 2008, was the first international test standard to introduce a test methodology based on a dynamic broadcast signal for measuring the average On mode power of TVs. The authors of the preparatory study recommended basing the Ecodesign and Labelling declarations on this methodology. Before 2008, according to IEC 62087:2003, a static three-bar black & white test pattern was used. Many manufacturers however also declared maximum power, established for safety testing [18].

c) October 2008: Consultation Forum
A working document (WD) on Ecodesign requirements for TVs was discussed at a Consultation Forum (CF). This was not the first WD but a version that had already been updated [20].

d) March 2009: Final Ecodesign draft
The Regulatory Committee approves the final draft Ecodesign regulation.

e) May 2009: Rejection of Energy Labelling draft
The energy labelling proposal is rejected by the European Parliament. The labelling scale in the proposal was based on the ‘A-20%’ format. The Parliament claimed that the Labelling format was confusing to consumers (the same day however the Parliament adopted a new Energy Label for refrigerators and freezers based on the same format) [21].

f) July 2009: adoption of the Ecodesign regulation
The European Commission adopts the Ecodesign regulation on TVs [14]. It enters into force in August 2009, and after one year the requirements regarding maximum On mode power apply. The requirements on Standby and Off mode power (max. 1W / 2W) apply already from January 2010.

g) February 2010: new Energy Labelling draft
A new Energy labelling draft is circulated for stakeholders' comments. The labelling scale is now based on the A+ format, which is in line with the recast of the Energy Labelling Directive to be adopted in May 2010 [3]. The A class limit has been shifted to a 20% more ambitious level compared to the proposal from 2009. Soon after (in March), a classification scale with an even more ambitious class limit is circulated.

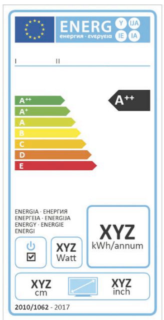

Fig 1: Energy Label for TVs

h) August 2010: tier 1 On mode power applies
New TV models put on the market after this date are required to have a power consumption in On mode corresponding to class F or better (‘normal’ resolution). Full HD TVs can have higher power, as defined in the regulation. Thus, class G is partly banned from August 2010.

i) September 2010: adoption of Labelling regulation
The new Energy Labelling regulation for TVs [16] is adopted by the Commission. The Energy Label with the classification scale proposed in March enters into force in December 2010. The classification scale of the Energy Label is based on the Energy Efficiency Index (EEI), which is also used in the Ecodesign regulation. The EEI expresses the power of a TV relative to the power of a reference model of the same screen size. The EEI and the Energy Efficiency class are thus indicators of the relative power (and energy consumption, as this is directly linked to power). Consequently, a large TV can be labelled with the same or even better Energy class despite consuming more energy than a small TV. The annual energy consumption is also indicated on the label (Fig. 1). It is however questioned whether consumers are responsive to this secondary information figure [24].

j) December 2011: the Energy Label applies
The transition phase of the Energy Labelling regulation is terminated and the declaration according to the Energy Label is compulsory.

k) April 2012: tier 2 On mode applies (class D)
The second step of the minimum efficiency requirement of the Ecodesign regulation applies: new TVs put on the market must be in class D or better.

Present / Future developments:

The Ecodesign regulation for TVs [14] asks for a review of the regulation in 2012. The revision process has started in 2012 with the publication of a discussion paper [15] and a Consultation Forum. The adoption of the revised Ecodesign and Labelling regulations is planned for the fourth quarter of 2013 [4].

Development of the Best Available Technology (BAT)

Topten [23] is an online tool to inform about the most energy efficient products. Topten selects its products according to official Labels and Standards. In 2009 the European Topten website started to list TVs according to the Energy Label draft. The rapidly increasing efficiency of the TVs listed on Topten.eu demonstrates the fast technological development that happened along the discussions and already before the introduction of the implementing measures. In September 2010, when the Labelling regulation was adopted, Topten already listed 60 class B and 5 class A TV models. One year later, when the Energy Label applied, there were 110 class A TVs and 17 A+ TVs on Topten.eu. By April 2012 the number of A+ TVs on Topten.eu has climbed to 99 and the lists showed that the first A++ TVs had emerged on the market [25]. At present, there are more than 170 A+ TVs and 21 A++ TVs on the lists of Topten.eu, despite additional selection criteria such as a strict maximum On mode power of 64W (the model numbers include all similar models on the market. Some might be of similar construction).

Data and Methods

Coverage

GfK [26] is a professional market analysis company present around the world. In Europe GfK covers over 90% of the markets in all 27 Member States. Sales data plus many product characteristics are obtained from retailers. For this market monitoring TV sales data were obtained from GfK, for the years 2007 – 2012. The data covers TV sales in the EU-24 plus additionally sales on country level for six countries (table 1).

Table 1: Countries covered and population

Country	Population[2]
EU-24*	499.3 Mio
Germany	81.7
France	64.7
UK (without Northern Ireland)	62
Spain	46
Poland	38.1
Denmark	5.5

* EU-24 includes Germany, Denmark, United Kingdom, Italy, Poland, Spain, Austria, Belgium, Bulgaria, Estonia, Finland, France, Greece, Hungary, Ireland, Latvia, Lithuania, Netherlands, Portugal, Czech Republic, Romania, Slovakia, Slovenia and Sweden.

For the years 2007 – 2011 sales numbers, price and annual energy consumption as declared for different size categories and TV technologies were retrieved. As power was not available, it was re-calculated from annual energy consumption. From 2008 - 2010 for about 80% of the TVs power was declared according to the IEC 62087:2008 standard. Annual energy consumption was declared according to the calculation formula that was included in the Energy Labelling regulation later ($E = P*1.46$) (for more details on measurement and calculation methods see below). After November 2011 the Energy Label for TVs became compulsory [16]. So, for the 2012 dataset also the energy efficiency class was included. No information on brands or models is included.

Sales of CRT TVs are included in the total sales and in the average price, but no detail information such as size, price or power/energy consumption is available for CRT TVs sold in Poland, Germany and Denmark. After 2010, CRT sales were 0 in these countries, and the missing information concerns only the years before. The details of the data gap are shown in [28].

---

[2] Data from Eurostat: http://epp.eurostat.ec.europa.eu/portal/page/portal/eurostat/home/

On mode power – changing measurement methods

Between 2007 and 2010 the declaration of the TVs On mode power changed, because a new measurement methodology was introduced. IEC 62087:2008 was the first international measurement standard to introduce a testing methodology based on a dynamic broadcast signal for measuring the On mode power of TVs. The Ecodesign regulation [14] refers to a dynamic measurement method. Since 2010 On mode power of TVs on the European market is declared according to this measurement method.

Experts were developing the new test standard since 2004 already. Also the authors of the preparatory study recommended the new method based on the dynamic broadcast content signal to be referred to for the Ecodesign and Energy Labelling regulations in 2006/2007 [17]. At the same time it was decided that annual energy consumption would be declared, based on an assumed daily use in On mode of four hours and not considering low power modes. Major manufacturers started to apply this methodology from 2008 [18].

Which of the On mode power testing methods (static 3-bar signal of IEC 62087:2003, dynamic signal contained in IEC 62087:2008 or maximum On mode power as declared for safety testing) and annual energy consumption calculation methods were used in the declarations before 2008 is not known. Additionally before 2010 there was no obligation to declare a power or energy consumption value according to a given test standard. Therefore the power values before 2009 / 2010 should be interpreted with caution. It is assumed that for 2008 – 2009, about 80% of the TVs were declared according to the measurement and calculation methods used today in the Energy Labelling regulation for TVs [18].

Not included: Standby power and total energy consumption

Information on Standby and Off mode power is not included in the TV Monitoring project. These were certainly relevant modes for the energy consumption before the TVs Ecodesign regulation became effective in 2010, and which limited the power of these modes to maximally 2W. Before 2009 Standby and Off mode power were not declared in a standardised way, and since 2010 these low power modes are no longer crucial for the total energy consumption.

The monitoring project does not present total energy consumption values, even though this figure can be calculated from the On mode power and the sales – based on the calculation formula used in the Energy Label. The Labelling regulation assumes a daily On mode duration of 4 hours [16], based on the findings from the preparatory study [17]. The authors of the preparatory study expected that the On mode duration per day would rise to an average of 5 hours in the future. Daily viewing time may differ between countries, but also for different TVs. The DEFRA study 'Powering the nation' from 2012 for instance found an average daily TV watching time of six hours in UK, the average household possessing 2.3 TVs [27]. The study does not differentiate between different TV sets. Assuming that larger TVs are used in the living room than in the sleeping room and that average viewing times for the two TV types differ, this influences the total energy consumption. Considering this, the different methods used for declaring the On mode power over the years plus the decreasing importance of the low power modes (without having information on it) it was decided to only present On mode power figures instead of annual energy consumption. The data presented however allows deriving estimations on the evolution of TVs' energy consumption in Europe.

Results and interpretation

The graphs and results presented below represent a 'best of'-selection. The full results are publicly available in the full report: *European TV market 2007 – 2012: development of energy efficiency before and during the implementation of the Ecodesign and Energy Labelling regulations* [28].

From 2007 to 2010 the number of annually sold TVs increased by 50% - from 37 million to 56 million units per year (fig. 2). These figures impressively show the impact the introduction of new technologies have had – assumedly especially the switchover from analogue to digital TV. After 2010 the sales decreased at a similar pace – back to 47 million units in 2012.

Not only were more TVs bought, but also larger ones: Fig. 3 shows the on-going trend towards larger screens. Between 2007 and 2012 the sales have generally shifted to larger screen sizes. Fig. 3 shows a constant decrease of the sales proportion of very small TVs (screen diagonal < 20 inches) and a constant increase for the two largest size categories (screen diagonal between 40 and 50 inches and 50 to 60 inches). The sales proportions of the intermediate sizes (20'' – 30'' and 30''- 40'') show less clear trends but some fluctuations over the observed years. This graph can be interpreted

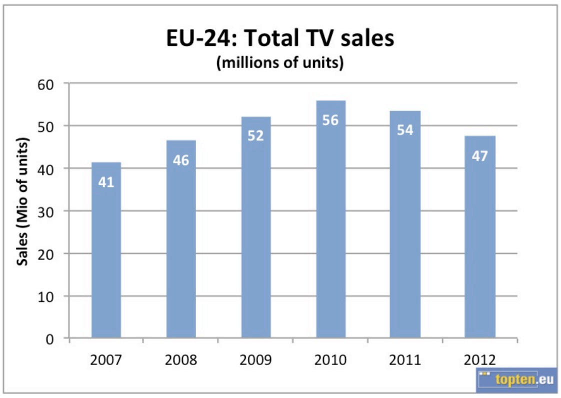

Fig. 2: Total annual TV sales in the EU-24

Data source: GfK

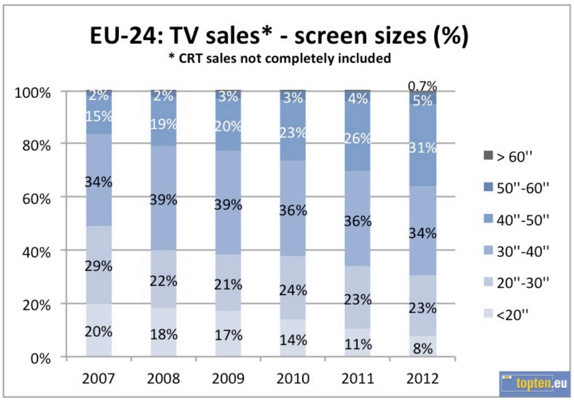

Fig. 3: TV sales in the EU-24: percentage of different screen size categories

'' = inches; 1 inch = 2.54 cm. Data source: GfK

with the trend towards two or more TVs per household in mind. While living room TVs are clearly getting larger, TVs bought to be placed in bedrooms will usually be smaller. Looking at the detail screen sizes and the 2012 EU sales, 32'' and 40'' – 43'' turn out to be by far the most popular screen sizes: these two categories together accounted for 53% of the sales in 2012 (32'': 29%; 40'' – 43'': 24%) (graph in [28]).

From 2007 to 2012 two interesting market transformations regarding technology happened: CRT TVs disappeared completely from the market and were replaced by flat panel TVs (LCD and Plasma), and the first generation of LCD-TVs (with Cold Cathode Fluorescent Lamps (CCFL)-backlight) was replaced by the next LCD-generation, using LED for the backlight (fig. 4). The Plasma technology never reached the breakthrough and the sales share always remained below 10%. Also Rear Projection TVs ('Rear Pro') do not reach a noteworthy market share.

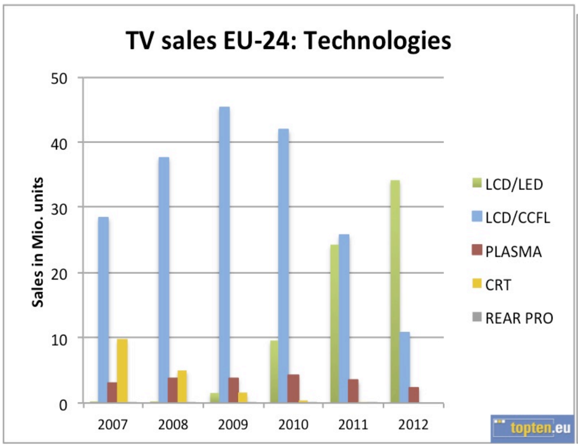

Fig. 4: EU-Sales of different TV technologies

Data source: GfK

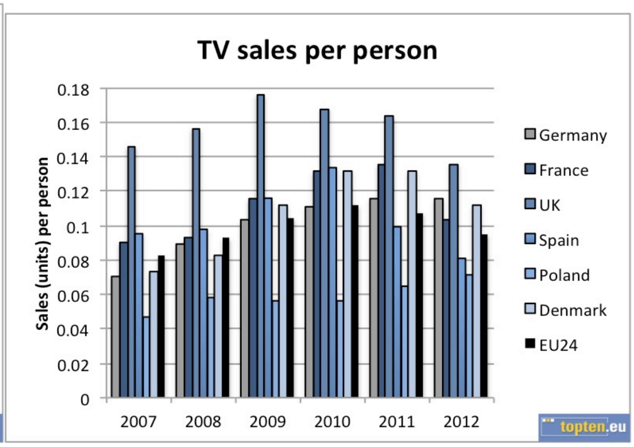

Fig. 5: TV sales per person

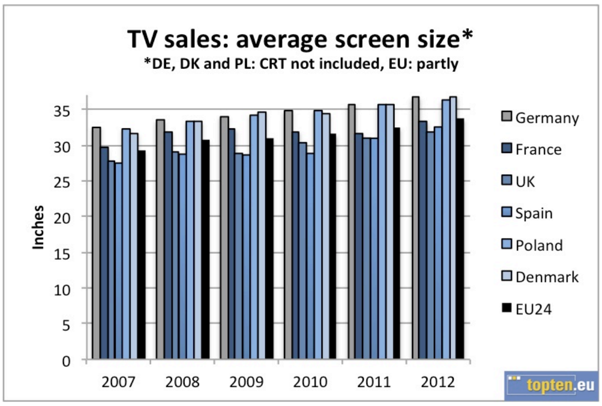
Data source: GfK

People do not show the same readiness to buy new TVs all over Europe; there are considerable differences between countries (fig. 5). Most striking is the buying behaviour of UK consumers: in 2007 the British bought almost twice as many TV sets per person as the EU average. At the other end of the scale is Poland: from 2007 to 2011 Polish were around 50% less likely to buy a new TV than the EU average. Contrary to the other countries however, sales in Poland continued to increase until 2012.

Fig. 5 cannot be interpreted without also looking at fig. 6, which shows the trends in average screen size in the countries. As fig. 3, also this figure impressively shows the strong and on-going trend towards larger screen sizes. Across the EU-24, the average screen diagonal increased from 29.3” (74.4cm) by 4.5 inches (+11.4 cm) to 33.7” (85.6cm) between 2007 and 2012 – equalling an increase of 15%.

Fig. 6 also shows that in the UK, where people buy most TVs, they buy smaller TVs than in other countries. UK is a very mature TV market with an average of 2.3 TV sets per household [27]. The smaller average size will be a result from a high sales percentage of secondary TVs, which are placed in the sleeping room or kitchen. These TVs are smaller than living room TVs. The contrary applies to Poland, where comparatively few but rather large TVs are sold. Are these mostly living room TVs, and therefore on average larger? The number of TVs Germans buy is close to the European average, but the average screen size is among the largest. In France the trend towards larger screen size stopped in 2008, the sales per person remained near the EU-average. Also in Spain TV sales per person were near the EU-average, but dropped to lower values in 2011 and 2012. The average screen size however was higher in these two years, after having been among the lowest before. Danish TV consumers compete with Germans and Polish for the largest average screen size, while sales per person increased to values a bit higher than the EU average. When dividing the sales by the number of households instead of persons and thus considering for different household sizes, the outcome is not changed much, but some of the differences between countries become smaller [28].



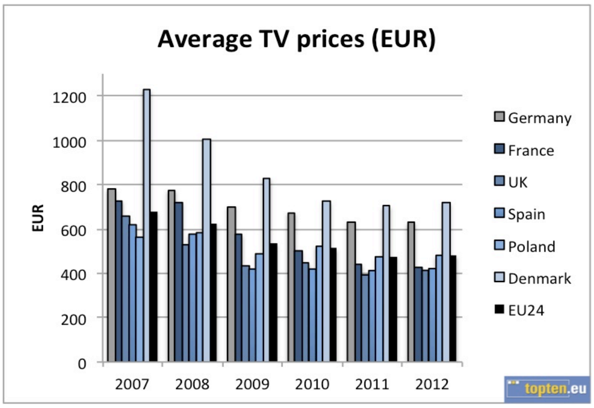


Fig. 6/7: TV sales– average screen size / Average TV prices in EU and countries

Data source: GfK

Despite growing screen sizes, average TV prices in general decreased from 2007 to 2012, at a slowing rate which seems to have stopped in 2011. Average price reduction in the EU was 29% from 2007 to 2012, but around 50% when looking at certain size categories and thus minimising the effect of increasing average screen size [28]. The price decrease over these years was smallest in Poland (-15%) and Germany (-19%), and strongest in Denmark (-42%) and France (-41%). Not surprisingly, the two countries with lower average screen size, UK and Spain, also pay the lowest average prices for their new TVs. Prices in Poland have been similarly low, probably mostly due to the rather low Purchasing Power (PP)[3]. French average prices decreased to be among the lowest after 2010, more or less in line with shrinking screen sizes. In Denmark, which has the highest PP of all EU Member States, the highest average TV prices are paid.

The analysis of the 2012 data in the full report [28] shows that TV prices are closely linked to screen size, but not to energy efficiency.

Larger TVs (of the same technology) have higher power in On mode [17] – this easy-to-understand rule which is also embedded in the EEI calculation formula of the Ecodesign and Energy Labelling regulations (larger TVs can have higher power), leads us to fearing that the strong trend towards

---

[3] Source: Eurostat

http://epp.eurostat.ec.europa.eu/statistics_explained/index.php/Comparative_price_levels_of_consumer_goods_and_services

larger screen sizes observed above goes hand in hand with higher average On mode power. Fig. 8 makes clear that this fear is not justified: despite the TVs getting larger, the declared average power in On mode has dramatically decreased, especially between 2008 and 2012.
As mentioned in the chapter 'Data and Methods', On mode power values before 2010 have to be interpreted with caution. Before 2010 manufacturers were not obliged to declare power values, and before 2009 different and changing measurement standards were used. Despite these restrictions there are no large discrepancies or jumps in the power values from 2007 – 2009. From 2007 to 2008 the declared average power values increased a bit – probably due to the application of the new measurement method IEC 62087:2008. When going more into detail and looking at certain sizes and technologies, the graphs in the full report [28] show a power 'jump' especially for Plasma TVs, while there was little change in the average power of LCD TVs. It is not known according to which measurement standards the On mode power was declared before 2008, and we'll only consider the information from 2008, when assumedly most manufacturers would use the same method as recommended later for the Energy Label, when looking at the development in On mode power,

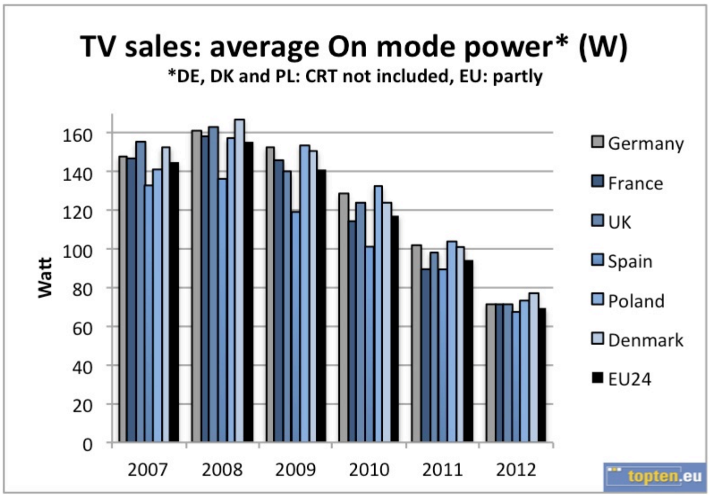

Fig. 8: Average TV On mode power

Data source: GfK

After 2008 the average power of TVs decreased continuously: from 2008 to 2012 the average On mode power of TVs sold in the EU-24 decreased by impressive 55% - despite an average screen diagonal increase of 10% over the same period. In 2008 the average TV sold in the EU reached an On mode power of 156W – by 2012 the average On mode power was 70W.

Not surprisingly, average power is higher in those countries with large average screen sizes: Germany, Denmark, Poland. In Spain and, from 2010, France, where consumers preferred smaller TVs, average On mode power is lower. The average power of TVs in UK was close to the European average, even though average TVs are smaller in UK than in the EU average. The differences between countries became smaller over the years. Especially in 2012, average power is much more levelled across the countries than before. Graphs 9 and 10 show that this cannot be the effect of the On mode power Ecodesign requirements (because their level was clearly above the average power). Was it the effect of the newly compulsory Energy Label, leading manufacturers to design their models along the energy class limits? Another factor is certainly the number of market players that was reduced: the number of different TV brands available on the EU market declined from 746 in 2007 to 480 in 2012 (minus 36%; source: GfK). It is thinkable that the market transformation process towards flat panel and especially LED-backlit LCD TVs eliminated a number of market players, who could not keep up with the pace of development and dropped out of the competition. The reduction of competitors may have lead to a reduction of product 'diversity' on the market and thus contributed to a more uniform market also regarding average power in different countries.

The reduction in average On mode power is impressive. But the graph does not answer the question on the role of the Ecodesign regulation in this development. Obviously most of the trends leading to higher efficiency (e.g. flat panel TVs, LED-backlight) had started a long time before the implementation of the Ecodesign regulation. So, does the graph above show a 'natural' market development that would have equally happened without implementing measures, or did the Ecodesign regulation lead to the product improvement? Toulouse et al. [24] state that the On mode power requirements of the Ecodesign regulation had practically no impact on the market, because both tier 1 and 2 requirements were already met by most main manufacturers. Also the Evaluation of the Ecodesign Directive from 2012 [8] concludes that the Ecodesign requirements for TVs were at a lower level (in terms of energy efficiency) than many products already on the market, while more ambitious requirements could have been introduced.

The detail market data on power for specific screen sizes here allows to investigate this question further. In order to find out more about the effect of the Ecodesign regulation we need to look at certain screen sizes, since the 'cut-off' level of the Ecodesign regulation is dependent on the screen size. The two most popular screen sizes (32" and 40" – 43") are selected for the detail analysis regarding On mode power development. The arrows in the figures 9 and 10 indicate the progress in standardisation and policy making and implementation. It should be noted that before decisions were taken, yearlong discussions including the industry (and some other stakeholders) took place. Many manufacturers were aware of the standards' and regulations' content some time before their publication.

k) April 2012: application of tier 2 On mode power (class D)

Figs. 9 + 10: Average On mode power and Ecodesign requirements for 32'' and for 40"-43"TVs

Data source: GfK

For the 40'' – 43'' TVs, the Ecodesign limits were calculated for a screen size of 41.5 inches. Between 2008 and 2012 the average On mode power decreased by 57% to 64W for 32'' and to 85W (-65%) for 40'' – 43'' TVs.

Tier 1 of the Ecodesign requirements on On mode power applied from August 2010. For both screen sizes considered here the level of tier 1 was close to the average power from 2008, but clearly higher than the average power in 2010. For 32" TVs the limits were 31% (full HD) and 18% (other resolutions) above the average power, for 40" – 43"-TVs 45% (full HD) and 31% (other resolutions). The percentage of full HD TV sales was not assessed in this study.

In April 2012 the tier 2 On mode power requirement applied, corresponding to class D. A quick glance forward at fig. 11 shows that class D had almost entirely disappeared from the EU-market in 2012, and that this measure must have been of very little impact: only 1% of the TVs sold in the EU in 2012 were class D TVs – the least efficient class still allowed on the market. For both screen size categories in figs. 9 and 10 the average power of the complete 2012 sales was even more below the Ecodesign limit than for tier 1: for 32'' TVs the average On mode power was 78% lower than the second Ecodesign limit, for 40'' – 43'' TVs the average was even 113% lower. The average power of this latter size category was below the tier 2 limit in 2010 already.

Based on these figures we can agree with the studies mentioned above [24 and 8] and conclude that, for the two most important screen sizes, all On mode power limits of the Ecodesign regulation had practically no impact on the market. The efficiency development was happening anyway, the Ecodesign regulation did not have any effect on it. The discussions about energy efficiency may however have supported the technological development to focus also on this aspect, and not only on increasing screen size and additional functions.

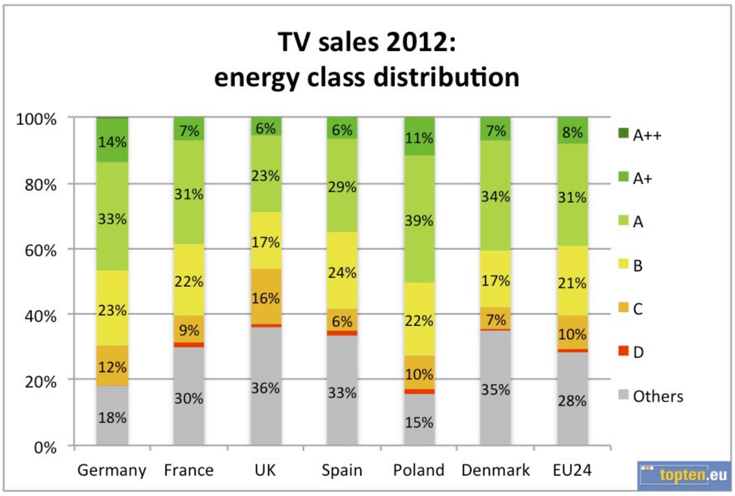

Fig. 11: Energy efficiency of TV sales, 2012

Data source: GfK

Fig. 11 comes close to the simple type of graph we are suggesting to update and publish on an annual basis for all products with an Energy Label in place: evolution of the efficiency, shown in the classes, over the years (as in [10]). Because for TVs the Energy Label was only compulsory after November 2011, such 'dynamic' graphs for the different countries will only be possible from next year. Figure 22 shows the distribution of the 2012 sales on the Energy Classes in the countries and the EU-24. 'Others' include sales of models that were marketed before December 2011 and were not required to have a label, and new models, for which the label information was missing. Fig. 11 lets us draw interesting conclusions:

- In the first full year of the new Energy Label, between 29% (UK) and 50% (Poland) of the sold TVs were in class A or better. Across the EU 39% were in class A or better.
- Class D is no longer visible on the market (EU: 1%). Class D corresponds to the tier 2 power limit enforced in April 2012.
- 6% (UK) to 14% (Germany) of the sales were of class A+, across the EU A+ accounted for 8% of the sales. This class was not expected to appear on the market before 2014; only then will this class have to be shown on the Energy Label.
- For many models the information on the Energy Class was missing: between 15% (Poland) and 36% (UK) of the sold TVs were not labelled. The EU-average is 28%. These figures also include models that were marketed before December 2011 and do not need to have the Label. A figure containing only data on 2012 models in [28] shows that also many of the new models were sold without Energy Label (21% across the EU).
- The most important class regarding sales share in 2012 is class A: class A has the largest sales share in all countries observed. Across the EU, 31% of all TV sales were class A TVs.
- Once again, differences between countries are considerable. Quite surprising is the high sales share of A and A+ TVs in Poland. The explanation might be linked to the findings above

that consumers in Poland buy larger (but fewer) TVs than in other countries and that larger TVs reach better efficiency classes.

- The possibility to provide an overview on the efficiency of the market with simple graphs like fig. 11 is one of the strengths of a compulsory Energy Label. The opportunity to observe the market development on a regular and systematic basis should not be missed.

Conclusions

General

The reduction in average declared On mode power of 55% between 2008 and 2012 is impressive. The gains in efficiency on a power per screen area basis have been clearly stronger than the trend to larger screen sizes. What this means for the effective electricity consumption by TVs is however not clear. Several factors drive the electricity consumption to higher values than declared for single TVs or to higher values than some years ago for the entire EU (more details in [28]):

- The real average TVs use duration in On mode, and of primary and secondary TVs, is not known and has most likely become longer than before the market transformation to flat panel TVs.
- Real On mode power is in most cases higher than what is declared, up to 30% according to [30].
- Only in 2012 the average declared On mode power was back at the level of the On mode power the old CRT TVs [28]. The sales peak in 2009 – 2010 occurred before the efficiency gains through technological development made up for the increased functionality and screen size of the flat panel TVs. These 'energy hungry' TVs remain installed for the next decade or so.

Evaluation of Ecodesign requirements and Energy Label

Ecodesign requirements on On mode power

The results show that the development towards lower power in On mode has started in 2008 / 2009 and that the development was much faster than anticipated. The development towards better efficiency seems mainly to be linked to the new technologies that were introduced, especially LED-backlit LCD-TVs. The efficiency development clearly outran the Ecodesign regulation, which was left without any impact.

According to the Ecodesign Directive [1] the minimum requirements should be placed at a level which aims at the Least Life Cycle Cost (LLCC) for consumers. Because the question on the credibility of the data provided by the industry lead to intense discussions and because it was difficult to predict the market development based on the data at hand, the Commission decided to define cautious minimum requirements but to include an early revision date [23].

However, when the Ecodesign regulation was adopted in mid-2009, even the availability of sound data on average On mode power like the one presented here would not have much helped the Commission to define more appropriate power limits. The trend towards lower power started only in that year, and because of changing measurement standards and no obligation to declare standardised power values, also the data up to 2008 would not have allowed to predict the fast development of the years to come. Only manufacturers might have been able to make more adequate estimations.

Energy Label

With the Energy Label for TVs, a brand new Label was designed. Since there was no existing older Label, there was no resistance about possible downgrading of existing products, and clearly the original A to G scale should have been aimed at. This is what the Energy Labelling Directive [3] stipulates: "The format of the label shall retain as a basis the classification using letters from A to G (…)". And only the next paragraph adds the possibility to go beyond A if needed: " Three additional classes may be added (…) if required by technological progress. Those (…) will be A+, A++ and A+++ …". However, already in the first year of the Label being compulsory, 8% of the products were in class A+ across the EU. A+ was not expected to be reached before 2014 and therefore does not have to be displayed on the Label. Obviously the development towards higher efficiency has been faster than anticipated when the Energy Label was designed in 2010.

However, also when the Energy Label was adopted, the rate of improvement to come was difficult to be predicted – even with more up-to-date data at hand. With data up to 2009, only the beginning of the efficiency development could have been observed, and the sales share of LED-LCD-TVs was only 3% in that year and just starting to grow. The number of TV models on the product lists of Topten.eu [25] shows that a rising number of models met the class B limit, but only very few the class A limit at the time of adoption.

A positive point is that, contrarily to the situation for most Labels that have been revised (refrigerators, washing machines, dishwashers, tumble driers), the top class of the TV energy Label is still empty [6]. Also the A++ limit seems yet to require a lot of technological efforts and the use of the discount granted for Automatic Brightness Control (ABC) [30]. The current Energy Label continues to provide an incentive for further efficiency developments.

In addition the Label now provides a basis for a continuous and easy market monitoring, and it will be interesting to see if the market continues to evolve at the current pace – or even faster, now that the Label is in place.

Combined effect

The Ecodesign regulation and Energy Label did have only a faint influence on the trend towards higher efficiency of TVs. It can however be questioned whether without power and energy consumption of TVs being a topic of interest, information obligation, minimum requirements, and the possibility to market high efficiency TVs with a good label class, manufacturers would have used the new technologies to the same extent. The improved measurement standard combined with the introduction of the implementing measures has certainly supported the market development towards better efficiency.

Recommendations for revision

The revised Ecodesign regulation on TVs must avoid setting requirements that would not be ambitious enough and only leading to administrative efforts without effect. The market overview provided in the present paper can be used for more precise prognoses about the future market development. The insights gained here can support the setting of ambitious minimum requirements. Today's class A should be defined as minimum requirement from 2015, A+ announced as second step.

At the same time the Energy Label should be revised to restore the original A to G scale. Class A could be the 'incentive' to be reached by future, even more efficient TVs, and correspond to today's class A+++. Today's best TVs are in A++ [6]. Considering the fast efficiency development of the last few years and the even more efficient OLED technology, which is expected to enter the market in the future, a future-oriented labelling scale is appropriate.

Another point that should be tackled is the strictly linear relative efficiency approach. The current EEI formula and Labelling classification scale allow large TVs to reach a good Energy Class despite consuming more energy than smaller TVs (which can get a worse classification). This approach does nothing to stop the continuing trend towards larger screen sizes, as shown in fig. 6. Up to now, the increasing efficiency of the products has the stronger effect on average power than the growing screen sizes, and average power has been decreasing dramatically in the last few years despite TVs getting larger. At some point however the efficiency potential will become smaller, and a Labelling / Ecodesign approach favoring large TVs will impede reaching the targeted energy savings. Therefore a digressive or even capped approach (like Energy Star Version 5.0 for TVs, which introduced a maximum power in On mode of 108W in 2011 [31]) should be considered for this revision, for both the Ecodesign requirements and the Energy Label.

Systematic market monitoring is essential

Whether the European Commission would have been able to define more appropriate Ecodesign requirements and Energy Label, had there been market data at hand the way it is presented here is not clear because there were changes in the measurement standards, no declaration obligation and a very fast technological development. With the present situation with an Energy Label in place, it is however easy to track the market. The chance for a systematic market monitoring must not be missed. The data exists - professional market analysis companies like GfK collect the data anyway – mainly for their primary costumers, the industry and retailers. The data is not too expensive, and it is more cost-effective to buy it and analyze aggregated figures, which needs not consume much time, on a regular basis than to hire consultants to search for freely available data whenever a revision or an impact analysis is due. The data presented here is up-to-date, complete (covering all countries, manufacturers, technologies, …), sales-weighted and the assessment method remains the same. Therefore it can be compared between countries and over time, which is not true for the data now collected for preparatory studies and impact assessments. On a longer term sound, aggregated sales data could also be provided by a mandatory product registration database – if such a system is set up in the future. A systematic market monitoring based on sound data allows seeing in advance if the Ecodesign and Labelling regulations need to be revised. It allows evaluating the effect of implementing measures, and it serves as a sound basis for the decision on the level of the revised Ecodesign requirements and Labelling scales. After some years (equaling the average lifetime of a product) the data can serve as a basis for quite precise models on the development of the energy consumption by the stock of the monitored products across the EU. With high quality data at hand, the time-consuming task of data collection and discussions about the credibility of the data are unnecessary. The policy making process can be sped up, and the resulting regulations will be of higher impact. Therefore, a systematic market monitoring - based on sound market data – in Europe is a need, for all product categories with an Energy Label.

The electricity consumption of household appliances in the European Union and the effects of existing EU energy efficiency policies on its evolution

Abstract

The final total electricity consumption of the residential sector in the EU-27 has increased by almost 40% in the period between 1990 and 2010. Excepting a slight decrease in 2007, the annual variation trend of final per capita electricity consumption has been always positive during these two decades. However, important improvements in the energy efficiency of practically all domestic products consuming electricity have been achieved in the recent years and have contributed to lower the overall EU electricity consumption growth rate. The merit of this certainly goes also to EU and national energy efficiency policy measures so far implemented and expected to allow achieving a further and significant amount of energy savings by 2020. Nevertheless, the number and the capacity of models installed and consuming electricity in the households is raising, products are used for longer periods of time and many of them have more functions or special features that require more electricity. This trend weakens and sometimes counteracts the expected impacts of energy efficiency improvement measures.
This paper aims to analyse the present status of electricity consumption of domestic products and the energy efficiency progresses recently registered for each of the main product categories commercialized in the EU. The main energy efficiency policies implemented at the EU level in the residential sector are also described together with their expected impact on electricity consumption. Finally the paper identifies the main areas of possible improvement concerning the process leading to the implementation of these policies. These areas relate to the duration of the preparatory studies and their synchronization with the standardization activities needed, to the enforcement of market surveillance activities, to the definition of policy measures aiming at limiting the total energy consumption and not just the energy efficiency of products installed by households.

Key words

Electricity consumption, domestic appliances, energy efficiency policy

Introduction

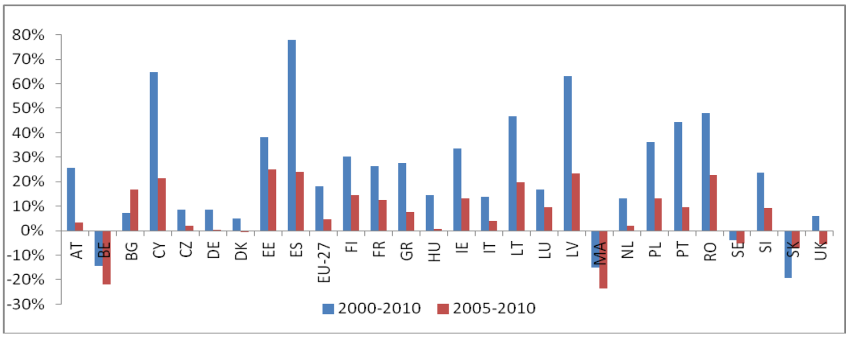
This paper describes the total final electricity consumption trends recently registered in the EU residential sector and complements this description with an analysis of the energy impacts and the effects of the energy efficiency improvements recently observed in the main residential electricity end-

uses. This allows drawing some general conclusions concerning the overall effects achieved by EU energy efficiency policies addressing these end-uses and the main areas of improvements for these policies.
The overview of the existing trends in the total final electricity consumption of the residential sector is based on the information presently available in the literature and in the Eurostat database. The breakdown of this consumption in the main electricity end-uses presented in the paper is instead the result of an on-going survey of statistical data performed by the Joint Research Centre of the European Commission and of the analyses presented in several studies and reports as of 2006.
The impacts on the EU electricity consumption and the energy performance trends of the main product categories installed in the households are described mainly based on the information available in the literature and in the preparatory studies performed by the European Commission for the implementation of the EU 2009/125/EC establishing a framework for the setting of eco-design requirements of energy-related products.

Overview of existing trends in the electricity consumption of the European Union

The residential final electricity consumption in the EU-27 accounted for 29% of the total final electricity consumption in the year 2010. In this year, the residential sector was the second major electricity consumer after the industry sector (36%) and achieved the same amount of final electricity consumed by the service sector [1]. Its annual electricity consumption results to have always increased with respect to the consumption of the previous year, at least since 1990 and with the exception of the year 2007[1]. The total residential electricity consumption grew by 40% in the EU-27 between 1990 and 2010, whereas it grew by 39% in the EU-15 and by 42% in the 12 New Member States (NMS-12) in the same period. In 2010 it reached 843 GWh in absolute terms in the EU-27; its highest point in 20 years.
When it comes to residential electricity consumption per capita, it can be observed that this consumption shows a same trend with a slower annual increase compared to total residential electricity consumption in the period between 1999 and 2010[2].
Concerning electricity consumption at the national level, the following 4 EU Member States (MSs) have registered negative growth rates in the period between 2000 and 2010 (see figure 1 below): Slovakia (-20%), Malta (-15%), Belgium (-15%) and Sweden (-4%). The ones with the highest growth rates were Spain (78%), Cyprus (65%) and Latvia (63%). The number of EU MSs with negative growth rates in residential electricity consumption in the period between 2005 and 2010 is instead 6. Besides the countries previously mentioned, also UK and Denmark managed to achieve a negative growth rate respectively of -6% and –1% in this period.

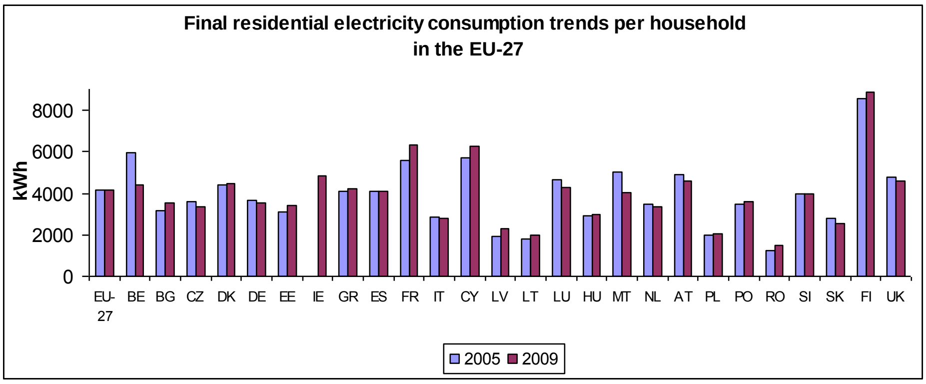
Figure 1: Final residential electricity consumption growth rates in the EU-27 (source Eurostat, JRC)



[1] In 2007 the residential total final electricity consumption decreased by 0.8% compared to the previous year. This can be related to the higher winter temperatures registered during 2007 (implying less electricity use for heating).
[2] In the EU-27 per capita residential electricity consumption was around 1470 kWh in 1999 and around 1680 kWh in 2010. In the EU-15 this consumption was instead around 1680 kWh in 1999 and around 1880 kWh in 2010. In the NMS-12 it was 725 kWh in 1999 and 900 kWh in 2010 (source Eurostat).

Per dwelling residential annual final electricity consumption was around 4100 kWh in the period between 2005 and 2009 in the EU-27[3]. As happened for the total EU electricity consumption, a slightly lower consumption was achieved in 2007 probably due to the unusually higher winter temperatures registered during this year.
The residential final electricity consumption per household shows a large dispersion across EU MSs (see figure 2). The highest residential electricity consumption per household has been registered in Finland. This is mainly due to its above EU-average household electricity consumption for heating and to the use of saunas which can be found in many Finnish houses[4]. It can also be observed that per household consumption variation between 2005 and 2009 is positive for some Member States, e.g. Finland, France and Cyprus, whereas it is negative for other Member States like, for instance, Belgium and Germany. Clearly, the average consumption per household shown results from an average over a wide variety of different household types.

Figure 2: Residential per household final electricity consumption trends in the EU-27 (source Eurostat)



Unfortunately, information and data available do not allow establishing with certainty whether the consumption trends so far described may be correlated to the variations of parameters like energy price, GDP, economies structural changes, degree days, technology energy efficiency improvements as registered at the national level in the EU MSs. Concerning energy prices, considering that the average electricity price increase between 2007 and 2011 has been of 9.72%[5] and given the low elasticity of electricity demand, it seems however quite unlikely that this increase alone may have significantly affected these trends. In any case, a detailed analysis of possible correlations would be surely worthwhile and would deserve more attention. The following paper sections can only try to highlight which are the trends in the diffusion and in the energy performances of existing domestic technologies in order to provide qualitative indications concerning potential correlations between technologies diffusion and energy performance trends and overall electricity consumption in the residential sector. These qualitative indications might represent the starting point for detailed and quantitative correlation analyses that could be undertaken in the future.

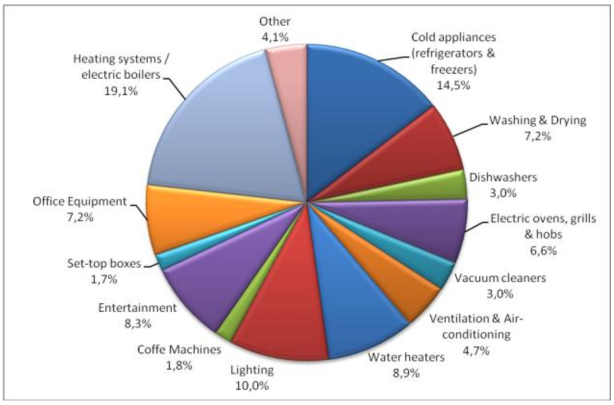
Residential electricity consumption breakdown and existing trends in the different end-uses

A breakdown of total electricity consumption is reported in the graph below (see figure 3 below) for the main electricity end-uses. This graph represents a Joint Research Centre (JRC) electricity consumption breakdown resulting from an on-going survey of statistical data and analysis presented in several studies and reports as of 2006. The estimates are in line with other similar consumption breakdowns such as the REMODECE project consumption breakdown [5]. They are also similar to the results of the analysis available in [4].

---

[3] Source: Eurostat
[4] It is worth mentioning that Finland and Sweden had the highest mean heating degree days in the EU-27 in the period between 1980 and 2004.
[5] Source: Eurostat. Datum referring to households consuming around 3,500 kWh/year.

Figure 3: Residential electricity consumption breakdown in the EU-27, 2009 (source JRC)

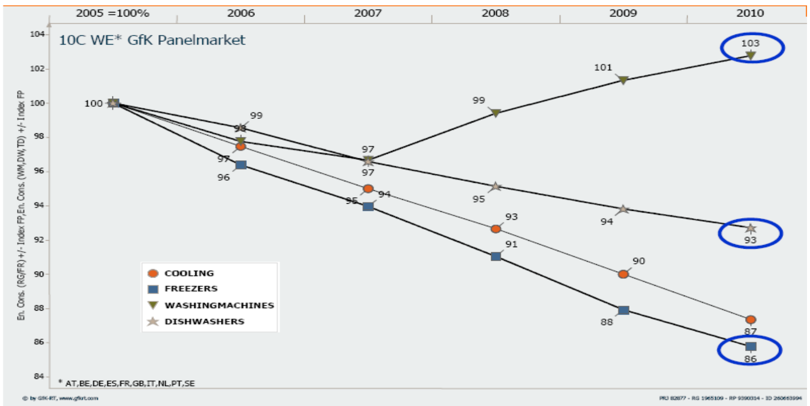


The picture above shows that electricity consumption for thermal uses (i.e. for space and water heating) has by far the highest share among the different electricity end-uses in the residential sector. Existing analyses indicated indeed that electricity consumption for thermal uses is above 20% in all EU countries excepting Romania, Slovakia, Lithuania and The Netherlands, whereas it is around or above 50% in Estonia, Sweden, France, Czech Republic and Ireland [4].
The following of this section is dedicated to a brief quick overview concerning the impact of the main household appliances on the overall EU electricity consumption and the recent developments in their energy performances. This will allow to get qualitative indications about possible areas of future policy intervention and the impacts of the current energy policies. Data concerning total electricity consumption in the EU of the existing appliances stocks are mostly taken from the EU Commission preparatory studies for the implementation of eco-design regulations.

White appliances

White appliances include refrigerators and freezers (cold appliances), washing machines, dishwashers and dryers.
According to GfK[6] data, the average annual consumption per appliance of these 4 product groups in 23 EU countries[7] was 246 kWh in 2010 and decreased by 7 % compared to the average of 265 KWh in 2005. Data available for Western EU (see figure 4 below) indicate that the average energy consumption of new products in Western EU was cut down by 7-14% depending on the category since 2005. The exception is washing machines due to higher loading capacities, as further discussed in the following.

Figure 4: Average energy consumption trends of new products in Western EU (source GfK)



---

[6] GfK is an international market research organization providing services in customer research, retail and technology, media (see www.gfk.com for further information).
[7] The 23 EU countries considered for the average were AT, BE, DE, DK, ES, FI, FR, GB, GR, IT, NL, PT, SE, BG, CZ, EE, HU, LT, LV, PL, RO, SI, SK.

Cold appliances

Over the last years, the refrigerator stock reached the saturation level with penetration rates of around 100% in almost all EU-27 countries. At the same time, the freezer market registered a significant decreasing tendency, due to the increased use of combined refrigerators/freezers [7].
The energy consumption of the cold appliance stock was estimated to be around 82 TWh/year for refrigerators and 40 TWh/year for freezers in 2005 [6].
In the five years between 2005 and 2010 the market share of cold appliances with NoFrost technology increased from 16% to 25% [1]. Appliances with NoFrost Technology are more practical for the consumer but also have higher energy consumption than cooling appliances without NoFrost technology. The trend shows that the NoFrost technology will continue to grow in the future. At the same time a recent Gfk panel survey of Western Europe shows that energy efficient appliances on the cold appliances market became less expensive over the last 10 years indicating that existing market conditions can actually stimulate energy efficiency improvements in the existing stock[8].
Despite the significant energy efficiency improvements achieved and the still relevant energy saving potential, the total energy consumption due to domestic cold appliances seems however destined to increase due to the increase in the household number and second appliance ownership.

Washing machines

Also the washing machines market has reached the saturation level with penetration rates of up to 100% in all EU-27 countries.
The Eco-design preparatory studies of the European Commission estimated an energy consumption of the washing machine stock in 2005 around 51 TWh/year, with an average yearly consumption per appliance of 295 kWh in the EU-27 households [7]. The energy consumption of the washing machine stock has increased between 2005 and 2009 mainly because of a continuous increase in the number of washing machines installed [8] and because of an increase in the number of washing cycles and in the load capacity of the new appliances bought [1]. Topten[9] identifies nowadays the ten most energy efficient products on the EU market every year and the most energy efficient washing machine with loading capacity smaller than 8kg[10] results to have an energy consumption of 158 kWh/year and 0.9 kWh/ 60°washing cycle.

Tumble driers

The market of tumble driers instead did not transform as fast as for example the cold appliance market. In 2005, 90% of appliances sold in the EU-25 were in the class C of the existing energy labelling scheme, and the overall consumption of the existing stock was 17 TWh (including both air vented and condenser driers). In 2007, the share of class C appliances dropped to 75% of all driers sold in the EU-20[11] and 16.7% of appliances sold were class B. The share of class A appliances was still very small with 1% [7]. In 2008, the sales share of A-class driers was already significant in some EU Member States, for example in Italy this share was over 10%.
As for washing machines, the average loading capacity of tumble driers has been increasing in the last years. In the year 2000, the average capacity of models available was 4.9 kg. In 2008, eight years later, the average capacity was 6.6 kg. Tumble driers became more efficient during this period: the product weighted performances fell from 0.71 kWh/kg to 0.59 kWh/kg.[12] However, this does not necessary imply that the energy impact of these appliances has or will be reduced in the future. Energy efficiency improvements may indeed have been due to the commercialisation of appliances with higher volumes which typically consume more electricity but have higher performances per weight unit dried. On the other hand, considering that this market is not yet saturated, it may happen that the reduction of energy consumption due to better energy performances of new models can be nullified by an increased product market penetration due to new buyers. Where possible, reducing tumble dryers usage through more use of natural air drying could very effectively reduce the electricity consumption these appliances are responsible for. In general the use of tumble dryers appears to be strongly affected by the cultural differences existing in the various EU MSs, by regulations banning outdoor clothes drying and by structural factors (e.g. linked to the reduced average dwellings' size) impeding that clothes can be dried indoor by natural air.

---

[8] In February 2011, the average price of an A+++ appliance (the most energy efficient class) was 1186 EUR, whereas the average price for an A appliance was 459 EUR [10].
[9] www.topten.eu
[10] The washing machine mentioned has a loading capacity of 7kg.
[11] Incl. AT, BE, BG, CZ, DE, DK, ES, FI, FR, GB, GR, HU, IT, NL, PL, PT, RO, SE, SI, SK.
[12] This decrease might be due to the higher capacity.

Dishwashers

Also dishwashers have a lower penetration level than other major appliances (e.g. refrigerators and washing machines) in the EU-27. Penetration differs from country to country and is around 50-60% [9]. The most energy efficient product on the market with a place setting of 13 consumes 205 kWh/year and falls into the energy efficiency class A+++ (source: Website Topten International Group 2011)[13]. Between 2001 and 2005 there was only a relatively small efficiency progress in the dishwasher market. The efficiency improvements started to be visible after the year 2005 when the total consumption of the existing stock was estimated to be around 19 TWh in the EU-25.

Cooking appliances

Electricity consumption of cooking appliances is a substantial portion of total residential electricity consumption and there is still a significant energy saving potential for them.

The total electricity consumption for electric cooking was estimated to be around 60TWh (electric hobs and grills together) in 2007 [7]. The JRC estimates the consumption in 2009 to be slightly higher than in 2007.

In 2007, five years after the introduction of the energy label for electric ovens, more than 50% of new sales were made of A class appliances. The impact of the energy labelling is hence already visible on the market [7]. However a European Commission working document on possible energy labelling requirements for domestic electric and gas ovens and electric mains-operated range hoods has been produced in 2013 and proposed new energy efficiency classes (from A+++ to D) for electric and gas ovens.

Space and water heaters

Space heating equipment is the single largest electricity end-user in the residential sector and caused an electricity consumption of 150 TWh in 2007, this including electrical equipment (electric boilers and radiators) and monitoring and control equipment of other heating equipment fuelled by gas or oil [7]. Electric water heaters accounted instead for 8.7% of total electricity consumption corresponding to 73 TWh consumed in 2009. The energy consumption due to single electric space and water heaters is generally decreasing due to their competition with gas boilers and heat pumps and their consequent energy efficiency improvements. Nevertheless their overall electricity consumption has not changed in the period 2007-2009 probably also because of the increased per capita dwelling size observed in the recent years. Concerning water heaters, it is worth mentioning that the solar thermal heating systems have had an impressive development on the EU-27 market in the last years with much of the market made in one and two family houses. The solar thermal market in the EU-27 had in general a strong performance in 2008, growing by 60% and allowing achieving an overall installed capacity around 18.97 GWth in EU-27 ([7], [11]). Between 2009 and 2011, the EU market experienced an overall decrease in Europe but still remained above its 2007 level [12].

Residential room air conditioners

The European market for air-conditioning is still relatively young and still growing substantially. Summer periods represent more than 80% of the total yearly market volume for most of the regions [13] and weather conditions during these periods have a strong influence on the related market trends. In 2007 the overall electricity consumption of the EU-27 air-conditioning stock was around 17 TWh for both the residential and the tertiary sector. Low market growth rates were registered during between 2008 and 2009 because of the particular weather conditions. The air-conditioning stock and the overall electricity consumption is hence estimated to have remained almost constant until 2009. The biggest EU markets are Italy, Greece, Spain, and Southern France. More than three quarters of total EU sales for residential use were realised in these countries in 2005 (cooling capacity) [7]. The current energy label still leaves room for important improvements in energy efficiency, especially for split products. This market is indeed characterized by a so-called "impulse buying" caused by warm temperatures and inducing people to buy low price and inefficient models not mounting any inverter technology. Nevertheless, a quite recent GfK market survey shows that the sales of class A residential room air-conditioners increased from 41% to 57% across Europe between 2007 and 2010.

[13] More information can be found under: http://www.topten.eu/

Lighting

Lighting represents around 10% of the residential electricity consumption, being the third main consumer after heating and food refrigeration. Electricity consumption of households lighting was estimated to be around 84 TWh in 2007. Since then the consumption decreased substantially compared to other appliances groups resulting in an estimated electricity consumption around 79.8 TWh in 2009. This trend is expected to continue in the coming years.

Compact fluorescent lamps (CFLs) represent one of the most efficient solutions available today for improving energy efficiency in residential lighting. The recent price drop together with several information and promotion campaigns have had a positive impact on sales. The observed price reduction has been triggered mainly by the EU ban on incandescent completed in Sept 2012. An eco-design preparatory study of the European Commission [14] estimates a growth of CFL sales around 340% between 2003 and 2007. These estimates include however both domestic and non-domestic sales. This increase in CFL penetration was strongly stimulated in many Member States with special national policies and measures like the white certificates schemes implemented in Italy and the energy supplier obligations implemented the United Kingdom.

LEDs are an even more promising emerging technology and fall under the energy efficiency class A of the existing labelling scheme [7]. LED lighting starts to penetrate the market for replacement lamps, and special purpose lighting, although the market price for LEDs was still very high and their market penetration rate was still very low in 2011.

Class C halogen clear lamps (xenon-filled) will remain on the market until 2016. Starting from this year the dominant clear lamps will be the class B low voltage halogen lamps, with integrated or non-integrated transformer, unless new technologies will emerge.

Information and Communication Technology

Information and communication technologies (ICTs) are among the fastest growing electricity end-use in the residential and tertiary sector. The market is expected to continue growing. The size of the digital technology sector in Europe represents 4.5 % of EU aggregate GDP and even more if value added of digital technologies in other sectors is also accounted for [15]. Televisions (analogue and digital services), set-top boxes, broadband communication equipment, personal computers, computer monitors, imaging equipment, and external power supplies/ battery chargers are among the main product categories that fall under the ICT category or that cause electricity consumption because of the installation of products falling under this category.

The most important trends concerning the market of televisions relates to bigger screen sizes, flat panel displays, digital television broadcasting and high-resolution television (HD).

In 2007, the estimated electricity consumption of televisions in Europe was around 54 TWh. Despite an increase in energy efficiency, the total consumption of TV sets has been raising over the last years. This consumption increased by 2-3% between 2007 and 2009 and reached 56 TWh in 2009.

The increasing of the viewing time per person is accompanying the increase in sales of TVs in the EU. On average, people in the EU watched televisions for 225 minutes per day in 2007. Two years later the average viewing time per person reached 231 minutes [16].

The electricity consumption of TVs in the EU-27 in 2007 is estimated around 60 TWh, 54 TWh of which are generated in on-mode and 6 TWh in stand-by/off-mode. These figures are expected to have remained almost constant in 2009. The increase in the number of models installed per household, the fact that the old TV sets are often kept in the households, and the increase in viewing-time are working against the efficiency improvements.

The energy consumption of TV sets depends heavily on the screen size. The bigger the screen size the bigger the energy consumption. In the years between 2006 and 2010 the average energy consumption per TV set decreased for all screens of a same size. However, there are still large differences in consumption between different TV display types[14].

Digital TV, in the form of digital cable, satellite, digital terrestrial (DTT), and IPTV (Internet Protocol Television), is fast replacing analogue technologies. The adoption of digital television in Europe should grow strongly over the next years, providing enhanced image quality and advanced features (greater breadth of content and bundled communications). Apart from this enhancement, the switch-off of analogue transmission is a further key driver for the transition to digital TV in the EU [7].

During the on-going transition from analogue to digital broadcasting, TV sets not adapted to receive digital signals will need to be accompanied by simple set-top boxes (SSTBs) having the primary

[14] Plasma screens for example consume at least 35% more than LCD screens per screen unit area and tend to be larger than LCD screens (see 4E Mapping and Benchmarking report as available at http://mappingandbenchmarking.iea-4e.org/).

function of converting digital input into analogue output signals. Taking into account the fast penetration of digital TV sets on the EU markets, it is expected that in the next years the SSTBs will lose importance in favour of the complex SSTBs including additional features like pay-TV and network connectivity [7].
The annual energy consumption of SSTBs is estimated at 6 TWh in 2010 and 14 TWh in 2014 (without any minimum efficiency standards) [17].

Broad Band Communication equipment
Broadband equipment is becoming an important electricity end-user in the residential sector and associated electricity consumption in the standby status is also becoming relevant. It is estimated to consume up to 50 TWh/year by 2015 in the EU-27. Its market penetration increased from 4.9% in 2004 to 25.6% in 2010 and continues to grow. DSL is the main technology in the EU fixed broad band market (77.5%), although its market share in the new connections was decreasing in 2010 compared to the year before. The highest growth took place in the mobile broadband market (dedicated data service cards/modems/keys) which grew by 30% in the period between July 2009 and July 2010.

Personal computers, computer monitors and imaging equipment
Computers have become ubiquitous and numbers representing their penetration in the household sectors are impressive. In 2010 their penetration has been above 80% in DE, DK, LU, NL, SE, FI, UK, above 70% in AT, BE, FR, IE, MA, SI, SK and below 50% only in RO and BG where it was anyhow over 30%. Practically all houses where a computer is installed have an internet access [18]. In order to grasp the impact of computer technologies and office equipment in general on the EU-27 electricity bill, it may be useful to consider that the electricity consumption due to this equipment has been around 50 TWh in 2010 (source Energy star programme in 2006-2010 and [19]). It has been estimated that without the EU Energy Star programme on voluntary energy labelling for office equipment this consumption will have been 20% higher in 2010 and 30% higher in 2020. Electricity consumption due to computers, displays and imaging equipment is expected to achieve 55 TWh in 2020.

External power supplies/battery chargers
Electricity consumption to be attributed to external power supplies (EPS) not including the electricity consumption of primary load products, was estimated to be around 17 TWh/year in 2009 [21]. According to [7], EPS for notebooks, set top boxes, mobile phones, DECT (digital enhanced cordless telecommunication) and printers represent respectively 32%, 11%, 23%, 15% and 13% of the above mentioned total electricity consumption. This consumption will be destined to increase in the next years especially due to the increase of ICT equipment installed.

Stand-by and off-mode losses
Standby functions and off-mode losses are a common feature of electrical and electronic household and office equipment (consumer electronics, information and communication technology equipment, personal care products, etc.). The users are often not aware of the electricity consumption and costs for stand-by/off-mode (small for a single product) and low power consumption in stand-by/off-mode is not an important purchasing criterion. Taking into consideration that a typical household is in general equipped with dozens of products having stand-by/off-mode, the resulting electricity consumption and the associated costs are significant. The technical solutions reducing energy consumption in stand-by/off-mode are frequently not applied, for example due to possible additional costs for the manufacturer, and also because it is not a market access requirement ([20], [7]).
Available statistics indicate that the total standby electricity consumption of home appliances in EU-27 in 2007 amounted to around 43TWh, representing 5.4% of total residential electricity consumption in this year [7]. According to a more recent study based on measurements in 1300 homes across the EU, the average standby electricity consumption is about 305 kWh per household per year, representing about 11% of the total annual electricity consumption per household [5]. Horizontal standby policy measures like those implemented in the EU represent probably the best approach to counteract the increase of standby and off-mode electricity consumption due to the constant proliferation and evolution of electrical and electronic equipment.

Summary on electricity consumption trends for the main residential energy end-uses

As showed by the data provided in the previous paper sections, the general trend for residential sector is an increase in its electricity consumption. Although many appliances are becoming more efficient, the number of installed appliances is raising, appliances are used more often or for longer periods of time, and many appliances have more functions or special features that require more energy.

For white appliances the case of washing machines is for example remarkable. Despite a significant increase in the energy efficiency of the models commercialized, the increase in the number of washing cycles and loading capacities seem to have caused an increase of the overall electricity consumption to be attributed to these appliances[15]. Tumble driers and air conditioners are other domestic appliances whose impact on the European electricity bill could rise despite important improvements in their energy performances. In this case this might happen because of an increased market penetration of these products caused by a change in building practices and in practices or regulations concerning how people dry their clothes or create good comfort conditions in their houses.

The evolution of the overall impact of space and water heaters on the EU electricity bill is being instead affected by different and counteracting trends. These trends are the increasing energy performances of these appliances, the increasing per capita dwelling size observed at least in the recent years, the possible push for a fuel-switching from gas to electricity caused by the increased penetration of renewable energy sources for electricity, the increased installation of solar thermal water heating systems.

An important contribution to increased EU residential electricity consumption comes finally from the ICT equipment. Televisions (analogue and digital services), set-top boxes, broadband communication equipment, personal computers, computer monitors, imaging equipment, and associated external power supplies/battery chargers and standby consumption represent together at least the second source of electricity consumption in the households and their increasing impact on the household electricity bills appears difficult to be counteracted despite the significant energy efficiency improvements registered.

There are, however, also end-uses whose overall energy impact is decreasing with time at the EU level. This is the case, for instance, of electricity consumption due to residential lighting. The decreased electricity consumption of residential lighting is to a large extent the result of the phasing-out of less energy efficient incandescent light bulbs caused by EU regulations. Also the large promotion of CFLs in many EU Member States, even before the incandescent lamp phase out period concluded in 2012, contributed to this success. Overall, EU policy instruments have in general the fundamental merit of having significantly reduced or at least increased awareness concerning the overall impact of practically all household appliances nowadays installed. The next paper section will be dedicated to a short overview of these instruments.

EU legislation on household appliances and related impacts on electricity consumption

Energy efficiency legislation of household appliances implemented at the EU level focuses on two main approaches: labelling and standard product information and minimum energy performance standards (eco-design). In the last four years two important directives concerning energy efficiency have been published: directive 2010/30/EU on labelling (*directive on the indication by labelling and standard product information of the consumption of energy and other resources by energy-related products*) and directive 2009/125/EC on eco-design (*directive establishing a framework for the setting of ecodesign requirements for energy-related products*). Both directives are new versions of already existing directives (directive 92/75/EEC for labelling and directive 2005/32/EC *establishing a framework for the setting of eco-design requirements for energy-using products).*

A list of measures implemented or in course of implementation under these two framework directives is provided in Table 1 below.

[15] It seems unlikely that the observed increase in the energy consumption can be attributed to any kind of direct or indirect rebound effect of the energy efficiency improvements registered in this sector.

Table 1: Measures implemented or in course of implementation under Directive 2009/125/EC on eco-design and Directive 2005/32/EC on energy labelling.

Product group	EcoDesign Measure Implemented
Dishwashers	YES
Washing Machines	YES
Air-conditioning	YES
Space and Combination Heaters	NOT YET
Water Heaters	NOT YET
Computers and Servers	NOT YET
Directional Lighting	NOT YET
Domestic Lighting	YES
External Power Supplies	YES
Laundry driers	YES
Ovens, hobs and grills	NOT YET
Refrigerators and Freezers	YES
Residential ventilation	NOT YET
Simple Set-Top Boxes	YES
Complex Set-Top Boxes	YES (VA*)
Standby and Off Mode	YES
Televisions	YES
Imaging equipment	YES (VA*)

Product group	Energy label implemented
Cold appliances	YES
Washing machines, dryers and their combinations	YES
Dishwashers	YES
Ovens	YES
Heat and water heaters	NOT YET
Lighting sources	YES
Air conditioning	YES

* VA = Voluntary agreement

The impact of the above measures on the electricity consumption of the products addressed is expected to be extremely relevant as indicated, for example, in the existing estimates concerning the annual energy savings that will be achieved in 2020 thanks to the eco-design requirements so far established (see Table 2 below). Moreover existing analyses of their cost effectiveness for the European Commission and the Member States indicate a potentially very high benefit to cost ratio [2].

Table 2: Estimated energy savings for eco-design regulations implemented in the residential sector[16]

Adopted implementing measures	Estimated savings (annual savings by 2020) in TWh
Standby and off mode losses of electrical and electronic equipment (household and office)	35
Simple set top boxes	6
Domestic lighting	39
External power supplies	9
Televisions	28
Circulators	23
Domestic refrigeration	4
Domestic dishwashers	2
Domestic washing machines	1.5
Air conditioners and comfort fans	11

Unfortunately the situation of general scarcity of market data does not allow performing precise evaluations on the electricity savings so far achieved because of the implementation of the above listed measures.

However, despite this data scarcity, despite several measures implementing eco-design requirements have been introduced very recently and despite their most stringent requirements (e.g.Tier-2 requirements) have not yet entered into force, evidences of the their positive impacts on residential electricity consumption already start to be available. Independent assessments of the impacts so far achieved by the eco-design regulations ([2], [3]) have indeed confirmed a positive and direct impact on energy efficiency of domestic lighting and an indirect role in the improvement in relation to standby and off modes. In the case of televisions, cold appliances, washing machines and dishwashers, existing evidences do not yet seem to allow to directly link the important market developments in the direction of a higher efficiency to the eco-design regulations addressing these products, although these studies admit that the regulations may have contributed to amplify existing improvement trends. No data are instead yet available to assess the impact of measures on battery charges and simple set-top boxes.

Concerning market impacts, no evidence on possible negative impacts of the regulations on the price of energy related products has been gathered and it is generally recognized that these regulations have not introduced excessive additional costs for the industry (although these costs may clearly represent a higher burden for SMEs than for larger industries). Moreover market operation does not seem to have been affected by adverse effects due to the regulations and a positive impact on technology innovation is widely acknowledged.

On the procedural, side some points of improvement have been identified, especially concerning the length of the procedures for the development of the implementing measures. It has been estimated that the time needed to implement a regulation from the starting of the preparatory studies to its publication is typically 4 years and often it tends to stretch out to 6 years [2]. Such a long implementation time is typically attributed to the scarcity of human resources available in the European Commission and may cause that requirements adopted are less stringent than expected

[16]Source:http://ec.europa.eu/enterprise/policies/sustainable-business/ecodesign/product-groups/ Some of the measures listed (e.g. external power supplies, standby and off mode losses, air conditioners and comfort fans) do not concern exclusively products installed in the residential sector.

because they are based on market data which may be outdated. For example, it has been pointed out that delays occurred in the development of the eco-design regulations for space and water heaters and for televisions may have caused the missing of an opportunity to realise much more energy savings [2], [3]. Synchronization between the development of implementing measures and the development of harmonised standards needed for the measurement of the energy performance parameters mentioned in the regulations is another important point of attention. Harmonised standards have indeed to be in line with the assumptions adopted in the EU Commission preparatory studies for the estimation of the energy performances of products and in the regulations for the definition of the parameters and the formulas whereby energy performance requirements and threshold values for possible energy efficiency indexes are established. If this is not the case, it may happen that the effects of the regulations result very different form the expected ones. It is for this reason that final harmonised standards should be developed *only once* at least a draft of the regulation requiring their application has been produced by the European Commission based on a as wide as possible consensus among all concerned stakeholders on the assumptions and the parameters considered in the regulation. On the other hand, measurement and testing methods adopted in the harmonised standards should not differ significantly (in terms of resulting energy consumption of products) from those assumed in the preparatory studies. Otherwise the consequent revision of these studies and of the analyses leading to the formulas and the requirements included in the regulations might cause a delay in their implementation.

Market surveillance and regulation enforcement at the national level represent a further important point of attention, as it is widely believed that sufficient resources for effective monitoring and enforcement are not allocated at this level.

A final point of attention relates to the co-ordination of existing EU sustainable product policies (i.e. EU policies concerning energy labelling, eco-label, green public procurement and eco-design). Although eco-design regulations are effectively linked with the EU labelling scheme, the EU Commission is working at possibly improving their co-ordination with the green public procurement (GPP) and the EU eco-label schemes in order to better integrate and streamline the implementation process of these policies.

Conclusions

The residential sector is the second consumer of electricity coming after the industry sector in the EU 27. Its electricity consumption grew by about 40% between 1990 and 2010 achieving 843 TWh (i.e. 30% of the total EU electricity consumption) in 2010. This consumption increased almost constantly during these two decades.

Space and water heating systems consume all together 28% of the final electricity used by EU households. They are the first electricity consumer in the EU and are followed by information and communication technologies in the electricity consumption ranking of domestic appliances. Important improvements in the energy efficiency of all domestic appliances sold on the EU market have been achieved and are responsible for the lower annual average electricity consumption grow rates being registered. The merit for this goes to policy induced and spontaneous technological improvements that have taken place in the domestic sector.

As far as EU policies fostering energy efficiency improvements are concerned, energy efficiency policy measures have been implemented at the EU level for practically all appliances used by households. Eco-design regulations for these products are expected in particular to allow achieving further and significant amounts of energy savings by 2020. Available data are however generally not sufficient to evaluate the overall impact on electricity consumption they have had until today. This difficulty is also partly due to the fact that several eco-design regulations have been implemented very recently and that their most stringent requirements have not yet entered into force. Nevertheless some evidences start to be available concerning a positive and direct impact had on energy efficiency of domestic lighting and an indirect role in the improvement in relation to standby and off modes.

Undoubtedly, it cannot be denied that improvements must be achieved in the field of data collection and data analysis in order to allow a proper monitoring and a better design and enforcement of the energy efficiency policies implemented. These improvements relate mainly to the following three areas:

a) standardization of test methods used to measure the energy consumption and other relevant energy related characteristics of the domestic appliance commercialized on the EU market;

b) availability of data and information concerning models put on the EU market for an independent evaluation of their energy performance and other relevant associated characteristics (e.g. models' sale price);

c) reliability of the reference consumption baselines used for the calculation of the energy performances of the products commercialized.

The proper realization of the activities to be accomplished under each of these areas require a strong and collective engagement of manufacturers who receive the highest benefit from their efforts to improve the energy performances of their products when independent (regulatory) bodies co-ordinate and support the standardization processes needed, provide suitable platforms for data collection while guaranteeing transparency and respecting possible data confidentiality issues, perform the analyses for the calculation of the expected energy efficiency improvements expected or achieved in the market. Although a huge amount of work has been and is still being carried out by all the actors involved, the amount and the quality of data available and the resources employed in the above areas do not always allow to exploit an important part of the economic and energy saving potentials associated to energy efficiency. Recent actions undertaken by the European Commission to achieve improvements under these areas are described in its communication COM(2012) 765 and include an increase in the level of involvement of other EU bodies (e.g. the Joint Research Centre), external experts and NGOs in the the standardization work concerning the measurement of products' energy consumption as well as the creation of a database on the energy efficiency and on other environmental aspects of products placed on the EU market. Another useful action not mentioned in the communication that could facilitate data collection and market surveillance activities would be the requirement for on-line registration of all new models put on the EU market by manufacturers.

Concerning the energy efficiency policy implementation process and the nature of the measures put in place at the EU level, the following three remarks can be formulated:
a) one area of improvement concerns the usually too long duration of the time period passing from the starting of the preparatory studies needed for the definition of the implementing measures to the actual implementation of these measures. There is also a need for a better synchronization between the processes leading to the definition of the implementing measures and the definition of the harmonized standards necessary for product performance measurement. Moreover an improved co-ordination and a more streamlined and integrated approach in the implementation of existing EU sustainable product policies (i.e. EU policies concerning energy labelling, eco-label, green public procurement and eco-design) has to be achieved. It is however worth mentioning that in 2012 the EU Commission started a pilot project carried out by the main directorates involved in the implementation of the sustainable product policies (DG ENER, DG ENTR, DG ENV) and by the Joint Research Centre in order to address these issues.
b) Market surveillance activities and EU regulation enforcement at the national level is another important area of improvement. In this case the contribution of the EU MSs is fundamental in order to ensure that market surveillance is properly realized, whereas the rules to be applied have to be defined at the EU level. In order to provide support on market surveillance, the EU Commission has launched an annual market surveillance data collection exercise and promoted a joint action on market surveillance among national authorities under the Intelligent Energy Europe (IEE) Work Programme 2013 to enhance the enforcement of the Ecodesign and Energy labelling legislation.
c) The trends observed in the evolution of electricity consumption of domestic appliances indicate that the improvement registered in the energy efficiency of products is not always accompanied by a reduction of the total electricity consumption these products generate in the households. As already mentioned in this paper, this may happen because of additional services attached to products (e.g. larger sizes, additional functionalities), more intensive usage, multiplication of same product types in the households (e.g. televisions, refrigerators), etc. This issue represents probably the main challenge of current policies and according to some experts it puts under question the actual effectiveness of energy efficiency policies as a whole. Finding solutions to face it is of paramount importance especially when it is taken into account that the shift towards renewable energies that is taking place in the EU seems to be destined to determine a fuel-switch towards electricity for many domestic and not domestic energy end-uses and that this switch will very likely make the problem of limiting total households electricity consumption even more important. Solutions so far proposed to address the problem basically propose to design policies promoting energy efficiency and simultaneously limiting total consumption growth. According to some experts this could be achieved by combining energy efficiency policies with policies aiming at increasing energy prices. According to others energy efficiency policies should instead be accompanied by measures limiting energy consumption growth directly (e.g. by establishing volume limits for refrigerators commercialized, by increasing the price of bits/sec. transmitted by communication technologies, etc.). Both approaches, however, can become questionable for different reasons. Whereas the former approach may raise social equity issues

connected to any energy price increase, the latter is often perceived as a limitation of individual freedom. A shift of paradigm is probably requested in this case and requires that mechanisms whereby human needs and wants related to energy end-use technologies are socially constructed are better understood and possibly modified through policy action. Unfortunately sociological studies do not have so far gained the attention they deserve in the energy policy field.

Trends in Residential Electricity Use and Other Lesson from Data Analysis

Virve Rouhiainen

Adato Energia Oy

Abstract

The paper analyses the trends in residential electricity use in Finland on basis of three cross section studies (1993, 2006 and 2011). In 2011 appliances stood for 41 % of the electricity consumption of household, sauna stoves and HVAC appliances for 9 %. The rest is electric space and domestic hot water heating. Between 2006 and 2011 electricity consumption in households increased by more than two terawatt hours (TWh) and is now close to 20 TWh. The increase is due entirely to the increase in electricity consumption associated with the heating of homes. A number of factors contribute to this development. The most important are increased number of heat pumps, increased secondary electric heat and increased mechanical ventilation and heat recovery. Adoption of energy efficient technologies in heating increases the use of electricity because the heating energy saved is other than electricity.

The electricity consumption of household appliances in 2011 was on the same level as in 2006, because the reduction in consumption in lighting and TV appliances offset the increased electricity consumption of computers, dishwashers and car heating. In appliances the most important trends are: electricity consumption of televisions is decreasing (reduced standby dominates), electricity consumption of computers (including internet connection) is increasing (volume effect dominates), lighting consumption is decreasing.

Number of smaller lessons can be drawn from the data analysis. These include a need to improve customer information on heating and ventilation especially in the segment flats, need to investigate further the actual performance of heat pumps in the field and effect of technology and price incentives on water usage patterns. Further prebound effect may be present in Finland.

Introduction

The Finnish Household Electricity Use Studies comprise three studies on the years 1993 [1], 2006 [2] and 2011 [3]. This paper describes the trends in residential electricity use in Finland on basis of these studies.

The paper is structured as follows. First, the studies and the used methodology and data are outlined briefly. Then the results are presented and discussed.

The results are: the country (area) level decomposition of electricity consumption to end-use categories, construction of example households used in customer communication and the distribution of consumption for the 40 reference groups for the user reports the Finnish electric utilities are required to send their customers. The two first ones are described in the paper in detail. The third result was introduced in 2010 and it is illustrated by appending the model report for time of use tariff. The comparison tables of this report show how electricity use varies between customer groups and are based on 2006 data.

One should note that the paper is highly descriptive in nature. The statistical methodology is only outlined, not discussed in detail in theoretical context. The need for these results is taken for granted and so the usefulness of this kind of description is not discussed. The focus of the paper is presenting the results.

Methodology

Figure 1 describes the types of data used to derive models and the three types of results of the study. The ellipses describe data. The studies use three or four types of data: purpose tailored survey combined with total measured electricity consumptions, measurements in the survey sample (optional), population data from Statistics Finland and data collected from other sources like laboratory measurements for energy labels.

The 2011 study used survey data on app. 4500 households. For 2006 the sample size was over 3000 observations and for 1993 over 2000. In the first two studies measurements were carried out in approximately 100 households. Number of measured appliances was app. 700 in 1993 and 950 in 2006

The first line of boxes describes analysis needed for generalization and model building and the second line of boxes describes model testing. The third line shows how these steps in the analysis are combined to derive results. Next these steps will be described briefly. A reader unfamiliar with statistical modeling and testing may wish to skip the formulas in the next three paragraphs. More detailed description of this part can be found in EEDAL09 proceedings [4].

The first stage of building the appliance models for survey data is to calculate unit consumption for all the major appliances in all of the surveyed households. As the 2011 study only used survey data, the model specified with the help of auxiliary data, was statistically tested and modified till the test indicated that the model was correctly specified.[1]

The test used was a variation of a standard test for testing restrictions set for parameters in linear regression models. In modeling the total electricity consumption y_i of each household i in the survey was decomposed on basis of the questionnaire data to end-uses EU_j and an error term ε_i, shown as formula (1).

(1) $$y_i = \sum_{j=1}^{k} EU_j + \varepsilon_i$$

This is then written in form of a linear regression by adding the regression coefficients β_j for all the end uses i.e.

(2) $$y_i = \beta_j \sum_{j=1}^{k} EU_j + \varepsilon_i$$

If the model is correctly specified, $\beta_j = 1$ for all j. To test the hypothesis of correct specification one estimates both the restricted and unrestricted model. The test statistic F constructed from the error sum of squares is

(3) $$F = \frac{(SSE_r - SSE_f)/(p-q)}{SSE_f/(n-p)} \approx F((p-q),(n-p)$$

The formulation above applies for homoscedastic error term, when in practice the error term is heteroscedastic. To allow for heteroscedastic errors one can use weighted least squares and replace SSE with weighted residuals to get an appropriate F-test. Another alternative is to use likelihood ratio tests, which also allow for testing non-linear restrictions. This is needed when testing heating models where additive structure of end-uses is no longer sufficient.

The analysis of representativeness and determination of weights is an extremely important part of the analysis. Of the random sample drawn, only 34 % responded, so the results are subject to non-response bias. The analysis revealed a picture similar to that of earlier studies: larger households, households in single family houses and houses with electric heat were clearly overrepresented. The weights were determined on basis of the analysis auxiliary population data and the model results were then weighted on population level via post stratification.

---

[1] In technical terms this means that H_0 hypothesis of correct model specification would not be rejected at 5 % confidence level.

Figures 2 and 3 illustrate[2] the effect of weighing with 2006 data. The data is divided into five strata which are weighted so that size of each stratum corresponds to its share of the dwellings in Finland[3].

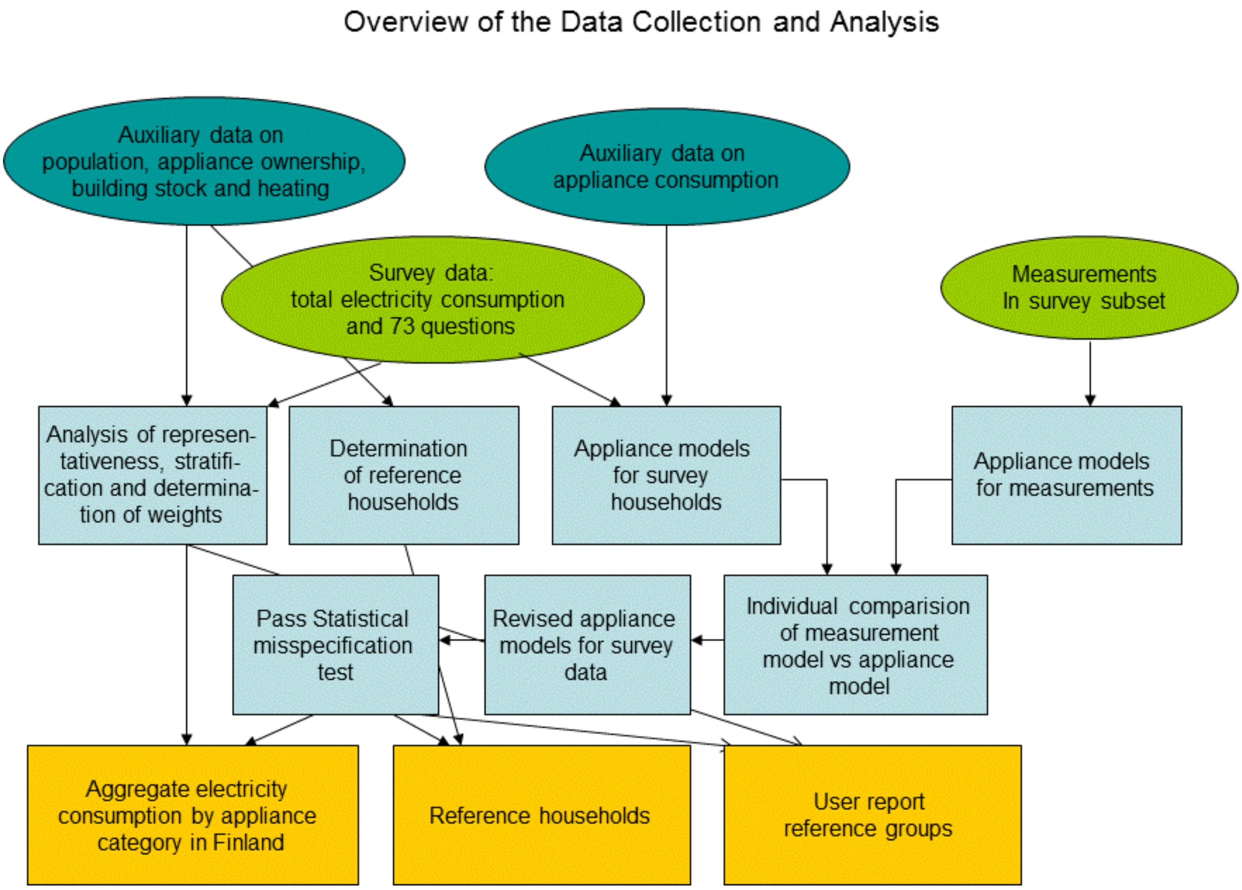

Figure 1. Overview of the Data Collection and Analysis

It is easy to see that the weighing changes the form of the histogram (or empirical distribution) considerably. The spike at 2000 kWh's is much clearer and the right tail considerably flatter in the weighted distribution than in the non-weighted distribution. Without weighting the estimate derived from the data for the total consumption of residential electricity in these segments is 25 % higher than actual known number. The propensity to answer is higher the higher the electricity consumption of the household. This makes the sample biased. Weighting is used to correct this bias.

The definition of strata depends on the available population data and expected differences between the strata. The five segments in figures 2 and 3 are clearly different. First explanatory factor is whether the home is electrically heated or not. In Finland approximately two thirds of residential energy consumption is space heating [4], so this component, when electricity, is large. However, practically no apartment block in Finland is electrically heated. The dominant heating form is central heating with district heat. In addition, in apartment blocks the electricity used by the heating system, car heating, common saunas and hallway and garden lighting is billed from the housing company and paid by the households as a part of a maintenance fee. Similar arrangement is typical in three out of

---

[2] The word illustrate is used because the number of strata in the actual weighting was 35, not 5.

[3] This data is based on population and building register and the data on number of occupied and unoccupied dwellings and number of occupants is highly accurate. There's more uncertainty with main heating energy source, because change of heating energy source is not always registered. Statistics Finland is now working to improve this information,

four row houses. Approximately 25 % of the dwellings in row houses use direct electric heat and residents pay for their heating in their electricity bill. In contrast, a resident of single family house is billed for all residential energy by the energy company[4].

This means that electricity companies bill residential energy including electricity from housing companies. In electricity this component amounts to approximately to 2 TWh at country level [4]. This electricity is not covered by this study, though it is included in the official residential energy statistics of Finland. Same applies to holiday residences, second homes and vacant dwellings. Finland has app. 280 000 dwellings without permanent residents. That is 10 % of the dwelling stock. These include both second homes and vacant dwellings. In addition, Finland has app. 500 000 holiday homes.

The sampling frame in 2011 covered these, but only 2 % of answers belonged to these strata. This data set was not large enough for any meaningful generalization, so the results presented here describe electricity use of permanently occupied dwellings excluding electricity paid by the housing companies.

Results

Results at Country Level

Table 1 shows how the total electricity consumption of permanently inhabited dwellings falls into three broad categories in 1993, 2006 and 2011. The first category is appliances and lighting, the second category is sauna stoves and heating and ventilation equipment and the third category is electric space heating and domestic hot water. These categories are further broken down in tables 2, 3 and 4 and the percentages calculated from the grand total.

Table 1. Electricity consumption of permanently inhabited dwellings in Finland 1993, 2006 and 2011.

End use category	1993 GWh	%	2006 GWh	%	2011 GWh	%
Appliances and lighting	6379	44 %	8201	46 %	7935	41 %
Sauna stoves and heating and ventilation equipment	1089	8 %	1473	8 %	1809	9 %
Electric space heating and domestic hot water	6894	48 %	7996	45 %	9493	49 %
Total	14362	100 %	17670	100 %	19237	100 %

Table 2 presents the electricity consumption of appliances and lighting in Finland by appliance category in 1993, 2006 and 2011. The classification of the earlier studies has been changed to correspond to the concepts used in the official statistics. The first thing to note is that the total of consumption by appliances and lighting decreased from 2006 to 2011 in absolute terms. The largest reduction is estimated in lighting by app. 900 GWh and the second largest in televisions by app. 270 GWh. Categories cooking, cold appliances and washing and drying laundry also show slightly reduced consumption. The computers show the largest increase in electricity consumption by app. 440 GWh. The second largest increase is found in car heating by app. 350 GWh and the third largest increase in dish washing by app.100 GWh.

[4] This is a simplification. A number of Finnish households use wood that they obtain from their own forests or receive from relatives. They, however, are aware of the fact.

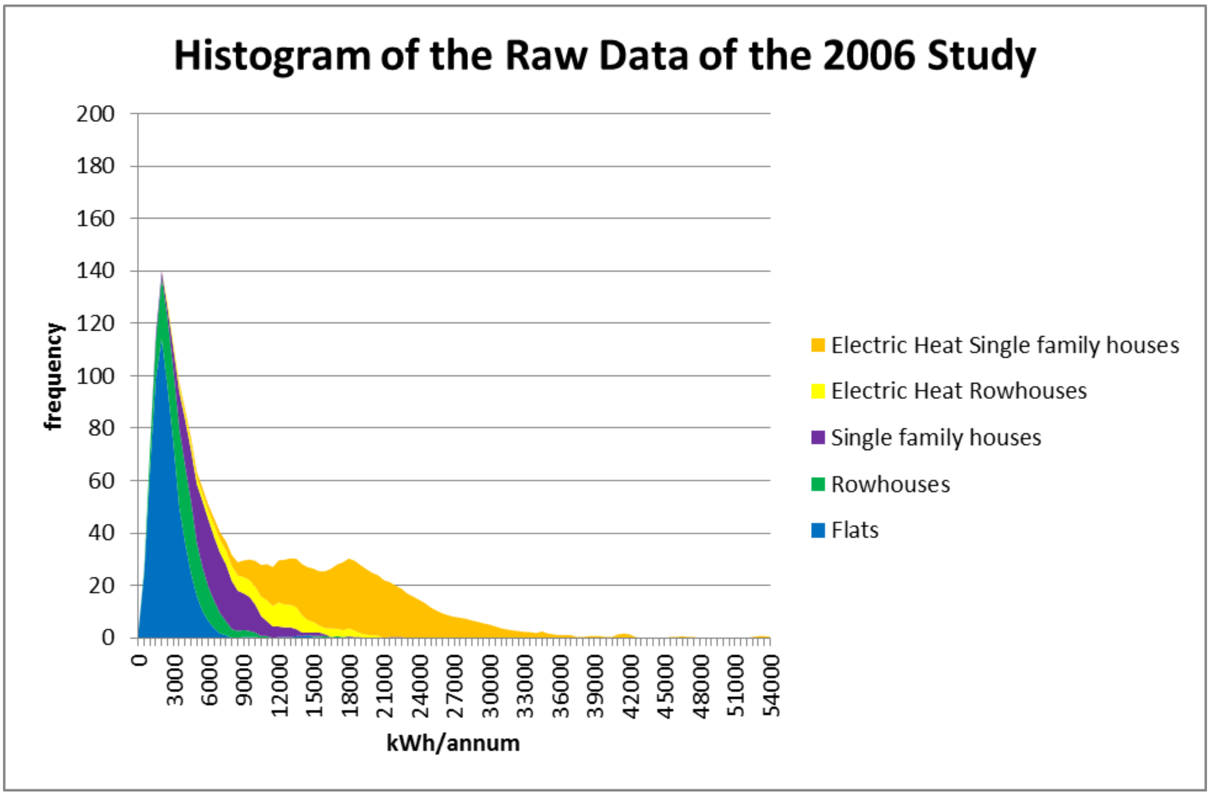

Figure 2. Histogram of the total electricity use by strata using the non-weighted data of the 2006 study.

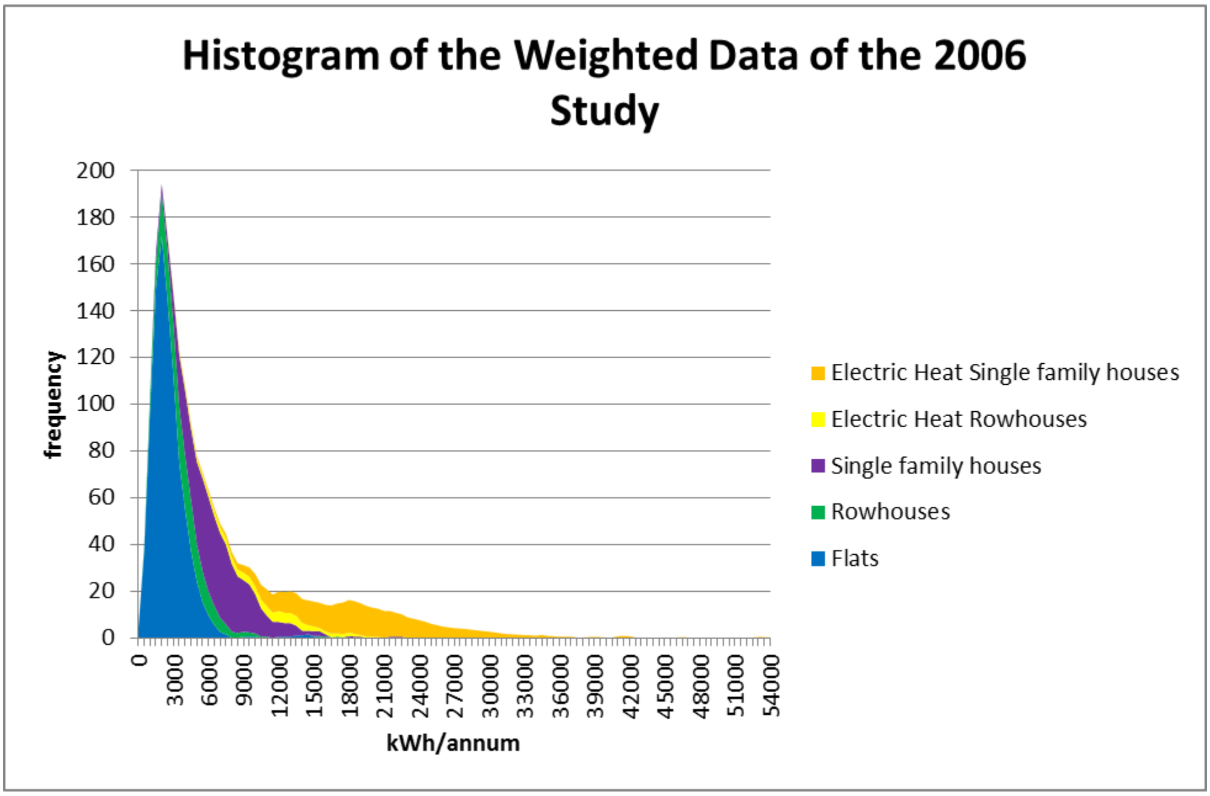

Figure 3. The histogram of the total electricity use by strata using the non-weighted data of the 2006 study.

Both in lighting and television the reduction results from increased energy efficiency. The number of TV's is no longer growing. During the years 2007-2010 over 1.7 million LCD televisions were sold [6], so that 70 % of the total television stock was renewed, the new appliances having stand by below 1 W and an inbuilt digital receiver. This resulted in large decrease energy consumption. The energy efficiency of computers also increased during 2007-2010. Today 63 % of computers are laptops compared to 40 % in 2006. In measurement studies the average laptop consumes 80-90 % less than an average desk top [2,7,8,9]. However, the number of computers and broad band connections are increasing at a very rapid pace. In 2006 40 % of Finnish households did not have a computer or a broadband connection, In 2011 this share was 15 % [10]. In 2006 a laptop was used on average 2 hours per week. In 2011 the average was 4. In 2006 the average desk tops usage was 4 hours a week, in 2011 the usage increased to 4,5 hours. Between 2006 and 2011 total share of computer increased from 123 % to 153 %, which means that second and third computer became increasingly common. This resulted in an overall increase in electricity consumption.

Table 3 shows the electricity consumption of heating and ventilation equipment and electric sauna stoves. Both categories show increase in absolute consumption as well as their share of the total consumption. The electricity consumption doubled from 1993 to 2011, yet it is worth noting that heating and ventilation represent just 8% of the overall dwellings consumption. Much from the increase is attributable to heating and ventilation equipment which are increasing in numbers and to an extent in intensity of use. Existing building regulations require use of mechanical ventilation with heat recovery.

Table 2. Electricity consumption of appliances and lighting in Finland in 1993, 2006 and 2011

Heating of annexes	209	1 %	303	2 %
Air conditioning	0	0 %	46	0 %
Total	**7996**	**45 %**	**9493**	**49 %**

Electric heating in table 4 is divided into three categories. These are non-electrically heated homes, hydronic heat pump systems, and traditional electric heating. In addition, electric heating of ancillary buildings and outdoors, air-conditioning and hot domestic water each form a category.

Electricity is used in non-electrically heated homes to provide alternative or additional heating. Non-electrically heated homes include all centrally heated dwellings in apartment blocks and row houses irrespective of heat sources and single family dwellings with central heating using district heating, oil or wood or pellet as a heat source. Additional heating is sometimes called comfort heating as the most common form is floor heating in bathroom.

Secondary electric heating of living space is divided into three groups: floor heating (electric cable), heat pumps and other additional electric heating. The increase in floor heating is of the same magnitude as the decrease in the consumption of televisions and it can be seen in all dwelling types. Heat pumps in this category are usually air-to-air heat pumps mostly found in single family houses with central oil fired heating. 22 % of these houses have an air-to-air heat pump used for heating. Other additional electric heating includes electric radiators and similar items. They are seldom used in centrally heated dwellings unless part of dwelling is without central heating.

Hydronic central heating with heat pumps includes ground source heat pumps, the air-to-water heat pumps and part of the exhaust air heat pumps. As the figures show a ground source heat pumps dominate this group. Geothermal energy is used for space heating in nearly 6% of the Finnish single family houses [11] and this share is increasing rapidly. The group secondary electric heating covers floor heating with electronic cable, air source heat pumps and separate electric radiators.

The traditional electric heating is divided into two categories dry systems and water based systems. In both groups heat pumps are becoming increasingly common. In 2011 approximately 40 % of the electrically heated single family houses also used heat pump. But that is not the only additional heat source, namely 75 % of these households use wood in heating as well. Figure 4 shows how this is reflected in electricity use.

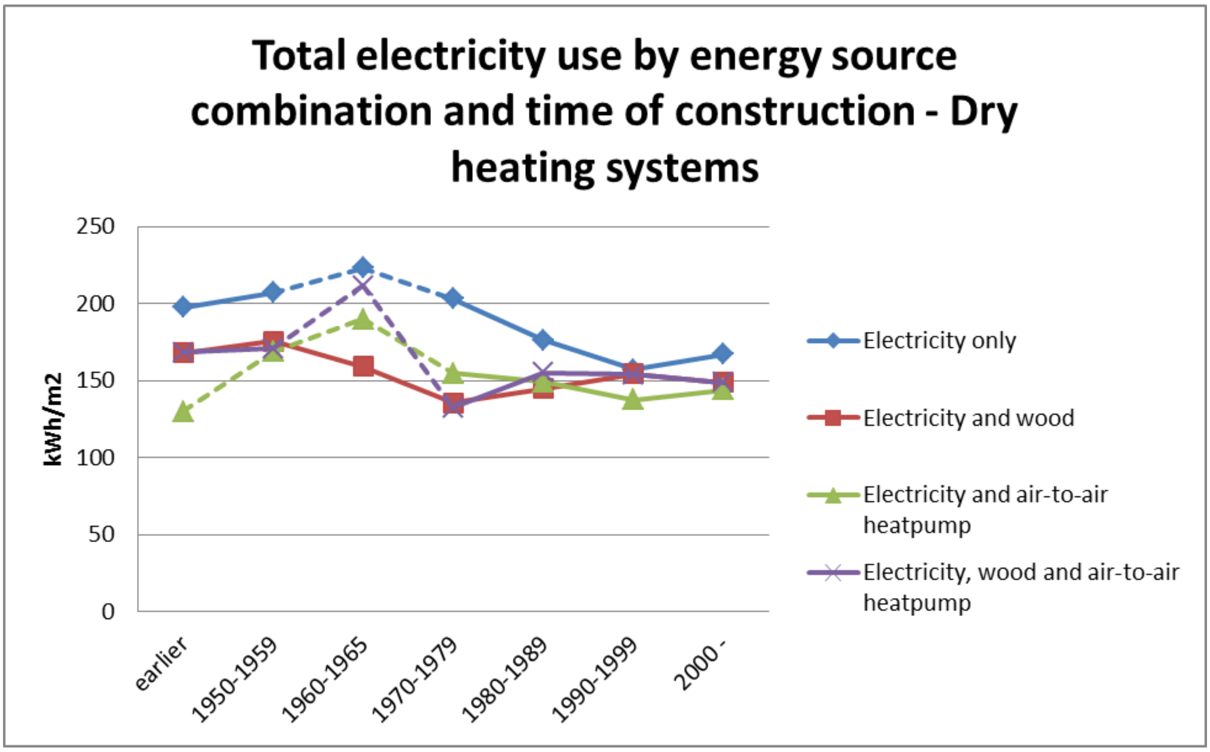

Figure 4. Total electricity use per square meter by heating energy source combination and time of construction, single family houses with dry heating system.

Reference households

The reference households are used as a communication tool, the most important target group being household customers. Most customers are interested in their electricity bill, thus the reference households are defined so, that they cover the variation in electricity use and analysis is limited to the electric energy paid directly by the consumer. Figure 7 shows the total consumption and its development in time for each reference household defined in the three studies. Note that the number of reference households has been increasing. The 2011 study included electric heating so two new reference households were defined. In 2006 study, four new households were defined and one definition from 1993 was revised.

The upper level definition is based on dwelling type (flat, row house, single family house) and number of inhabitants. The equipment stock and level use is determined from the data using set principles:

1. If 50 % or more of the household type in questions owns an appliance then it belongs to the equipment stock of the typically equipped reference household.

2. If app. 10 % of the household type in questions owns an appliance then it belongs to the equipment stock of the highly equipped reference household.

3. In both groups the amount of use of the appliances corresponds to median. The reason for this is for skew distributions that median is better suited for comparison as 50 % of the observations are below and 50 % of them are above median.

Basing the definition of the reference household on data defined statistics also facilitates comparison over time. Though this typically is not necessary in customer communication, it helps explaining the development of the aggregate figures.

Figure 1 shows the numbers for a single in flat and figure 2 for a family of four in a detached house. In these examples district heat is used as heating energy, though for different reasons. In flats this reflects reality – 90 % of Finnish flats use district heating. In 2011 only 7 % of the detached houses used district heat, in central heating the most common energy source was fuel oil. The analysis of data, however, revealed that what was typical for fuel oil was atypical for district heat. Namely, the combined share of electric floor heating and air-to-air heat pump in house using fuel oil as main heating energy was over 50 % and thus secondary electric heating would be part of a typical appliance stock in these houses. Though adding up 30 % of the typical consumption of the floor heating and 20 % of the typical consumption of air-to-air heat pump would result in a plausible figure for floor heating, the adoption of verbal description of the situation was preferred to incorporating this kind of calculation into the example.

This development has more general bearing. As time passes by the appliances that once belonged to the highly equipped house become part of a typically equipped house. Secondary electric space heating is now about to become part of the typical equipment stock in single family houses and similar phenomenon is emerging in flats. Mechanical ventilation was included as part of a typical equipment stock in detached houses in 2006 and now in 2011 it is emerging as part of the high equipment stock in flats. A dishwasher and a computer which in 2006 were part of the appliance stock of a highly equipped flat became part of the typical equipment stock of a flat in 2011, hence the increases in home electronics and cooking and dishwashing. The increased energy efficiency of home electronics show as a reduction in consumption only in highly equipped households, most notably in flats were the volume effect is negligible. The total electricity consumption is increasing in all of these four reference households. Only one of the eight reference household defined in 2006 and 2011 show a slightly decreasing trend namely a family of three in flat. See figure 7 for details.

This analysis suggests that the heating related electricity end uses will continue to increase in importance. Mechanical ventilation and heat pumps in principle enhance energy efficiency though they increase electricity consumption when the heating energy used is not electricity.

Lesson from data analysis

The reliability of survey data is often questioned and it is true that the formulation of the questionnaire affects the answers. People cannot answer to questions they do not understand nor if they do not know the answer. Badly designed questions are not a fault in the method, but a fault in the execution. People not knowing the answer on the other hand indicate issues that might need addressing in communication. Further, analysis of data and model testing may reveal unexpected patterns and these in turn indicate issues for further investigation. The following are examples of the issues that emerged in the analysis of 2011 data:

- 32 % of households living in block of flats did not know the heating energy of the apartment block, in row houses this percentage was 8 % and in single family houses 0 %. In population terms, 15% of households did not know the energy source of the two largest residential energy end use components. Targeted communication is obviously needed.
- People in flats also lack knowledge on the ventilation system of the apartment block and the share of apartment specific mechanical ventilation was not as high as expected in the flats built after 2000. The likely reason for this is that the occupant is unaware of the systems existence. The other alternative, severe breach of existing building regulations, is much less likely. This also has communication implications.
- The variance of total electricity use per square feet of living area in houses heated with electricity was lower than that of houses heated with ground source heat pumps. (The data was controlled for the year of construction.) This indicates that similar performance problems to those found in Energy Saving Trust's heat pump field trial [11] may be present in Finland.
- The testing of the model revealed that domestic water consumption is lower in houses risking running out of hot water. This is the case when hot water is produce night time taking advantage of the time of use tariff, a practise very common in Finland. Similar results to this can be found in measurement studies from the 1980's in Finland.
- The construction year did not affect the energy consumption as much as expected and the observed trends were in line with those of Norway and Sweden. This indicates that the prebound effect introduced by Sunikka-Blank and Galvin could also be present in Finland [13].

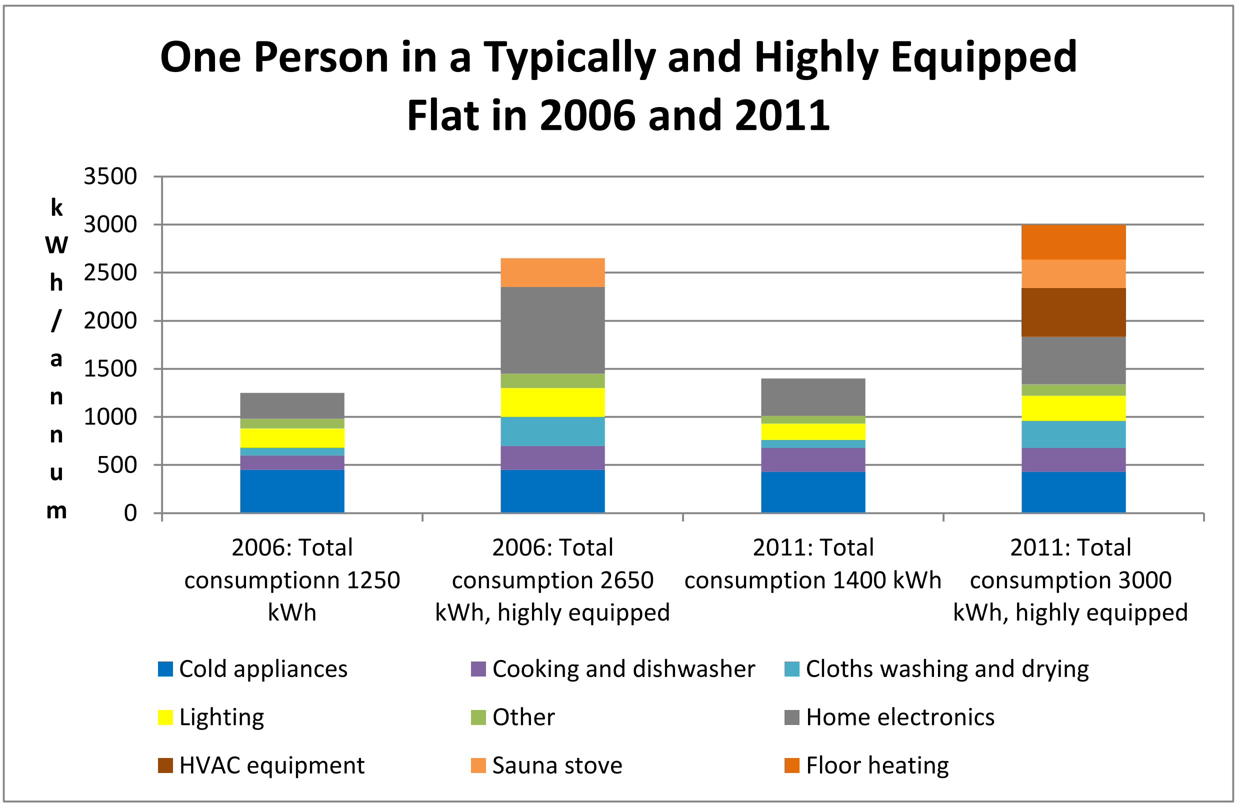

Figure 5. Reference household, one person in a flat.

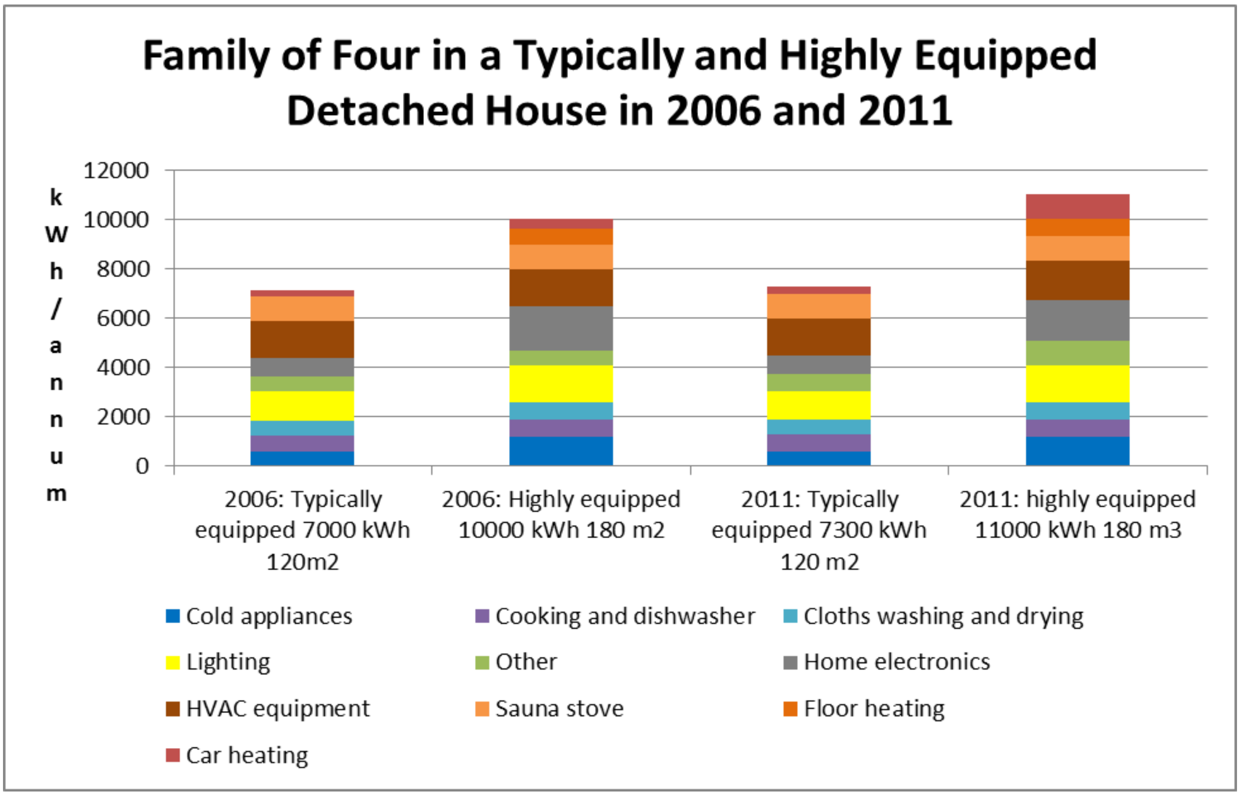

Figure 6. Reference household, a family of four in a detached house

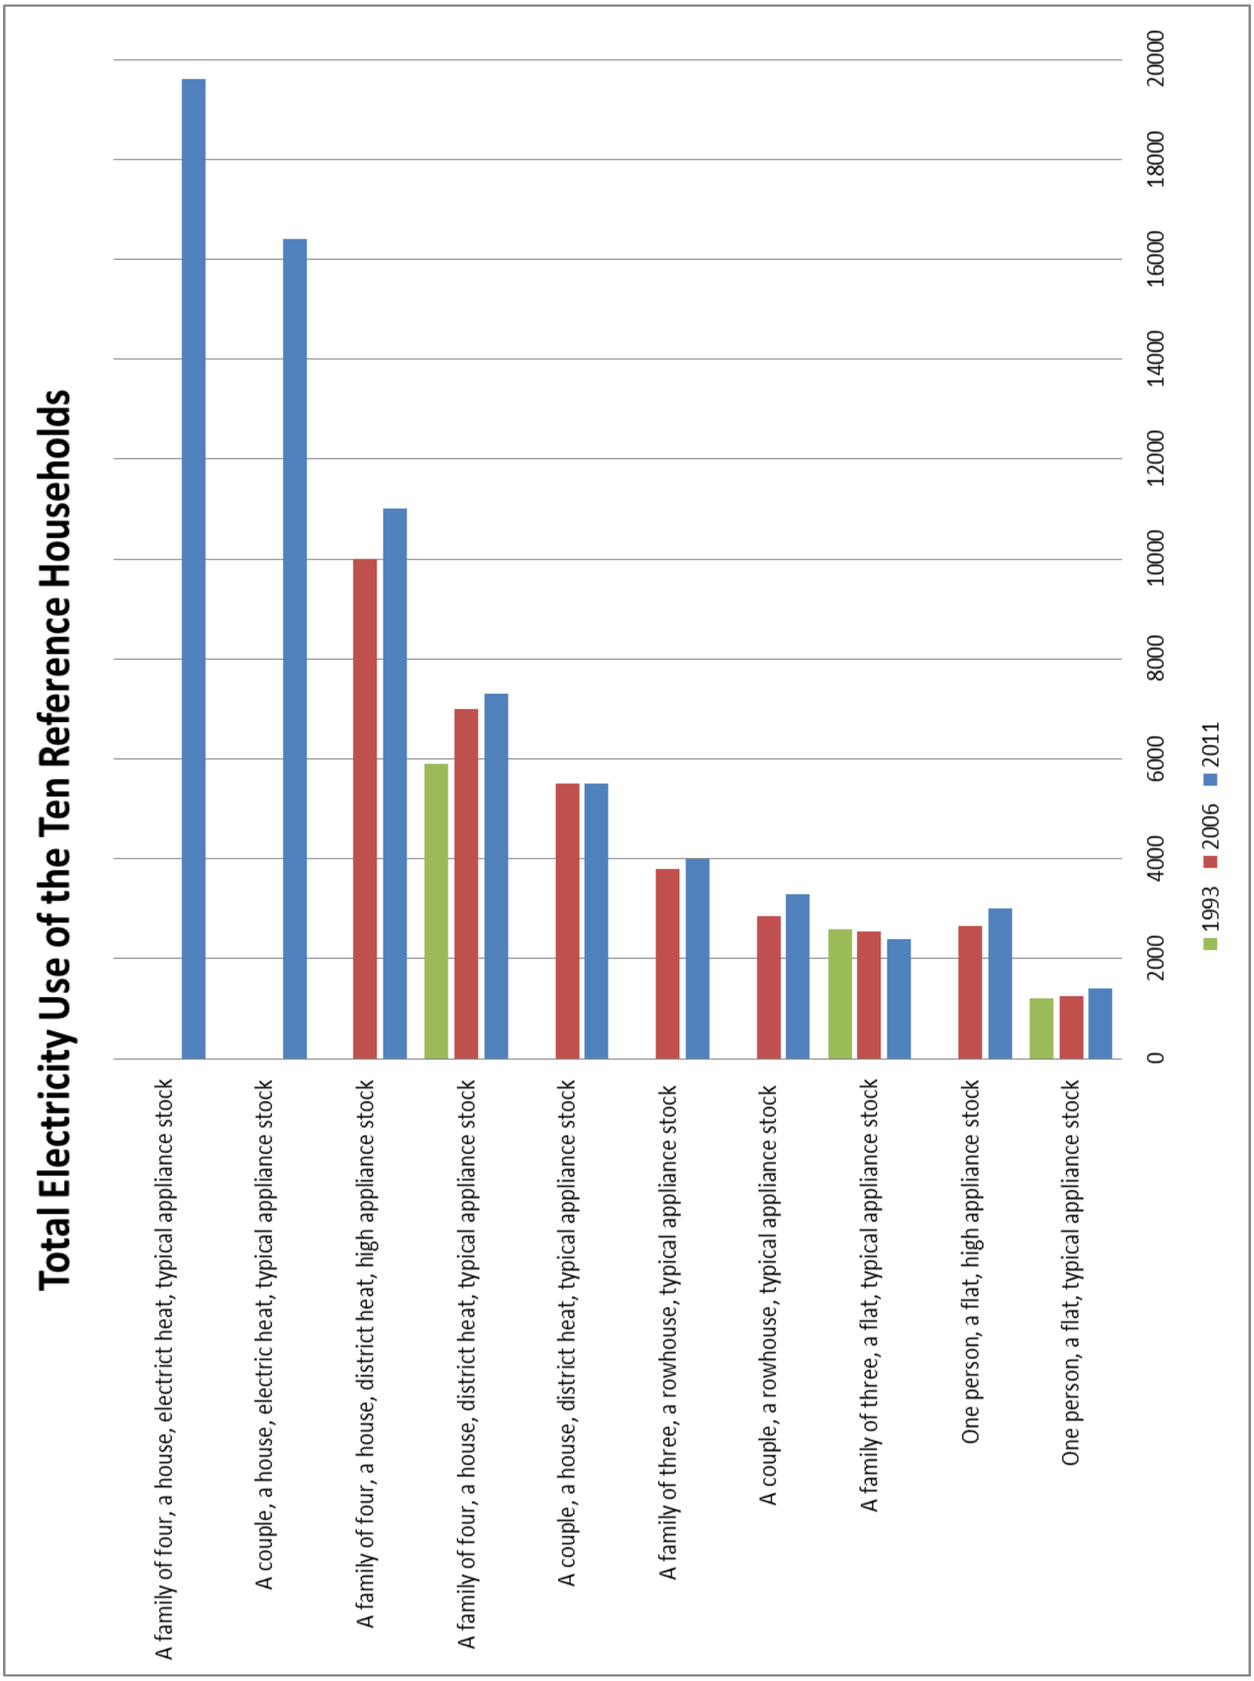

Figure 7. Summary of the total annual electricity use in reference households in 1993, 2006 and 2011.

Conclusions

Electricity consumption in households has increased by more than two terawatt hours (TWh) from 2006 to 2011 and is now close to 20 TWh. The increase is due entirely to the increase in electricity consumption associated with the heating of homes. A number of factors contribute to this development. The most important are increased number of heat pumps, increased secondary electric heat and increased mechanical ventilation and heat recovery.

The electricity consumption of household appliances is on the same level as before, because the reduction in consumption in lighting and TV appliances offset the increased electricity consumption of computers, dishwashers and car heating.

The reduction in consumption is attributable to the regulations issued under the EU Directive on Ecodesign. Electricity consumption for lighting is approximately halved. Lighting accounts for only 8 percent of electricity consumption in the residential sector, while the share in 2006 was 14 percent.

The electricity consumption of TVs fell 32 percent over five years and represent now just 3 percent of electricity consumption in households. Their number hardly increased and much of the equipment was replaced with new ones during 2007-2010. In most of the new TV sets it is the consumption in standby and off mode under 1 W, which explains this share reduction in electricity consumed.

The electricity consumption of IT devices increased rapidly, doubling in the past five years as the equipment became more common. The increased efficiency brought by the switch of desk tops to lap tops was not large enough to compensate for the increased volume. he number of computers has increased dramatically and fewer households cope without a computer and broadband connection. The proportion of such households was only 15 percent in 2011, while their share even in 2006 was as high as 40 percent.

Number of smaller lessons can be drawn from the data analysis. These include a need to improve customer information on heating and ventilation especially in the segment flats, need to investigate further the actual performance of heat pumps in the field and effect of technology and price incentives on water usage patterns.

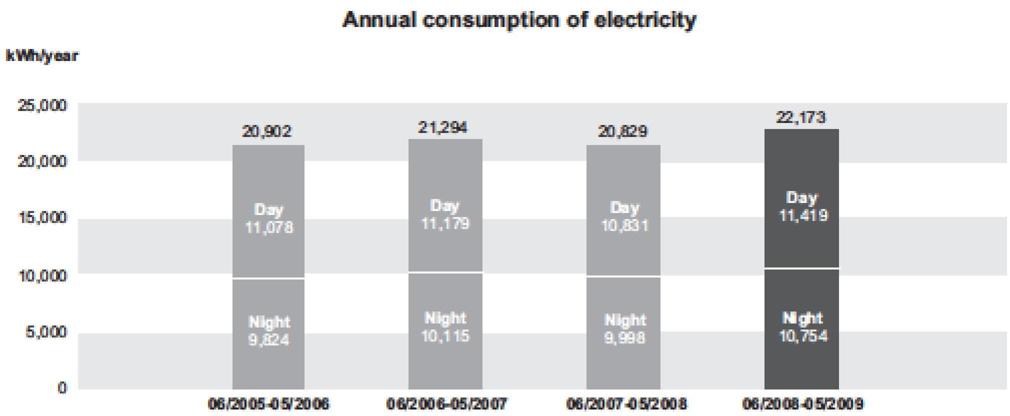
APPENDIX 1: A Model of the Year Report of the Household customers, time of use tariff

adato

YEAR REPORT
10 June 2009

Customer	Eric Electrician
Address of the metering point	Substation Road 2 86000 Town
Metering point ID	12345689

Basic model (two-rate product)



Your household's annual electricity consumption for the period 06/2005-05/2009 is presented in the graph.

You can compare your electricity consumption with other users by looking up a similar household in the comparison table on the reverse side. The tables comprise the data of several thousands of electricity users. Further information on the comparison is available on the website www.motiva.fi/kayttoraportti/.

Tips

You may get an unpleasant surprise if your home electronics are kept switched on at all times. For example, a PC that is always on may consume as much as 1,000 kWh of electricity a year. This equals the annual consumption of an electric sauna stove in a detached house.

Constant use	1,000	2,000	4,000	4,500	4,000	8,000	16,000	18,000

Average annual electricity consumption describes normal electricity use in each group. A quarter of the households in each group consume less electricity than the figure for economical consumption. Only average annual consumption is given for holiday homes.

The amount of electricity used for heating depends strongly on the heating need, which varies in different years and locations. The comparison figures for electrically heated households are adjusted to the temperature of a normal year in accordance with the location of your metering point. The temperature of the normal year is calculated as average of actual temperatures over 30 years. Further information about the temperature adjustment is available on the website www.motiva.fi/kayttoraportti/.

Assessment of electricity consumption explanatory factors for large electrical appliances

Bruno Lapillonne and Carine Sebi

Enerdata

Didier Bosseboeuf

ADEME

Abstract

This paper aims at identifying and quantifying the main factors influencing electric consumption for large electrical appliances. Results are illustrated in the case of France and Germany.

The role of various factors have been considered: appliance ownership, appliances' size, efficiency level according to energy label class, equipment features, equipment price according to respective energy efficiency, consumer attitude, and electricity tariffs. A technico-economic decomposition analysis of energy demand changes has been developed to quantify each factor's impact for five of the main observed factors. The analysis has been carried-out by type of appliance. The results show that only two factors significantly impact consumption: the equipment ownership rate and the energy label penetration; however, they tend to offset each other. Qualitative factors (e.g. behaviours, retailers' strategies, policy factors) have been also considered and some of which were assessed. In conclusion we will show how these factors explain the difference in the specific consumption of appliance in France and Germany.

Context and objectives

Residential electricity consumption for domestic appliances and lighting is on average steadily increasing: the unit consumption per dwelling for lighting and electrical appliances has been increasing by 1.3% per year at EU level during the period 1990-2008 (Figure 1), and up to 4% per year for Greece, Cyprus or Ireland[1]. This paper aims at identifying and quantifying the main factors influencing electric consumption for large electrical appliances. To illustrate the different trends, we will study in particular the cases of France and Germany, where detailed data by appliance type were made available[2].

---

[1] The trends are on purpose shown over the period before the start of the economic crisis.

[2] http://www.odyssee-indicators.org/publications/PDF/Summary-benchmark-electricity-EN.pdf

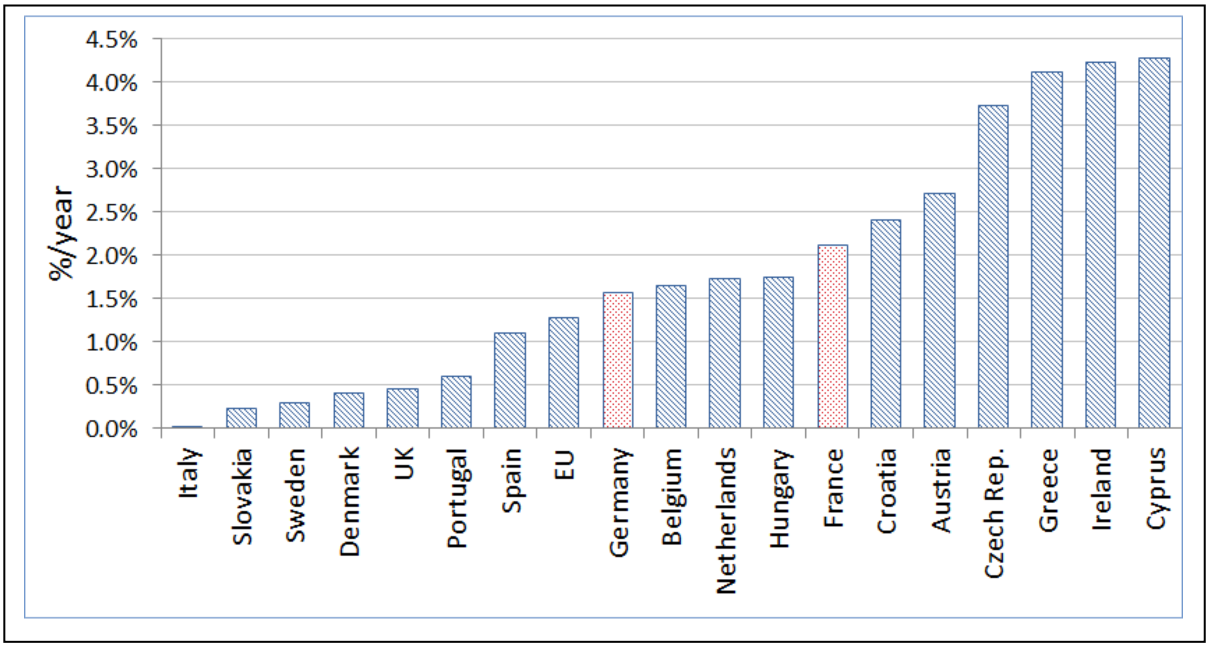

Figure 1. Annual trends in household electricity consumption for appliances and lighting between 1990- 2008

Source: Odyssee

Driving factors of the energy consumption

The analysis focuses on large domestic appliances, which present the largest available set of data and consume more than 40% of captive uses, on lighting (which accounts for 15% of specific electricity), and on the main consumer electronics (TV, computers). As shown in Figure 2, we will try to understand the factors behind the changes in the household electricity consumption of large appliances, so as to asses why it been increasing in France since 2008 and not in Germany. Several explanatory factors will be considered such as:

- **Equipment rate** in large appliances, home entertainment electronics (TVs, PCs) and lighting;
- **Appliances' size**, especially for cold appliances and TVs;
- **Equipment features and functionalities** impacting consumption (upright versus chest freezers; frost-free and built-in cold appliances);
- **Efficiency level** according to energy label (A, A+, etc.); for the diffusion of the different class we will take into account the equipment price for energy efficient classes and the potential role of electricity price.
- Finally, the **consumer behavior** (frequency of use and preferred temperature for washing appliances; duration of use of TVs and lighting equipment);

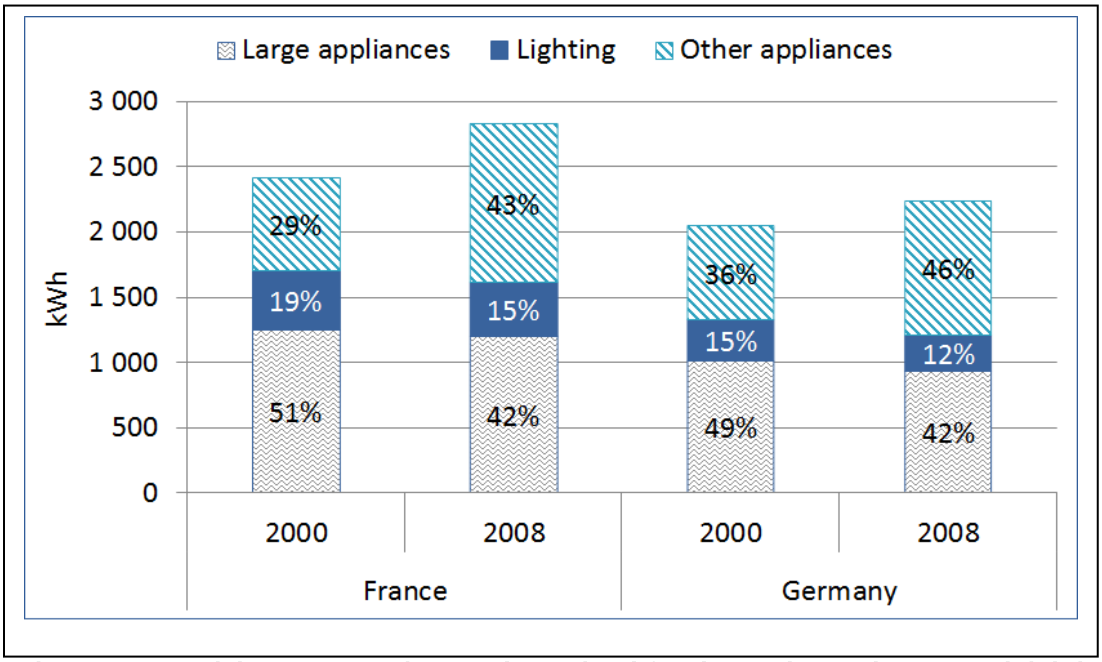

Figure 2. Electricity consumption per household for domestic appliances and lighting by end-use in France and Germany

Source: Odyssee

Large domestic appliances

Equipment rate and size

Except washing machine where equipment rates were roughly steady during 1990-2008, for all other large appliances their diffusion increased, especially for freezers, dish washers and dryers. For instance we observe an increase of 34 points in Germany for dish washers and of 20 points in France for freezers and dryers (Figure 3). Although both countries' equipment rates are close, Germany's rates are higher. But France is gradually reaching similar rates, in particular for freezers, refrigerators, and washing machines.

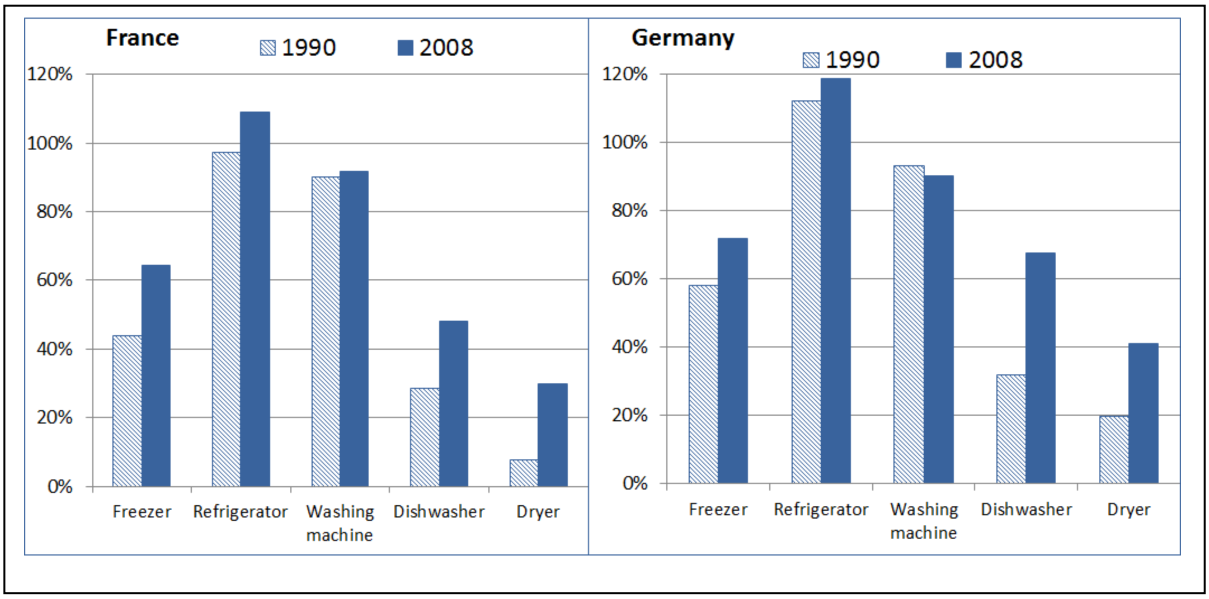

Figure 3. Equipment rate in France and Germany

Source: Odyssee, INSEE, SOFRES

For large domestic appliances, the size of new appliances has been increasing: since 2004, increase of 2% for fridges sold in France (and almost +7% in Germany), average size increase of 2% for freezers in both countries and significant increase for washing machine capacity (+20% in both countries, Figure 4).

Refrigerators and freezers sold in France are larger than the ones sold in Germany (+30% and +23% respectively): it may be partly explained by the average size of household, i.e. the average number of inhabitant per household, that is 13% higher in France, and by the fact that dwellings are on average smaller in Germany (by about 9%), due a larger share of apartments compared houses. The size difference for washing machines and dishwashers is hardly significant.

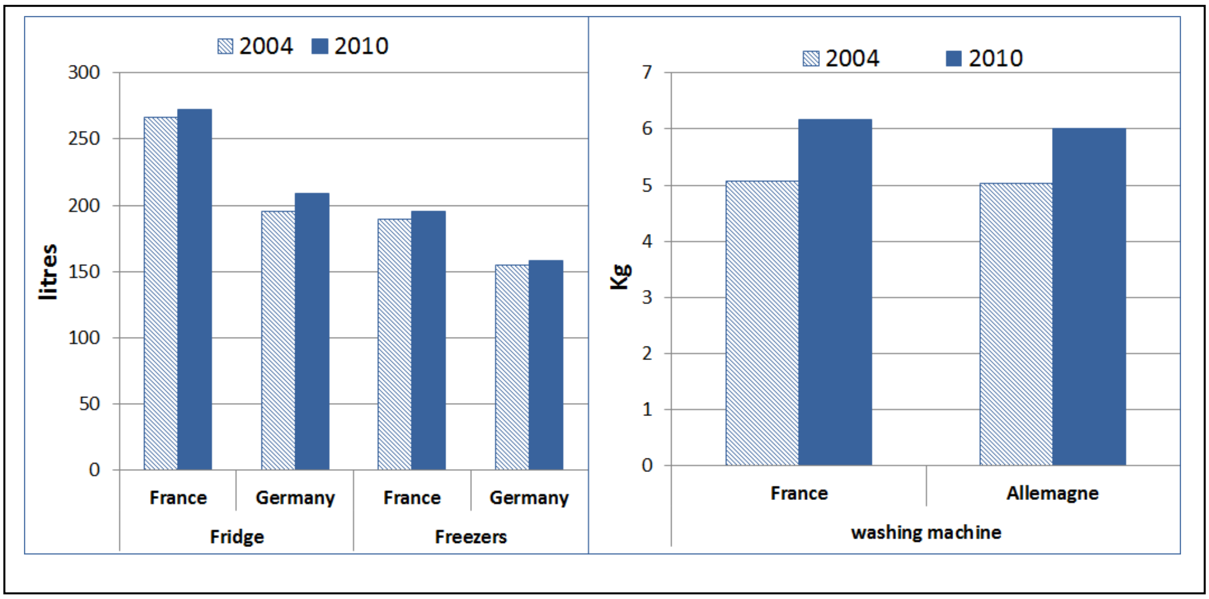

Figure 4. Average size of new appliances in France and Germany

Source: GfK, Enerdata calculation

Equipment types and functionalities

Sales of less electricity intensive cold appliances' (table-top, 1 and 2-doors[3]) are decreasing since 2004 in both countries: from 77% to 67% of sales in France and from 75% to 56% in Germany between 2004 and 2008. And the sales of these "less intensive equipment" are higher in Germany than in France (Figure 5). French consumers buy twice the number of frost-free refrigerators (32% of French sales in 2008, versus 11% in Germany). This system is more energy intensive. On the contrary, the German market share of built-in refrigerators, which are less energy-efficient, was 41% in 2008 vs. only 15% in France.

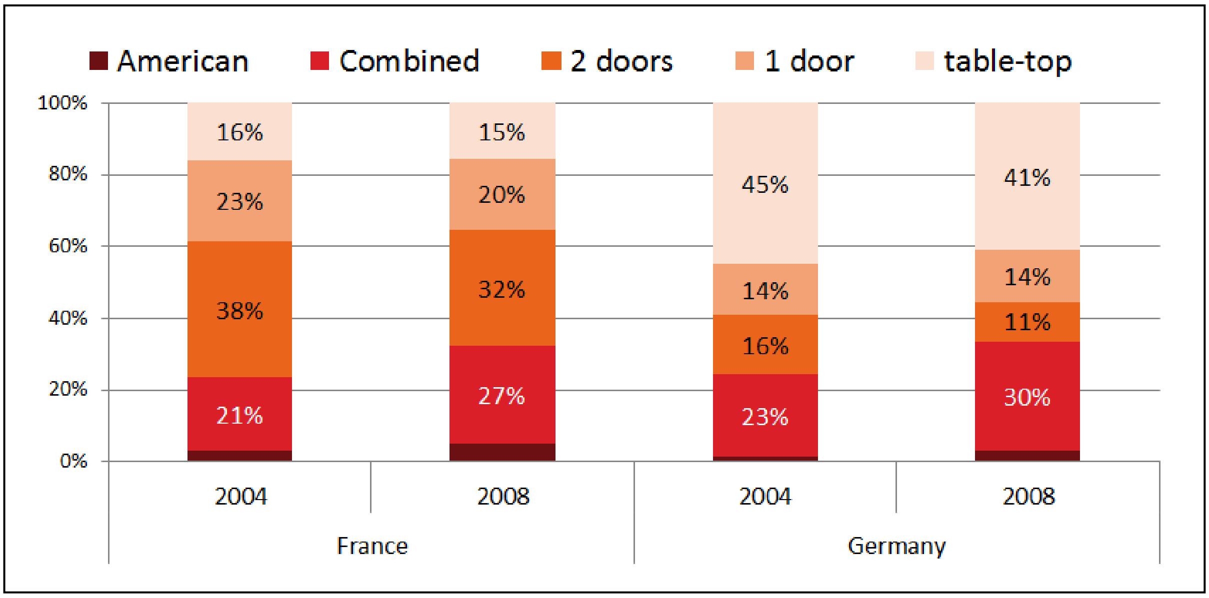

Figure 5. Sales of fridge according to main features in 2004 and 2008

Source: GfK

The market share of upright-freezers', which are more energy intensive than the chest type are slightly increasing over time (Figure 6). It is 30 % larger in Germany than in France. Frost-free freezers' market share is also higher in Germany (23% vs. 10%). Freezers sold in Germany are thus more energy intensive than the appliances sold in France.

[3] "Table-Top" models are 1-door refrigerators, with a 90 cm maximum height.

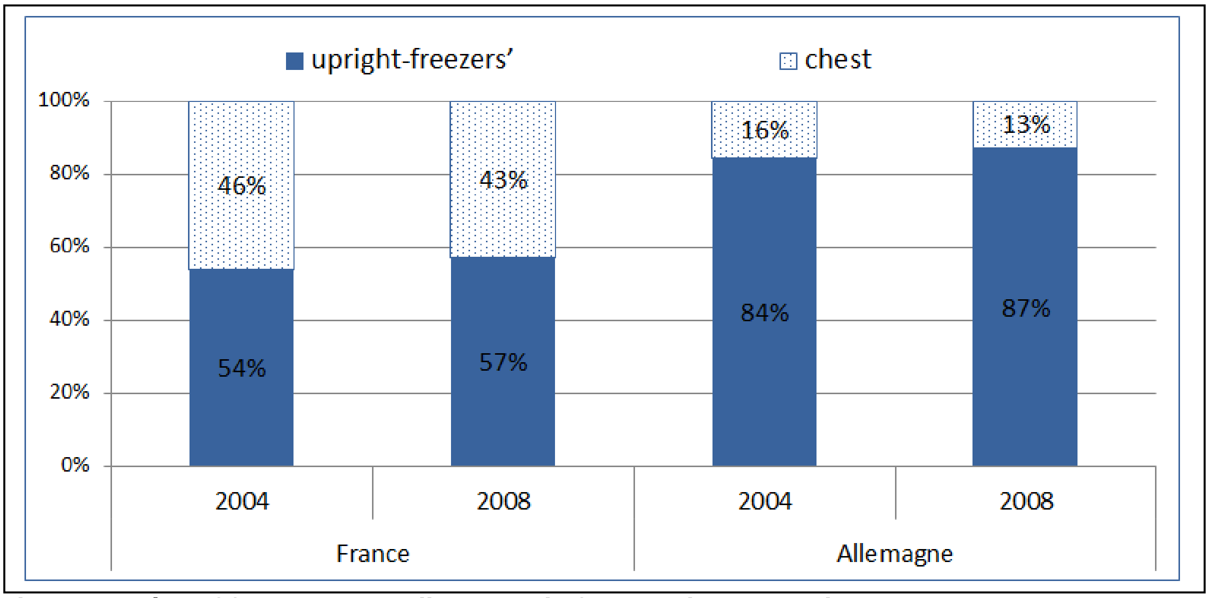

Figure 6. Sales of freezers according to main features in 2004 and 2008

Source: GfK

Front-loading washing machines' sales are higher in Germany (90% vs. 59% in France), but their share has been quickly increasing in France (from 25% in 2000 to 59% in 2008). Top-loading washers are usually less efficient than the front-loading type[4].

Since 2004, the sales of less efficient type of equipment are increasing, such as combined or American fridges or upright freezers. While refrigerators and washing machines bought in France are overall more energy intensive than in Germany, German consumers tend to buy freezers with more energy intensive functionalities than the products favoured by French consumers.

Equipment efficiency

Thanks to the Energy Labelling Directive the share of energy efficient appliances has remarkably increased since 2002, but at a different pace among countries (Figure 7). The penetration of very energy efficient appliances[5] has been much higher in Germany than in France: in 2010[6], A+ rated washing machines' market share is 10 points higher in Germany; the share of A+ and A ++ labels is respectively 34 and 47 points higher for refrigerators and freezers.

---

[4] Top-loading washing machines lower efficiency level can be explained by their relative small market share, and by the fact that manufacturers choose to invest in the front-loading range optimisation.

[5] For washing machines the most efficient label is officially A but manufacturers are allowed to use "A+".

[6] There has not been massive subsidy programmes in Germany to explain such differences. Prices are on average lower in Germany for the most efficient appliances (e.g. 10% of difference for a given A++ freezer), because demand for these types of product is higher thanks in particular to awareness programmes and the marketing strategy of suppliers and resellers(see below for further explanations). There has not been massive subsidy programmes in Germany.

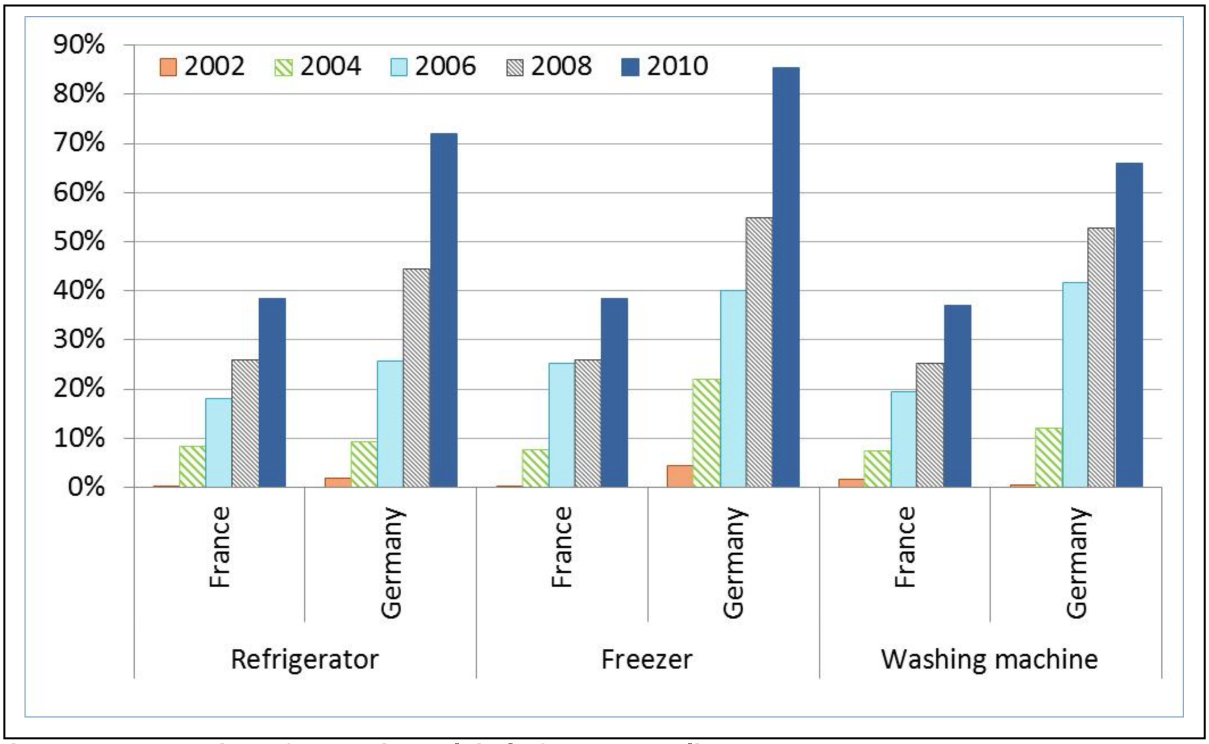

Figure 7. Penetration of A+ and A++ labels for new appliances

Source: GfK

These different trends between France and Germany may be partly linked to the fact that efficient appliances are cheaper in Germany than in France and that the price of electricity is twice higher in Germany.

Most energy-efficient cold appliances are more expensive in France than in Germany. The price difference can reach up to 20% for class A+ or A freezers and 13% for A+ refrigerators. In addition, the price difference between an A and an « A+/A++ » washing machine is higher in France than in Germany (39% vs. 23%).

Sales prices according to the energy label are partly determined according to market shares. High efficient appliances (A++ and A+) market share is notably lower in France compared to Germany. The price difference can be explained by the smaller size of the market, and the lack of trust of manufacturers in the French consumer "green" awareness, which leads them to market less energy-efficient models.

The average electricity price for households in France is currently about half of the German price[7]. Half of the difference can be explained by cost differences and the other half by a different level of taxes. VAT weighs equally in both countries (around 15%). Other taxes are much higher in Germany, accounting for 27% of electricity total price (of which an 8% eco-tax since 2000), versus 10% in France[8].

Behaviours

[7] Source : Enerdata Global Energy & CO2 data.

[8] Source : IAE Statistics, Energy prices & taxes – quarterly statistics.

If Germans use higher temperature[9] water to wash their laundry and dishes than French households, they will use more frequently economic cycles. In addition, German households tend to load more their washing appliances, reducing the number of cycles and the electricity consumption (Remodece, 2007[10]).

French households declare cleaning the refrigerator's rear grid more often (25% monthly vs. 5% in Germany; and 38% once a year in France vs. 15% in Germany (Remodece). French consumers defrost their refrigerators and freezers more often. In Germany, over 20% of respondents declare having set the thermostat on the lowest temperature, vs. only 3% in France (Remodece).

Although it is impossible to quantify each attitude's impact in terms of consumption, they tend to partially compensate each other, and hardly play a part in the observed consumption discrepancy.

Lighting

Lighting electricity consumption is decreasing over time in both countries by 1.4%/year (Figure 1). However, it is notably higher (+49%) in France than in Germany in 2008. This consumption gap does not lie in the number of lighting points, because it is identical in both countries: 25 lights on average per household.

In contrast, the German households have installed twice as many compact fluorescent lamps as in France (6,5 /house in Germany vs. 3 in France). Compact fluorescent lamps' penetration can explain most of the difference in consumption. According to Remodece report, the differences in consumers' attitude for lighting offset each other.

ICT appliances

The average number of TVs per household is similar, with around 1,5 TV/household in 2008 in both countries. TV size and duration of use are also close and increasing over time (Figure 8).

---

[9] In Germany 50% of households wash their laundry at 65°C vs 29% in France. In Germany, 44% of households wash their dishes at 65°C vs. 21% in France.

[10] This study involved a panel of 500 households in the two countries. Although it was led in 2006, it helps understand consumers' attitudes differences between the two countries "Residential monitoring to decrease energy use and carbon emissions in Europe"; EIE project, 2007.

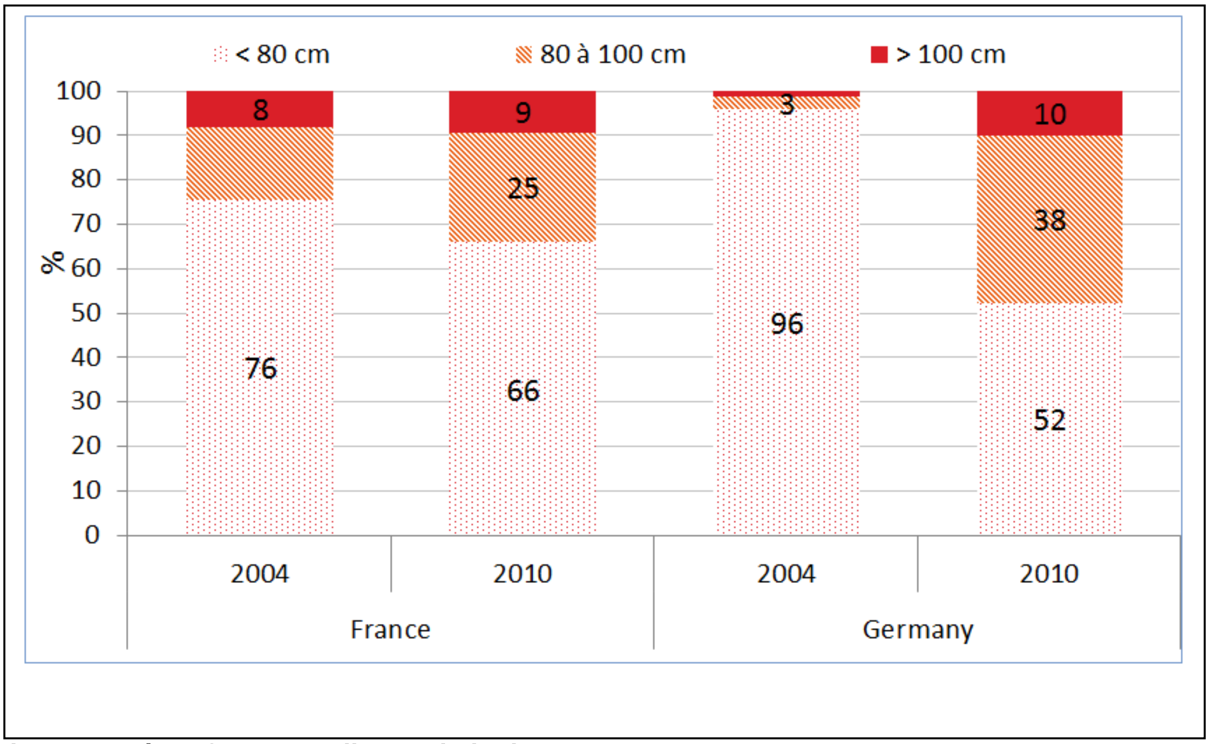

Figure 8. Sales of TV according to their size

Source: GfK

The equipment rate in computers is higher in Germany. Screens sold in Germany are slightly larger than the models sold in France: *21" vs. 20" in 2010.*

Laptops spreading encouraged multi equipment in PC's. The average number of PCs per household has grown from 56% in 2003 to 103% in 2010 in France; and from 82% to 110% in Germany. It has been paired with the Internet development, resulting in a higher penetration rate in Germany than in France (82% et 75% en 2010).

Set-top-box systems have also rapidly grown in the last ten years, again spreading faster in Germany than in France.

With a higher equipment rate in PCs, electricity consumption is also higher in Germany: in 2008, the consumption of these three appliances accounted for 200 kWh in France and 250 kWh in Germany.

Factors responsible for the consumption variation of all electrical appliances in both countries

In order to quantify the effect of the different factors on the consumption variation, a bottom-up model was developed to simulate the change in the specific consumption of the stock of the different appliances based on the characteristics of the appliances sold every year in France and Germany over the period 1990-2010[11]. For that purpose a detailed database was compiled with information per

[11] The model simulates the consumption of new appliances sold per year as well as the average annual consumption of the stock based on the evolution of equipment rate and market shares of energy labels from 1990 to 2010. The final results for

country regarding sales of appliances, rate of equipment, stock of appliances, type of appliance and specific electrical consumption per energy efficiency class.

For each appliance, different types or categories depending on some particular characteristics were considered, such as the layout of a freezer or the average load of clothes for a washing machine (see previous analysis). Thanks to this model, several parameters that affect the electrical consumption of appliances such as types of appliances, energy labelling and penetration of new equipment can be identified and their impact can be estimated.

Figure 9 shows how much the consumption of all major electrical appliances has changed between the years 2000 and 2009 in France and in Germany and what factors are responsible for this change. The factors for which the effect on the electrical consumption have been quantified are the equipment rate, the total stock of permanently occupied dwellings (effect of demography), the shares of new appliances sold per energy class and the specific consumption of new appliances sold per energy class (energy efficiency effect).

It can be observed that total electrical consumption for large appliances (fridge, freezers, washing machine and dish washer) in France has risen by nearly 3 TWh. The growing number of households and increasing equipment rate have strongly contributed to this rise (for the equivalent of 7 TWh); this increase has been partially offset by almost 4 TWh of energy savings caused by energy efficiency improvements, namely energy labelling. In other words, without any energy efficiency measures France's electrical consumption would have risen by 7 TWh. The rise of the total consumption in Germany is considerably smaller compared to France (around 0.2 TWh). The effect of demography is almost half as significant compared to France, whereas the increase of equipment rate is analogous to the French one. In addition, the impact of energy efficiency measures is stronger than in France, resulting in energy savings of 4.5 TWh.

---

every appliance were compared with other relevant studies, such as the "Benchmarking of Domestic Cold Appliances" by IEA 4E and the "Reestimation en 2005 de la consommation d'électricité par usage fin" by CEREN.

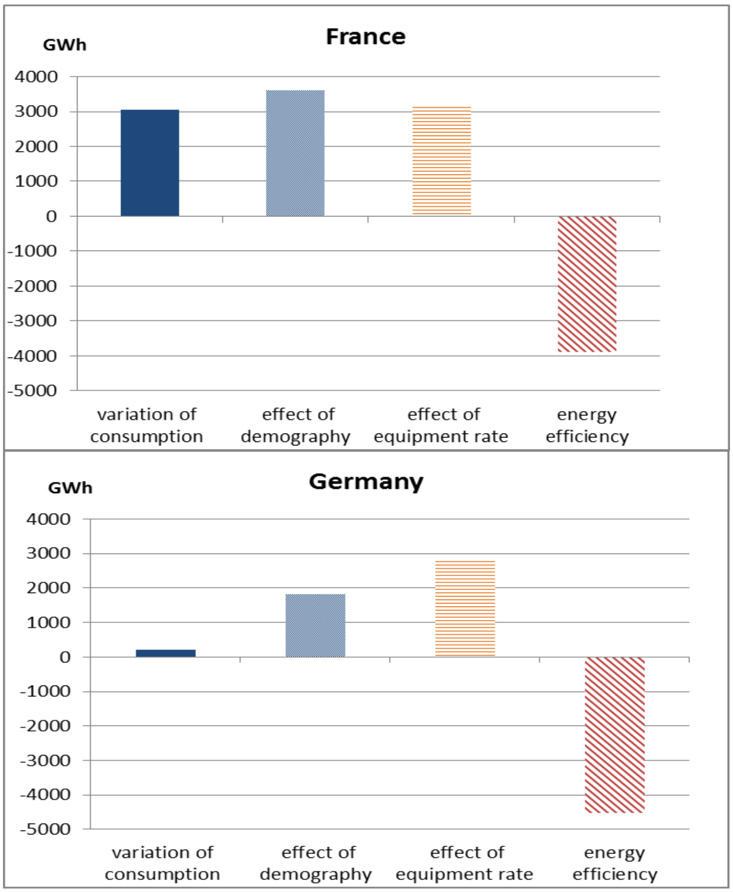

Figure 9. Factors responsible for the total variation in the consumption of all electrical appliances in France and Germany between 2000 and 2009

Source: Enerdata

Comparison between France and Germany

As seen above in Figure 2, France is not performing as well as Germany regarding captive uses of electricity[12]. A benchmarking of household specific electricity consumption in ODYSSEE (2012) shows that households' specific electricity consumption was 26% higher than in Germany in 2008[13] (Figure 10). Italy and Spain are also in a better position. However their good ranking can mainly be explained by the lower income and consequent lower equipment rate, compared to France[14]. To explain the gap between France and Germany and in particular as to the role of the different factors presented above, adjusted indicators of specific electricity consumption have been designed to quantify each factor's impact in the observed discrepancies between the two countries.

---

[12] Captives uses, also referred to as "specific electricity uses" or "specific electricity consumption" in short, include all non-thermal uses, i.e. small and large domestic appliances, consumer electronics and lighting.

[13] 2008 is the preferred reference due to 2009's particularity with the economic crisis.

[14] In addition, most Italian households benefit of a 3kW subscription contract, because of inclining electricity tariffs, which limits their consumption level.

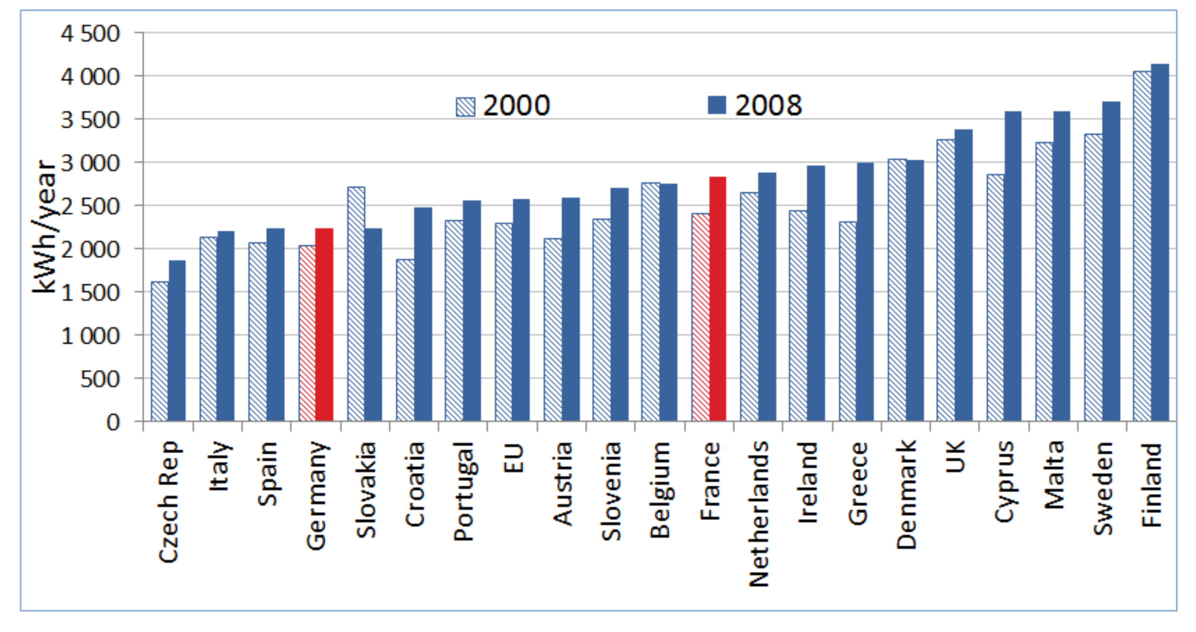

Figure 10. Household electricity consumption for appliances and lighting

Source: Odyssee

Adjustments have been made on the following factors of differences between France and Germany: equipment rate and size (for large domestic appliances[15]), energy labels penetration (for large domestic appliances and lighting), and appliances' features and frequency of use (for washing machines). They have been calculated for each appliance (fridge, freezer, TV, etc.) and then sum up by type/group of appliance: large domestic, lighting, consumer electronics and small electric appliances. This allowed calculating for each of these factors a fictive Germany's specific electricity consumption adjusted to French conditions: for example, with the equipment rate adjustment, we apply the rate observed in France to Germany for each type of appliance to calculate the fictive specific consumption of Germany adjusted to French equipment rate, all else being equal.

Adjusting the German unit consumption to the French equipment rate enlarged the initial gap between the two countries from 26% to 33,5% (Table 2).

Table 1. Adjusted Germany's electricity consumption to France's equipment rate (2008)

kWh/household/year	Large domestic	Lighting	Consumer electronics	Small electric appl.	Other	Total
Germany	929	278	569	394	67	2,237
Germany, adjusted to equipment rate in France	**820**	278	**507**	**445**	67	**2,117**
France	1,195	414	507	425	284	2,825

Source: Odyssee, adjustment calculation Enerdata

[15] Large domestic adjustments were calculated thanks to a model simulating stock evolution from annual sales (to take into account the impact of new appliances sold since 1990 and according to different criteria: label, type and size of appliance).

The adjustment for the higher penetration of efficient appliances in Germany reduced the spread between the two countries, from 26% to 15% (Table 2): in conclusion, 40% of the gap could be explained by the difference in penetration of highly efficient appliances.

Table 2. Adjusted Germany's consumption to France's energy label penetration rate (2008)

kWh/household/year	Large domestic	Lighting	Consumer electronics	Small electric appl.	Other	Total
Germany	929	278	569	394	67	2,237
Germany, adjusted to energy label penetration in France	**1,002**	**372**	569	394	67	2,404
France	1,195	414	507	425	284	2,825

Source: Odyssee, adjustment calculation Enerdata

The adjustment of German specific consumption to the average size of appliances sold in France only reduces slightly the spread from 26% to 25%. This means that the size of large domestic and lighting equipment[16] plays a minor role. Technical features and functionalities have also a marginal impact as the adjustment only shows a reduction of the difference by 2 points. And finally, when adjusted to frequency of use in France, the German specific consumption only increases marginally (20 kWh).

The respective weight of the above five adjustments differ, as only two adjustments significantly impact the specific electricity consumption: the equipment rate and energy labels penetration. Unfortunately, these two factors partly offset each other, which cannot explain the total performance gap between France and Germany. The calculation shows that only 21% of the observed difference can be explained by these factors (Figure 11).

[16] Indeed, the equipment rate for lighting corresponds to the number of lighting points, which is the same in France and Germany: on average 25 lighting points per dwelling.

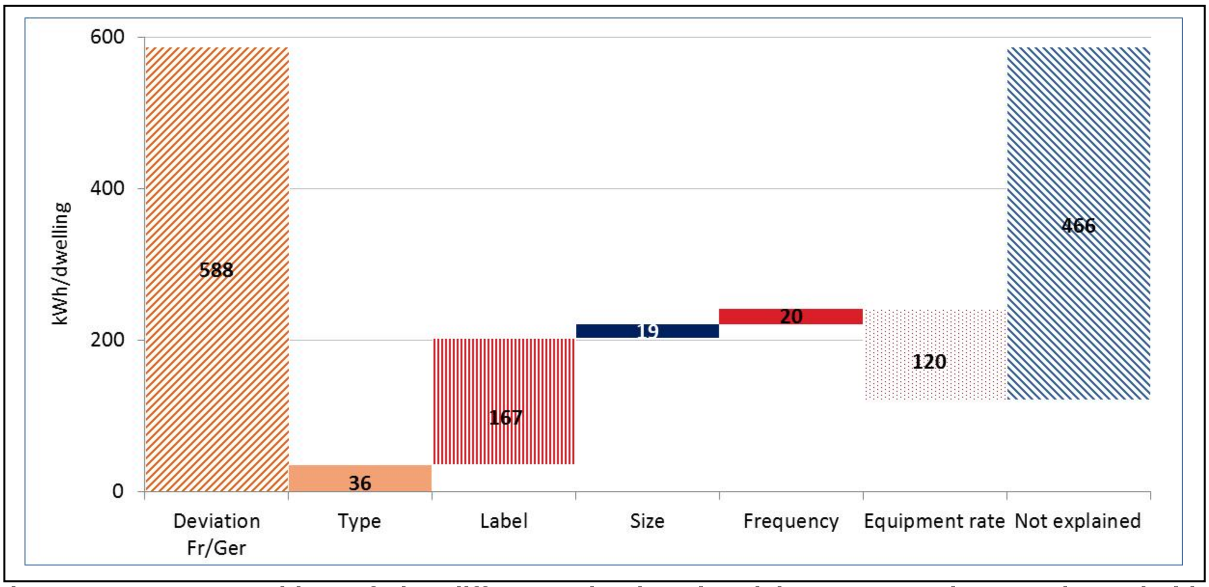

Figure 11. Decomposition of the difference in the electricity consumption per household between France and Germany for captive uses

Source: Enerdata

Conclusion

Thanks to several existing databases (GfK, Odyssee, etc.), the main driving factors behind the change in the residential electricity consumption for domestic appliances have been analysed for France and Germany. To complete this descriptive analysis, a model was developed to provide a complete evaluation of the impact of these factors on specific energy consumption of new products sold as well as the stock of electrical appliances over the period 1990-2010. The results show that indeed equipment rate, total stock of households, size of appliances, and market shares of efficient equipment and behaviour influence the electrical consumption of appliances at a country level. Differences in these parameters from country to country could explain why a country has a better performance that another.

Two main factors partly explain the higher specific consumption in France:

- Large domestic appliances are larger in France than in Germany: over 20% larger refrigerators and freezers, which are both the most common and the most energy consuming appliances in households.
- A larger penetration of very efficient large appliances in Germany (washing machines, cold appliances, and lighting), which can mostly be explained by the lower price of these products in Germany.

In order to quantify the respective impact of these factors, we have calculated a fictive specific consumption per household for Germany adjusted to France's specificities. The results show that only two of the five adjustments significantly impact the consumption: the equipment rate factor and the energy label penetration; however, they tend to compensate each other. As a result, the five adjustments only account for 21% of the performance gap observed between France and Germany, i.e. 125 kWh for an initial difference of approximately 600 kWh.

How could the residual gap be explained? One can think of qualitative factors such as prices, policies and all other qualitative factors reviewed above. Electricity is 50% cheaper in France; it certainly plays a role, but an econometric analysis carried out in the framework of the study failed to quantify the impact. It could be linked to statistical problems[17]. The analysis of policy instruments in France and in Germany shows that Germany has implemented public awareness programmes for longer that France, and with more continuity and that German households benefit from numerous DSM programmes implemented locally by Länders, cities, and more than a thousand electricity providers.

GOVERNMENT SUBSIDIES TO REPLACE ENERGY INEFFICIENT APPLIANCES; THE OUTCOME AND IMPACTS ON THE CONSUMERS AND THE LOCAL MARKET

Eddie Bet Hazavdi
Rachel Zaken

Abstract

In 2010 the state of Israel announced a new energy efficiency plan aimed to reduce 20% of the total electricity consumption in 2020 at all the sectors in Israel. During 2011 the Ministry of Energy and Water Resources adopted the "national energy efficiency plan to reduce electricity consumption in 20% by 2020" with a budget of 85 million US$ just for the domestic sector.

Among the activities that were done in the residential sector we introduced a set of new appliances regulation and launched a national project of replacing old and inefficient appliances with new ones. The state subsidizes the replacement of new highly efficient refrigerators, air-conditioners, solar installation and lighting.

The paper will include the outcome of two projects (replacing refrigerators); the regulations and the impacts on the local appliances market (this case, refrigerators).

The paper will focus on the Israeli consumer behavior toward efficient appliance and the changes in the market.

In addition, barriers and obstacles in promoting such projects are identified, and the influence of those projects on energy saving and the indirect benefits is also introduced.

The paper is based on the national energy efficiency program, an appliances market analysis and a research that was conducted to evaluate the influence of the projects on direct energy savings and indirect energy savings.

Introduction

The Energy Conservation and Efficiency Division at the Ministry of Energy and Water Resources works to improve Israel’s energy balance by more efficient energy use and optimal exploitation of energy, and promote the use of alternative energy resources.

The Division takes the lead in all facets of energy efficiency: regulation, enforcement, planning, and initiation and execution of the energy efficiency projects at all sectors.

To meet government's decision, energy savings of at least 20% by 2020, the Ministry of Energy and Water Resources published in 2010, The National Energy Efficiency Program.

According to government resolution, the Division of Energy Conservation and Efficiency will promote energy efficiency activities in the domestic sector, by replacing old inefficient appliances with more energy efficient appliances.

Among other activities the Division proposed a plan to replace via incentive old inefficient appliance with new and highly efficient once. The program was first introduced to an economically weak population and then, added with two projects to the entire population.

In order to determine which refrigerator will be subsidized, bids were given by the producers and importers for three size groups, suggesting best energy efficiency performance. Offers were scored according to energy consumption and performance, lowest price and other characteristics.

Since December 2011 till June 2011, taking advantage of the projects, up to 110,000 households replaced their inefficient refrigerators.

Work purpose

The purpose of this paper is to show the impact of old refrigerators' replacement on the refrigerators' market in Israel, and the change in consumer behavior toward efficient appliances.

Methods

The assessment of attainable energy efficiency was performed for each and every project. In every project a database was built, through a governmental system. Access to the system was for suppliers and appliances stores, each and its own level of access, one refrigerator allowed for each consumer.

The data were examined and then, analyzed, in order to evaluate the savings out of carrying the projects and lessons learned for following projects.

Summary

Electricity production capacity of the State of Israel is not growing at a rate of consumption growth and the state of Israel suffers from chronic limited power supply. The domestic consumption of electricity in the last decade is ranging from 30 to 32 percent of the total annual consumption. In 2002, the domestic consumption was 32 percent and reached 12,747 million kWh and in 2011 reached 15,909 kWh (30 percent of total consumption).

Energy performance and label regulations for refrigerators and freezers came into effect on January 2005. Till then, 500-liter refrigerators' average consumption was about 4.5 kWh a day for non-frost tropical. With the regulation we achieved 2.2 kWh saving for a day per refrigerator.

As mentioned, the first project addressed the economically disadvantage families. According to the Central Bureau of Statistics, the monthly consumption expenditure for electricity is about 25 percent of dwelling and household maintenance expenditures. The relative expenditure for electricity, among the economically weak population, is higher than the relative expenditure for electricity among the economically strong population

Refrigerators offered under the project were divided into three orders of volumes, small, medium and large, 350 to 450 liter, 451 to 550 liter and 551 to 680 liter, respectively. The projects were led with campaign on TV, Radio and other media.

To date, three projects were held and the forth is ongoing. In these projects 110,000 households (5% of the total households), replaced old refrigerators with new, efficient ones. Consumers have shown great willingness to participate in operations, since in the beginning of the projects most of the refrigerators were purchased.

The projects boosted the refrigerators market, changed the energy rating distribution of the refrigerators that are being used by the population, reduced the price level of the refrigerators and change the consciousness of the consumer toward energy efficiency and energy rating at the appliances market.

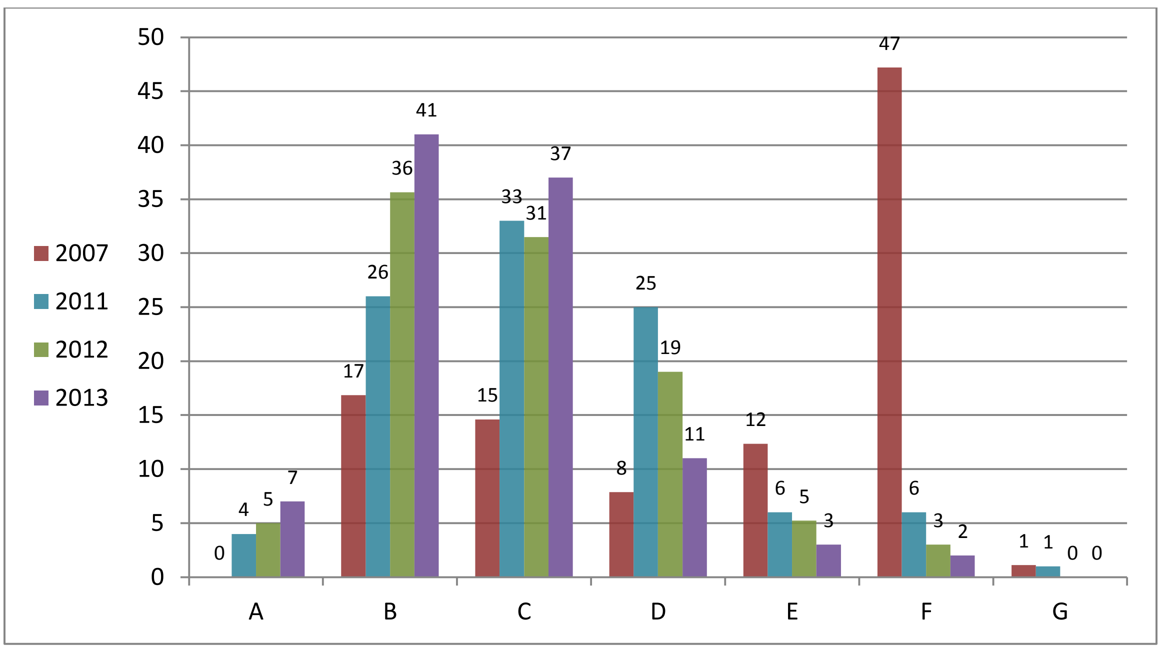
Energy Efficiency Rating

Since 2005 the Energy Conservation Division certifies every year the refrigerators models. A certification and label then issued to indicate the rate for each model. The impact of the project is well seen as the distribution of refrigerators by their rating is moved toward the “B” rating. At 2012, out of 645 models, 73% of the approved refrigerators were rated “A” “B” and “C”. In 2007, out of 89 models, only 36 percent were rated “A” “B” and “C”.

Table 1: Percentage of certified refrigerators, by energy efficiency rating, years 2007 and 2011-2013

Energy efficiency rating	Average annual consumption (For adjusted 500 liter)	Average annual consumption (For 500 liter)	2007	2011	2012	2013
A	082	402	0	4	5	7
B	072	600	17	26	36	41
C	767	705	15	33	31	37
D	407	784	8	25	19	11
E	606	879	12	6	5	3
F	487	870	47	6	3	2
G	607		1	1	0	0

Figure 1: Certified refrigerators, by energy efficiency rating and year



The data in figure 1 reflects the change in the consciousness of consumers, regarding to energy efficiency. The consumers go toward the energy efficient appliances (refrigerators rated A and B). Following the consumers’ requests, the suppliers’ requests, seeking to please the consumers, are to approve more and more A and B rated refrigerators.

The exception value in 2007 - Licensing 47% F-rated refrigerators - is due to toughening the energy rating that year. Changing the standards automatically decreased the rate for many refrigerators models to F.

The effect of the projects held on 2012 is notable. In one year, the weight of requests for B rated refrigerator have grown much higher (from 26% in 2011 to 41% in 2013).

Table 2: Number of certifications by energy efficiency rating (2007-2013):

Energy efficiency rating	Number of certifications
A	64
B	441
C	454
D	287
E	73
F	54
G	4
Total refrigerators approved:	**1,377**

Refrigerators' Energy Consumption

Compared with refrigerators approved before the changes in the regulations, the electricity consumption per adjusted liter fell by 65%. Following the tender requirements, the refrigerators consumption per adjusted liter decreased more by 20%. Refrigerators authorized and purchased under the projects have adjusted consumption average of 0.0020 kWh (small - 0.0022 kWh/liter, medium - 0.0020 kWh/liter and large - 0.0018 kWh/liter).

In 2007 most of the requests were to approve large refrigerators. The average energy consumption per adjusted liter for small refrigerators was the highest and reached 0.0049 kWh. The reduction in energy consumption for the refrigerators in 2012 is 14% for small size refrigerators, 28% for middle size and 25% for large refrigerators.

The Projects

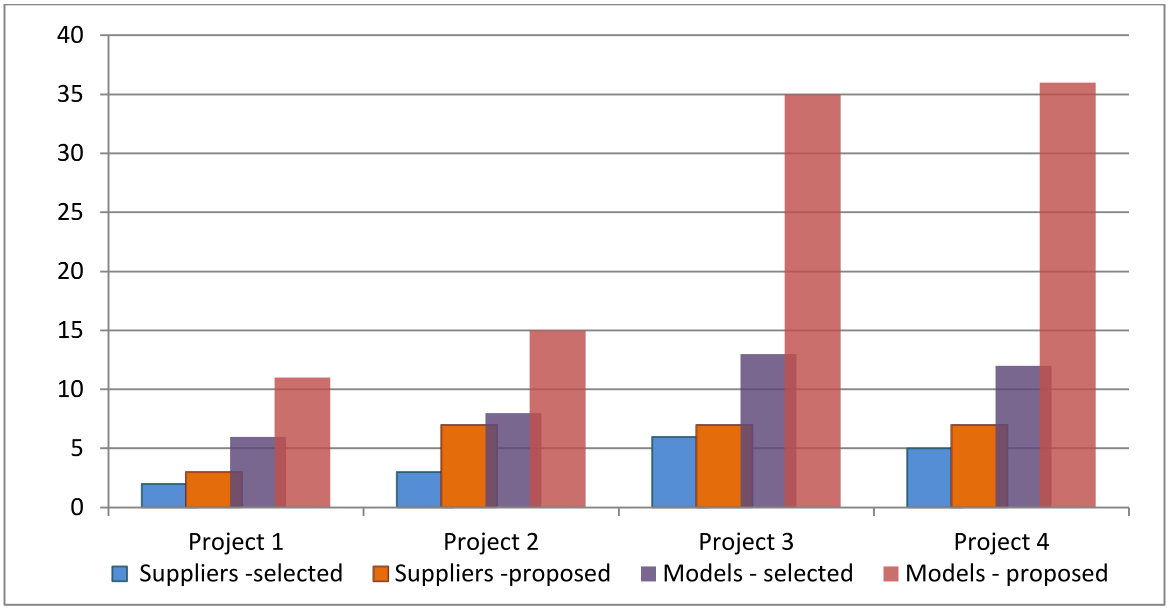
The projects of The Ministry of Energy and Water Resources to assist households, replacing inefficient appliances started at the end of 2011 and continued during the year 2012. All refrigerators that were authorized under these projects have energy rating "B" (A is most efficient).

The first project was aimed for disadvantaged population with a subsidy of 60% for replacing the old inefficient refrigerators with the new efficient ones. The refrigerator for replacement had to be in working condition, bought before 2005 and with a volume at least 300 liter. During this project, 22,245 refrigerators were replaced in less than one week.

The second and third project, of old refrigerators replacement, addressed the entire population with a subsidy of 30% subsidy. The conditions for the old refrigerator were the same as in the first project. About 50,000 refrigerators were replaced in the second project and already about 40,000 were replaced during the third and still ongoing project. In all projects the consumer had to give up his old refrigerator, to be sent to a scrapping site, authorized by the Ministry of Environmental Protection. According to the national energy efficiency program the estimated savings through the refrigerators projects, was supposed to reach 137,000,000 kWh a year. With a total of 125,000 old refrigerators replacement the estimated amount is higher and comes up to 156,250,000 kWh a year, a reduction of 114,348 tons in carbon dioxide emissions. Considering lifetime of 10 years for a refrigerator, we will have a total direct saving of 1,562,500,000 kWh.

Refrigerators Supply

Figure 2: Number of suppliers and models, by project



In order to be an authorized supplier within the projects, suppliers were required to meet a number of conditions, including low prices and low electricity consumption of refrigerator (given volume of refrigerator).

As shown in figure 2, number of suppliers has grown with projects as well as the number of models. In the first project, 2 out of 4 suppliers, and 6 out of 11 models, were approved to distribute and be distributed, under the project. In the second project, 3 suppliers and 8 models, and in the third project out of 7 suppliers and 36 models, 13 models were approved to be distributed by 6 suppliers.

The Increased number of bidders (suppliers) shows that the project is considered credible in the eyes of the population and does bring the buyers to stores.

In the year, 2012 the number of refrigerators sales reached 380,000 while in previous years the average number of refrigerators sales was 250,000. The increased number of sales, along with attractive prices, under the projects, affected the entire refrigerators market, and prices for similar refrigerators fell in about 45%. The stores raised the discounts flag on subsidized refrigerators, added more discounts for refrigerators that weren't included in the projects and offered removal and transportation as part of the deal.

In the fourth and upcoming project to replace more inefficient refrigerators for the disadvantaged famillies 13,000 refrigerators will be replaced.

Population's Participation

At the beginning of the projects the participation was high and most of the refrigerators were purchased. As shown in figure 3, the middle size refrigerators were first to sell.

Figure 3: Refrigerators sales, by month and size

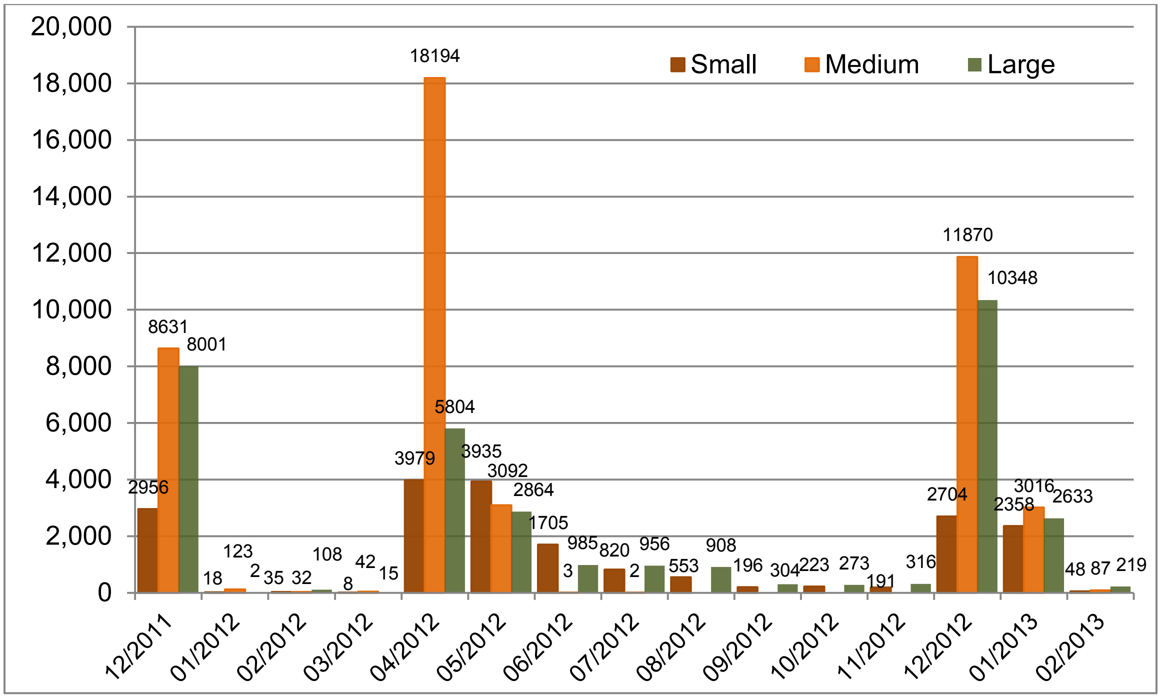


Figure 4: Refrigerators sales, by age of consumers and size of refrigerators (percent)

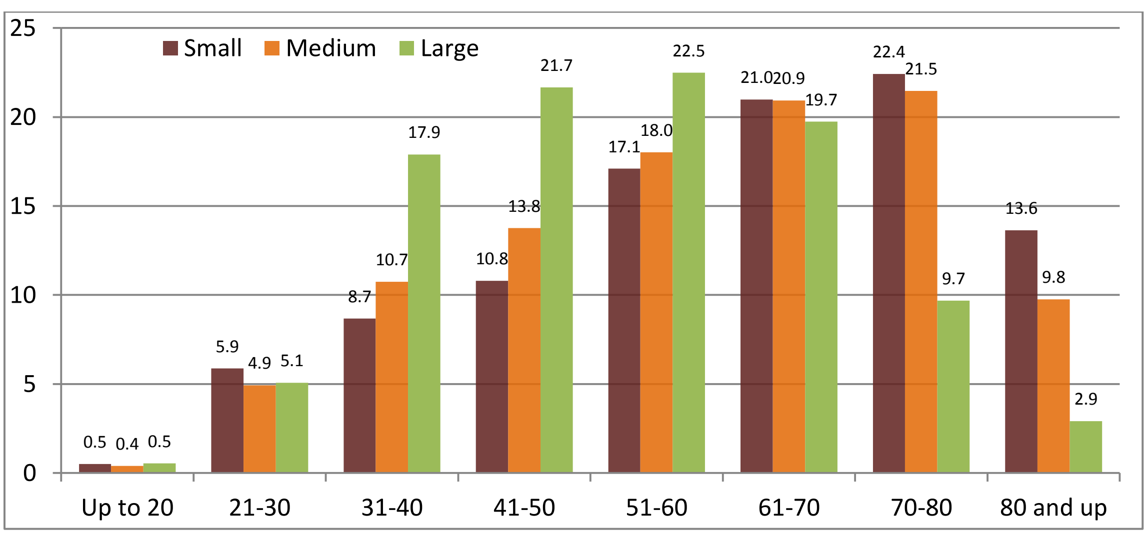

As shown in figure 4, up to 70 percent of the consumers, participating in the projects, were at the age of 50 years and older. Consumers ages 31-60 prefer large refrigerator, while consumers over 60 prefer the small and middle sizes.

Projects' cost

Table 3: Quantity and Government subsidy ($[1]) by population and refrigerators' size

Size group	Disadvantaged population		Entire population A		Entire population B		Total	
	Quantity	subsidy	Quantity	Subsidy	Quantity	Subsidy	Quantity	Subsidy
Small	3,029	1,089,627	12,352	2,718,418	9,247	2,197,509	24,628	6,005,554
Medium	9,077	4,521,437	21,327	5,796,475	19,434	5,235,417	9,838	15,553,329
Large	8,139	4,046,770	14,483	4,237,467	14,692	4,830,172	37,314	13,114,409
Total	20,245	9,657,834	48,162	12,752,360	43,373	12,263,098	111,780	34,673,292

Subsidy, the main component of the project cost is already 34,673,292$. Along with the cost, there are the savings that will come up to 700,483,570 NS (190,193,750$, calculated for 10 years).

Electricity Savings

Other than direct saving in electricity there are many other benefits in energy efficiency. The benefits include savings in energy and storage cost, saving water and fuel, used to produce electricity and savings in cost of emissions. Energy savings can, also, lead to a decline in demand and lower prices that can boost the economy, increase employment and energy security.

However, it is difficult to translate these benefits to money. Using energy efficient appliances, we save not only in kWh but also in other elements that are not necessarily connected to electricity.

The direct electric energy saving achieved from carrying out the projects, for a single year, comes to 117,787,719 kWh (As of June 2013).

Table 4: Savings in electricity and money, by refrigerators' size[2]

Size	Yearly saving (kWh)	Yearly saving (NS)	Yearly saving ($)
Small	27,805,320	16,535,824	4,489,770
Medium	52,163,139	31,021,419	8,422,867
Large	37,819,260	22,491,114	6,106,737
Total	117,787,719	70,048,357	19,019,375

The savings in electric energy, since 2005, are much greater, considering the new regulations along with the projects of replacing appliances.

The direct kWh savings were calculated as follow:

Saving kWh = $\sum(Co-Cni)*365$

Co – Daily consumption of old refrigerator

Cn - Daily consumption of new refrigerator

[1] According to exchange rate of 3.683, from May 31, 2013
[2] Savings were calculated according to ICE's 2013 rate for residential sector, 0.5947 ns per kWh (including VAT).

i – 1… 111,780 Refrigerators

Review of Regulations

The effectiveness of the regulations (which refer to electrical appliances used by the residential sector[3]) will be reviewed in accordance with the following parameters:

- The maximum electricity consumption required for an electric appliance according to the present regulations.
- The average electricity consumption of an electric appliance which has either been imported or manufactured in Israel during the last years.
- The average electricity consumption of new models of an electric appliance, which were authorized by the regulations during the last years.

In the near future

In the coming months several more projects will be implemented: replacement of air conditioners for the entire population; replacement of old refrigerators for disadvantaged populations and replacement of electric water heaters with solar water heaters for the entire population, as well as projects for the other sectors. Projects as chillers replacements or increasing energy efficiency will be promoted.

Bottom-up scenario calculations for 10 world regions reveal worldwide efficiency potentials of about 50 % for refrigeration and washing

Claus Barthel, Thomas Götz, Antoine Durand, Lena Tholen

Wuppertal Institute for Climate, Environment and Energy, Germany

Abstract

Domestic refrigerators, freezers and washing machines are among the most widely used electrical appliances all around the world. Currently, about 1.4 billion domestic cold appliances and 840 million washing machines worldwide use about 740 TWh electricity, which is more than Germany's total electricity consumption, cause CO_2eq emissions of 500 million tons and use 19 km^3 of water a year.

Although the specific electricity consumption per volume of cold appliances or per kg laundry in washing machines has decreased during recent years due to technical progress, total worldwide energy consumption of these appliances is on the increase.

In the framework of a new website "bigEE.net - Your guide to energy efficiency in buildings", which aims to provide information about technical options but also about policies to support the development of energy-efficient appliances, bottom-up scenario calculations were carried out for all 10 IPCC world regions by the Wuppertal Institute. Results show that about half of the specific energy consumption could be saved with the most energy-efficient appliances available today, and even higher savings will be possible with next generation technologies by 2030. According to the model, these savings are usually very cost-effective. The scenario results and policy strategies to address these potentials will be presented in this paper.

Introduction

Domestic refrigerators, freezers and washing machines are among the most widely used electrical appliances in the residential sector all around the world, contributing significantly by their electricity consumption to the greenhouse effect. Therefore political instruments focus on the introduction of labels, minimum energy performance standards (MEPS) or subsidies in order to improve the efficiency of appliances on the market. In addition, washing machines are related to water consumption, which could cause problems in regions of the world with drinking water shortages.

This raises the question of how high the worldwide electricity and water consumption of household appliances in the different regions of the world is today and how the number of devices and their consumption per unit and so their total consumption for cold appliances and washing machines will develop in the future in the business as usual case.

It is well known from international appliances databases like "Topten" (www.topten.info), which present the most efficient appliances worldwide, that significant differences in consumption between the average and the most efficient appliances exist. Based on this, the questions arise, what is the saving potential if only the most efficient appliances are purchased and what kind of policies and policy instruments are required for such a market transformation.

Distribution of current worldwide electricity and water consumption of domestic cold appliances and washing machines

Distribution of current worldwide electricity consumption of domestic cold appliances

Country specific bottom-up analysis – based on several sources[1] all around the world – shows that currently 1.4 billion refrigerators, fridge freezers and freezers are in use in households. The average electricity consumption of these cold appliances amounts to about 450 kWh per year and appliance. With an annual total electricity consumption of 650 TWh, they account for almost 14 % of the electricity consumption of the residential sector and cause worldwide annual greenhouse gas emissions of 440 million tons of CO_2eq.

Thereby, the distribution of domestic cold appliances varies widely between the different world regions. In North America (NAM), Western Europe (WEU) and Pacific OECD (PAO) about 1.7 people own one cold appliance, whereas in other world regions the level of ownership is still well below saturation (see figure 1). This is expected to change significantly in the future, especially due to the booming markets in Asia (CLASP / LBNL 2007).

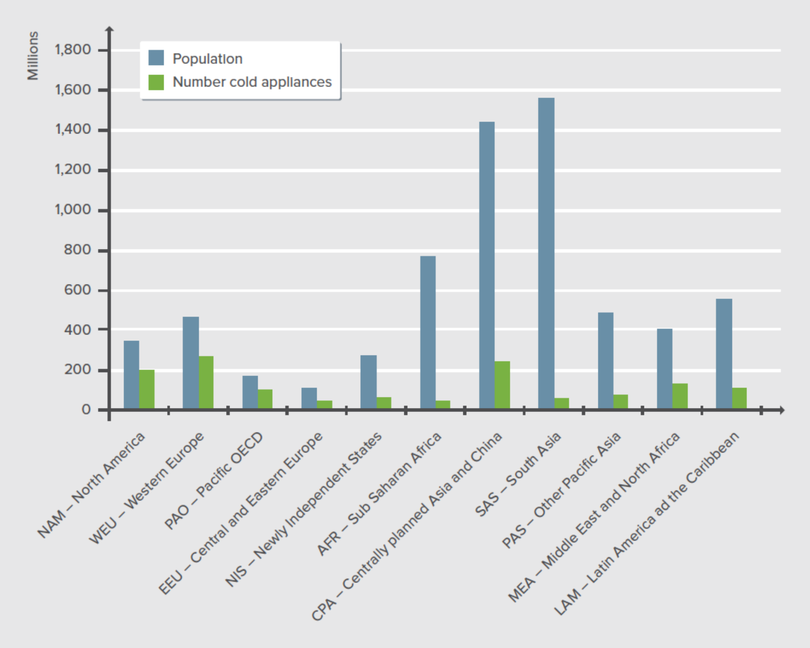

Figure 1: World population and number of cold appliances in the different world regions according to IPCC systematic in 2010. (Reference: Own calculation based on WEC 2009, IEA 2010 and other reports)

The worldwide uneven distribution of domestic cold appliances as well as their different size and efficiency levels lead to large differences in electricity consumption of this group of appliances in different world regions.

Distribution of current worldwide electricity and water consumption of domestic washing machines

The country specific bottom-up analysis for washing machines[2] shows that about 840 million domestic washing machines are in use worldwide. The average annual consumption of each of these washing

1 IEA 2010, WEC 2009, Department of the Environment, Water, Heritage and the Arts 2008, Hollanda 2010, Schaeffer 2008, Vendrusculo 2008, Natural Resources Canada 2010, Fridley 2007, 2008, Lin 2006, Lu 2006, Bertoldi 2006, Ademe 2009, Presutto 2007, Qader 2009, Hagan 2006, The World Bank 2006, 2008, 2009, De la Rue du Can 2009, Letschert 2007, Murakami 2009, Cabanas 2009, WECS 2010, Ministry of Economic Development 2010, Foran 2010, DOE 2009

2 Based on data by Pakula / Stamminger (2010) and other available reports (e.g. AATCC 2011, ACEEE 2011, Berkholz et al. 2006, Biermayer / Lin 2004, Faberi et al. 2007, GfK 2011, Josephy et al. 2011, RECS 2009, IEA-4E 2011)

machines amounts to about 110 kWh of electricity and 23 m^3 of water. With an electricity consumption of 92 TWh per year, they account for about 2 % of the total electricity consumption of the residential sector worldwide. Annually, washing machines also consume about 19 billion m^3 of water and cause worldwide greenhouse gas emissions of 62 million tons of CO_2eq.

Thereby, the distribution of domestic washing machines is very uneven between different world regions. In the world regions NAM, WEU and PAO, on average 2.9 to 4.4 people own one washing machine (see Figure 2). In other world regions the level of ownership is still well below saturation. For example in Sub Saharan Africa (AFR), there is on average one washing machine per 125 persons. However, this is also expected to change significantly in the future, especially in the booming markets in Asia (CLASP / LBNL 2007).

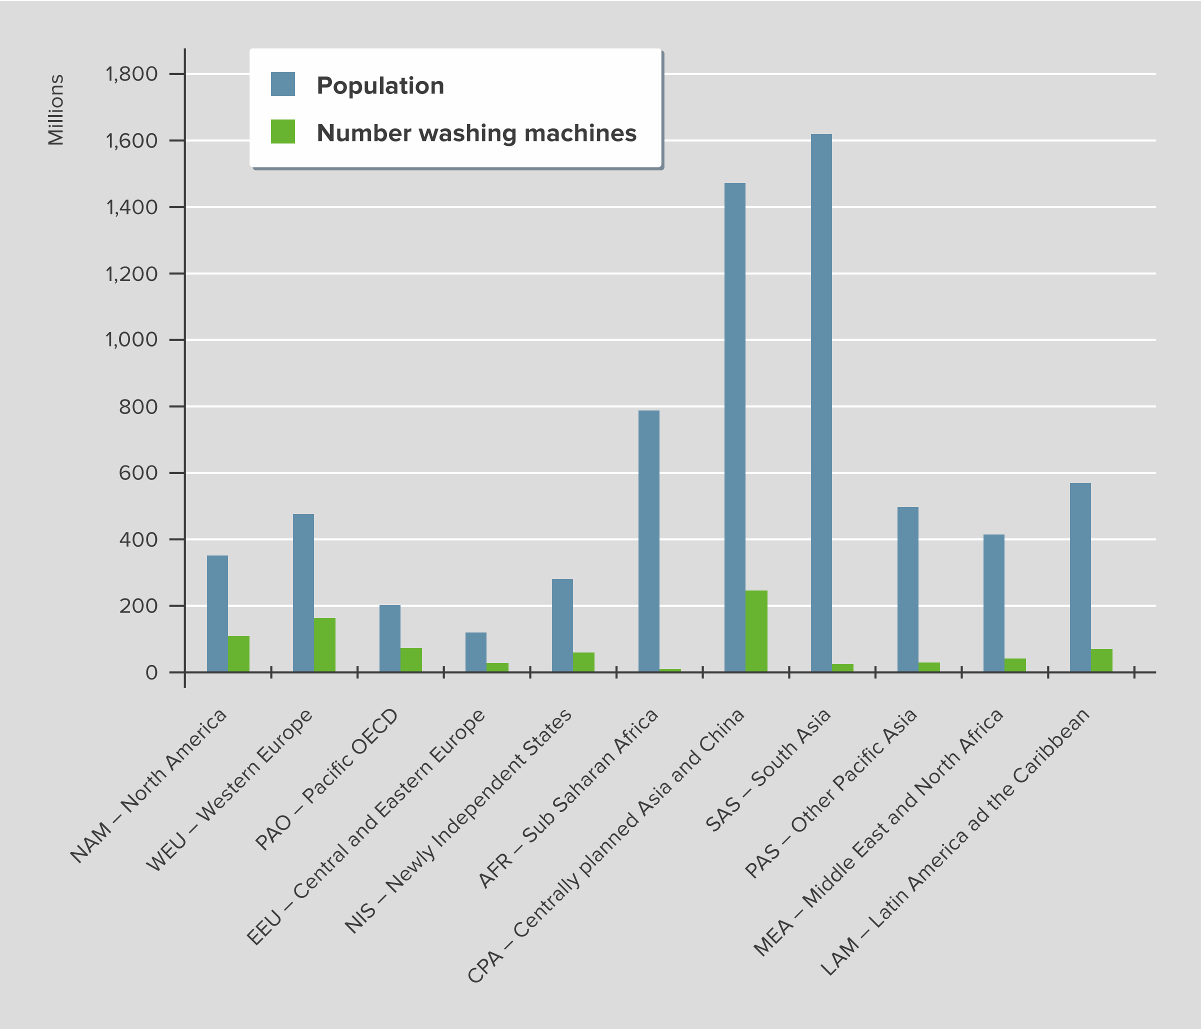

Figure 2: World population and number of washing machines in the different world regions according to IPCC systematic in 2010 (Reference: Own calculation based on IEA, Pakula / Stamminger (2010) and other reports)

The uneven distribution of domestic washing machines worldwide, different types of machines (different technologies like horizontal and vertical axis washing machines) and their various efficiency levels, as well as different wash habits and practices (e.g. wash temperatures, number of wash cycles per year) lead to substantial disparities in electricity and water consumption within the different world regions.

Types of automatic washing machines, main features and geographical distribution

While the technology for refrigerators, fridge freezers and freezers does not vary significantly worldwide, domestic washing machines can be assigned to two different main categories:

- Horizontal axis machines

In horizontal axis machines (Figure 3), only the bottom of the washtub is filled with water. Compared to vertical axis machines, significantly less water per wash cycle is used. Horizontal axis machines are commonly equipped with an internal electric water heating system. Hence, the energy consumption heavily depends on the chosen washing temperature. Modern washing machines with horizontal axis technology have an automatic load sensing function in order to reduce water and electricity consumption in response to consumer loads that are smaller than the rated capacity. Horizontal axis machines are gaining market shares in almost all markets worldwide (Pakula / Stamminger 2010).

Figure 3: Horizontal axis washing machine, front loader configuration. Source: iStockphoto (2013)

- Vertical axis machines

Traditionally, the tub of vertical axis machines (Figure 4) is entirely filled with water. Although most modern vertical axis machines also have automatic water level settings or the user can set the water level manually, even present-day machines often consume about twice as much water per wash cycle as horizontal axis machines. Vertical axis machines are usually not equipped with an integrated electric water heating system, but warm washes can be done by using hot water from external sources. This additional energy needed to heat up water from the tap is hard to estimate, because it can be done by electricity or other energy sources like gas, coal, oil or solar power (Pakula / Stamminger 2010). Vertical axis machines are still most widespread in America, Australia and Asia.

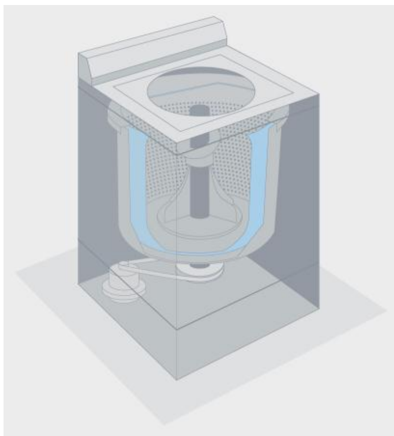

Figure 4: Vertical axis washing machine (Agitator type). Source: own illustration (www.bigee.net 2013)

Within these two basic categories, appliances vary in their configurations and the range of options. The most common types of automatic washing machines worldwide are:

Horizontal axis, front- or top loading washing machine (also known as "front-loader" or "drum type" machines).

These machines show large energy- and water savings when comparing most efficient to inefficient average models on the market, especially in Europe as such washing machines are most popular in this region. Additionally, the share of horizontal axis machines is also steadily rising in most other markets worldwide. Switching from vertical axis to horizontal axis machines offers another important water and energy saving potential, because horizontal axis machines usually consume significantly less (pre-)heated water per wash cycle than vertical axis machines.

In a horizontal axis washing machine, the textiles are placed in a horizontal drum and partially immersed in the washing water. The mechanical action is provided by the rotation of the drum about its axis. The drum is accessible from one single door on the front (front-loader configuration) or from several adjacent doors on the top of the machine and the drum (top-loader configuration). Many traditional horizontal axis machines have a minimum program temperature of 30°C, which means that these machines use electricity to heat up water even in the coldest program selectable (Pakula / Stamminger 2010). Since the introduction of high efficient low-temperature detergents, many contemporary washing machines have been equipped with 20°C, 15°C and “cold wash” programs to reduce the energy consumption significantly.

Horizontal axis drum type washing machines are used mainly in WEU/EEU, and increasingly in most other markets (Pakula / Stamminger 2010).

Vertical axis, top loading agitator washing machines

This type of washing machines shows large energy- and water savings compared to inefficient models on the market, especially in North- and Latin America, as such washing machines are popular in these regions. If cold water is used, the energy consumption per wash cycle is low. But although the majority of washing machines in North America are vertical axis machines without internal heating system, the average washing temperature is reported to be at about 30°C, which causes an electricity consumption of about 0.43 kWh per wash cycle (Pakula / Stamminger 2010). This might include warm water from the tap and thus energy from external resources, which are hard to quantify.

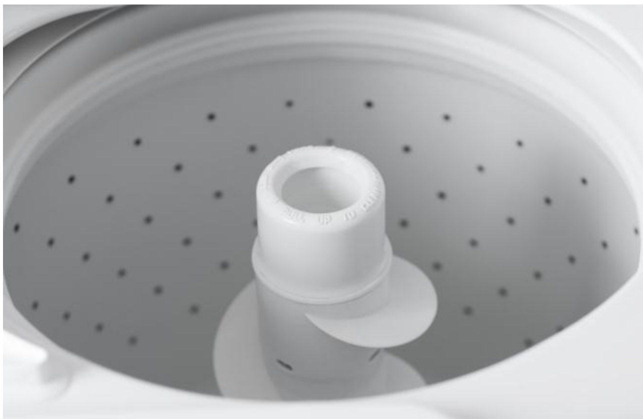

Figure 5: Vertical axis washing machine, agitator. Source: iStockphoto (2013)

Vertical axis, top loading impeller washing machines

These machines show large energy- and water savings compared to inefficient models on the market, especially in Asia (China, South Korea, Japan) and Australia as such washing machines are popular in these regions. The mechanical swirl-action is produced by a device, which is named by most manufacturers as ‘impeller’, rotating about its axis (Figure 5). During operation, the uppermost point of this device is substantially below the minimum water level (Faberi et al. 2007). This type of washing machines is traditionally designed as top-loading device (accessible from one single door on the top). If cold water is used, the energy consumption per wash cycle is low. However, although vertical axis impeller machines are usually not equipped with an internal water heating system, the usage of preheated water from external sources through a separate hot water inlet is commonly possible and is often reported (Pakula / Stamminger 2010).

Figure 6: Vertical axis ‘high-efficiency’ washing machine, Impeller, Source: iStockphoto (2013)

Occasionally, impeller-type washing machines are also referred to as “high efficient washers” (especially in North America) due to an improved washing process and a reduced water usage compared to inefficient agitator-type models. Nevertheless, a higher usage of bleach and other detergents, as well as washing treatments with relevant amounts of water and energy outside the washing machine may indicate only a mediocre level of washing performance provided also by these machines.

Techno-economical saving potentials

Description of the model calculations

The bottom-up model used for the purposes of this paper is a simplified version of the DEESY Stock Model developed by the Wuppertal Institute, which assesses scenarios with focus on energy and water consumption as well as costs[3]. According to the development of the stock volume[4] and the typical lifetime of an appliance (15 years for cold appliances and washing machines), the model calculates the per-annum market volume for each year of the covered scenario time period (2010 to 2030), including the first-time acquisition as well as the replacement of end-of-life appliances. The techno-economical characteristics of the typical product purchased in a certain year are dependent on the Base Case and Best Available Technology (BAT) available at the time of purchase and on a weighting factor reflecting the level of energy efficiency for the respective scenario. Future BAT technology, named BNAT (best not yet available technology), is becoming more efficient in terms of electricity and water consumption each year and is regarded in the model as well as additional costs for these product improvements. The modelling of the historical appliance stock purchased within the 15 years in advance of the covered scenario time period (1995 to 2009) is essentially based on the same methodology. However, the development of these preceding years is additionally calibrated for the base year (2010) to meet the expected stock volume in this year[5].

In order to assess the techno-economical saving potential of the most efficient appliances, subsequently two scenarios are compared: a Baseline[6] scenario, in which Base Case products have 100 % market share after 2010, and an Energy Efficiency scenario, assuming a 100 % market share of BAT products. The characteristics of the Base Case and BAT products are based on the country specific bottom-up analysis, which was performed as preparatory work for the modelling. Account has been taken to different regional economic and market specific conditions. Consequently, the savings in terms of energy, water and costs depend on the year and the world region considered respectively.

Results for domestic cold appliances

As the results from the model calculations show, large efficiency improvements can be achieved globally if the most energy-efficient appliances available on the market are systematically purchased instead of standard technologies. Despite the expected 27 % increase of the worldwide cold appliance stock in use by 2020 and the 62 % increase by 2030, the annual electricity consumption of domestic cold appliances could be reduced from 650 TWh in 2010 to 475 TWh by 2020 and to about 400 TWh by 2030 (see Figure 7) with the best available technologies on the market. The potential would be even larger and achieved faster if old and inefficient cold appliances would be replaced and recycled before they have reached the end of their technical lifetime.

The analysis also shows that the electricity consumption of domestic cold appliances per unit varies very much between the different world regions. As this consumption is not proportional to the typical appliances size in the respective region it can only be explained by different efficiencies.

---

If every time a domestic cold appliance is purchased in the efficiency scenario, the most efficient model is chosen instead of a standard model, 240 TWh of electricity and 158 million tons of CO_2-eq can be saved per year in 2020. Moreover, in 2030, even 360 TWh of electricity and 235 million tons of CO_2-eq can be saved per year. Based on the assumptions of the performed model calculation[7], over the whole lifetime of the energy-efficient refrigerators and freezers purchased until 2030, the total economic benefit (discounted) is 193 billion EUR[8] for end-user perspective and 105 billion EUR for societal perspective. However, the actually achievable savings are dependent on varying investment costs and electricity prices in the different world regions. For example, the incremental investment costs for BAT could be very low in countries where already high efficiency standards are established and high where no market and no manufacturer of efficient cold appliances exist.

Therefore, regionally optimized policy measures and programs have to address this technical efficiency improvement potential under consideration of cost-effectiveness for society as well as for end-users.

Results for washing machines

In order to assess the techno-economical saving potential of the most energy and water efficient washing machines, an identical approach to the domestic cold appliances has been followed. This also includes a comprehensive country specific bottom-up analysis and the same two-scenario comparison based on a typical lifetime of 15 years for washing machines.

As the results from the model calculations show, large efficiency improvements can be achieved globally if the most energy and water efficient washing machines available on the market are systematically purchased instead of standard technologies. By this means, a relative decoupling of the growth of the worldwide annual energy and water consumption and the increasing stock of domestic washing machines can be achieved. While the stock is expected to grow by 36 % until 2020, in the efficiency scenario the energy consumption would only increase by 12 % and the water consumption by 5 %. Although the stock is expected to grow by another 26 % until 2030, the increase of the energy and water consumption would be limited to half of that value (13 %), each for energy as well as water consumption (see Figure 8 and Figure 9). Thereby, higher living standards, represented by increasing appliance ownership rates, a more frequent usage of warm wash cycles as well as a technological change towards more water efficient horizontal axis washing machines already have

[7] Presuming an average worldwide electricity price for all world regions.

[8] For the purposes of the model calculation, all monetary figures are provided in EUR 2010

been anticipated. In contrast, in the baseline scenario, the energy and water consumption would increase by 43 % and 15 % by 2020 and additionally by 35 % and 18 % by 2030.

If every time a washing machine is purchased, the most energy- and water-efficient model is chosen instead of a standard model, 31.5 TWh of electricity, 2.2 billion m^3 and 20.8 million tons of CO_2-eq can be saved per year in 2020. Moreover, in 2030, even 65 TWh of electricity, 3.6 billion m^3 of water and 42.4 million tons of CO_2-eq can be saved per year.

Policy strategies to address the potentials

The previous section has illustrated the possible energy savings of refrigerators and washing machines worldwide and in different world regions. This means that energy efficient appliances can bring large energy savings, while providing the same or better service. The energy efficiency efforts do not only achieve high energy saving potentials. CO_2 emissions can also be reduced cost-effectively from a life-cycle perspective and thus provide economic benefits. Furthermore, several other co-benefits like energy security, health and increased competitiveness can be realised. By offering innovative products this can open up new (niche) markets, which will likely have a positive effect on the economy as a whole. Co-benefits increase social and/or individual welfare and come as a free add-on to the direct benefits of energy efficiency for investors.

However, there are still lots of inefficient appliances available on the market and market forces alone are often unlikely to bring a very high energy-efficient market development about (Sorrel et al. 2004; Thomas 2007). There are various barriers to manufacture, sell or buy energy efficient products that hinder a market transformation towards energy efficiency. All elements and levels of the appliances value chain have their own and specific characteristics. Financial, knowledge and technical barriers as well as lack of interest and the investor-user dilemma are some of the major reasons why there is a gap between the saving potentials and the energy savings actually realised by markets alone (Thomas 2006; IEA 2008).

Policy is needed to overcome these respective barriers and to exploit the existing potentials. Policy-makers have to intervene and develop adequate strategies to change this market development. The overall goal for policy makers should be to move the market towards to the best available technology and perspectively to the best not yet available technology (BNAT) with very high energy efficiency levels. Almost half of the energy saving potential could be achieved from the worldwide adoption of the most stringent energy efficiency regulations. Furthermore there are lots of energy efficiency technologies, which are already far beyond existing regulations, so the other half of the potential lies in reaching this “best practice” level. This emphasises that energy efficiency policy is incomplete. Even in economies that already have policies requiring or promoting high energy efficiency levels, significant savings are possible. Where requirements are limited, the savings from accelerated adoption of leading policies would stimulate much larger savings (Wuppertal Institute 2012).

Therefore, it is highly advisable for policy makers all over the world to pay attention to the large potentials and to energy efficiency improvements. It is important to abandon the prevailing approach of ‘as-fast-and-as-cheap-as-possible’ because it will be wasting vast amounts of energy and money throughout their lifetime. To tap this tremendous potential, appropriate and integrated packages of policies and measures are necessary, supporting very efficient appliances.

The first step is to pay attention to every actor in the value chain. By knowing the barriers and incentives of each type of actor, the policy package can be adapted to guarantee desired results and achieve the greatest possible energy savings. In order to be able to adequately design and implement energy efficiency policies and measures, political decision makers must have good knowledge of the concerned market actors and thoroughly analyse the specific incentives and barriers faced by each of them. These market actors are for instance manufactures, whole sales, retailers, investors and users. All of these actors make decisions that can influence the energy performance of appliances in question.

The second step concerns the following question: How can the incentives that market actors have be strengthened, and how can the barriers be overcome. Experience from pro-active countries and an analysis of market barriers show that several instruments need to interact and reinforce each other in a comprehensive policy package (cf. next box). Every policy measure is tailored to overcome one or a few of the mentioned market barriers, but none can address all these barriers (Tholen & Thomas 2011). The impact of well-combined policies is often synergistic i.e. the impact of two or more instruments is often larger than the sum of the individual expected impact. Therefore different policies addressing the demand- and supply side of markets should be properly combined according to regional circumstances. As pro-active countries have demonstrated, a comprehensive and coherent policy package for energy efficiency will usually provide a sound balance between clear ambitious mandatory measures, incentives, information and capacity building. It also needs a governance framework to enable implementation of these policies.

This governance framework includes a concrete and ambitious roadmap, an organisation to design, implement and monitor the policy (like an energy agency), and an independent test procedure. Furthermore a compliance system, and financial mechanisms such as Energy Saving Obligations and Energy Efficiency Funds to realise a successful implementation of specific policies in this package are needed. These specific policies are the following:

Legal provisions on minimum energy performance standards (MEPS) reduce search and transaction costs and partly overcome the investor-user dilemma. They are a cost-effective way to eliminate the segment of the worst energy-performing products from the market. However, they do not harness additional savings potentials due the most energy-efficient products in such cases. Therefore, appliance standards are often combined with labelling and rebates in order to give incentives for investments beyond the level required by the MEPS. Financial or other incentives can give the decisive push that makes people opt for the more energy-efficient investments. In addition, financing instruments such as soft loans can be needed to overcome potential incremental costs for BAT products and to enable investors to make more sustainable upfront investments.

To pull the market even more into an energy efficient direction, information programmes, trainings for sales staff and manufacturers, and especially procurement programmes can influence the market to promote energy efficient appliances. With procurement programmes but also with bulk purchasing projects and competitions it is even possible to go beyond the best available technology and to support a market development towards BNAT with very high energy-efficiency levels.

This general description of a comprehensive policy package should be adapted to national circumstances and to specific appliances. Each appliance and each market has its own specificity and the barriers as well as incentives for the market transformation are also diverse. Therefore the package must be adapted to specific circumstances of single product groups. For examples refrigerators have several specialities like the high energy and cost saving potentials as well as many differing technical characteristics (volume and additional features like climate class, built-in appliance, free-standing freezer, ‘no-frost’ function, etc). Policy makers should pay attention to all these factors and create policy packages that reach the desired results.

The next box shows how China has implemented an overall policy package to influence the market development of refrigerators and freezers. In some areas China is very successful with its policy package and is on a good way to promote energy efficiency.

China achieved a substantial transformation towards higher energy efficiency in the refrigerator market using a policy package adapted to its national conditions. Along with the rapid economic growth of the country in recent years, the sales figures of appliances also increased. The sales figures of top-rated energy-efficient refrigerators skyrocketed from 360,000 to 46 million units in nine years (from 1999 to 2008). In light of this development, it must be a top priority to the government to phase out the production of the least efficient products while promoting sales of highly efficient ones. Population size and increasing prosperity make China a highly attractive market for appliance manufacturers. This makes energy efficiency policies in the country even more important as policies can have huge impacts on greenhouse gas (GHG) levels. Moreover, China is regarded as the world’s workbench. Thus, policy makers can implement regulation targeting the production process of appliances directly. Due to this situation the Chinese government introduced a comprehensive policy package to increase the energy efficiency of appliances.

The 11th Five-Year plan (FYP) was established in 2005 and aimed at reducing energy intensity by 20% up to 2010. For the exemplary product group refrigerators, this meant that their average energy-efficiency indicator was to be reduced to between 62% and 50% by 2010, meaning they would be in the two most energy-efficient classes of the energy label (Zhou et al. 2010, p6442). According to results mentioned in the National 12th Five Year Plan, the actually achieved energy conservation and GHG emission reduction was 49%. The 12th Five-Year plan for 2011 to 2015 targets a total energy and carbon intensity reduction by 17%.

China has committed to achieving these goals through different measures. There has been a minimum energy performance standard (MEPS) since 1990 in order to eliminate very inefficient models from the market. The standards are mandatory, but compliance is sill a big issue and needs to be targeted (Zhou 2010). In addition to this MEPS regulation a mandatory comparative energy labelling system (CELS) was established in 2005. The label is based on the coloured arrows design of the European Union’s appliance energy label. However, it uses number 1 to 5 instead of characters A to G. The rating goes from grade 1, which counts for refrigerators having an energy consumption of at most 55% of the MEPS and goes over grade 2: 55-65%, grade 3: 65-80%, grade 4: 80-90%, to grade 5: 90-100%. The mandatory label uses the MEPS as a reference point for the thresholds. Refrigerators not meeting the MEPS will not be labelled, nor even produced (Fridley 2008, p. 6 f). This mandatory label provides market transparency on the energy efficiency of appliances to consumers.

Furthermore, China introduced a voluntary endorsement label, and refrigerators will only be provided with it, if they have an energy performance of at least a grade 2 level of the energy information label. To inform the consumers about the labels and energy efficiency in general several information and education campaigns were implemented. The energy efficiency information week takes place annually and focuses on different themes. A consumer education programme has focused on awareness raising towards energy efficient refrigerator advantages and the willingness of purchasing them. Assistance was also granted to engineers from refrigerator manufacturers who received training in international technology options. The international organisation, Top10 China, establishes an internet-based platform to provide independent and up-to-date information on the best available energy efficient products in the Chinese market.

The Chinese government also established a law obliging state agencies and organisations to purchase only energy-efficient appliances. The “Energy Efficient Products For Government Procurement” law tries to raise awareness of higher standards and the benefits of purchasing energy efficient appliances by setting a good example to the people. A series of energy efficiency appliance lists have been submitted by the Ministry of Finance and the National Development and Reform Commission (NDRC), where all appliances covered by that scheme are listed (State Council Office 2007).

Moreover, in 2012, the Ministry of Finance (MoF) has launched a financial incentive programme offering grants for the purchase of energy saving refrigerators (and other appliances) of up to 70-400 Yuan depending on the product size. Consumers receive the subsidies immediately at the retailers. Funding, which totals 26.5 billion yuan (~3.3 billion EUR), has been provided for the period from June 2012 until May 2013.

Conclusion

Within the bigEE project, an extensive data gathering was carried out for domestic cold appliances and washing machines worldwide as well as a modeling work, in order to assess the saving potentials in terms of energy, water, GHG emissions and costs. The results show between 2010 and 2030 a stock increase of more than 60 % worldwide for cold appliances and of about 70 % for washing machines. Consequently, in the baseline scenario, which already includes a moderate efficiency improvement, the electricity consumption is to be expected to rise by 20 % for cold appliances. For washing machines, even an increase of 93 % for electricity and 36 % for the water consumption is expected.

However the modeling has also shown that with existing (BAT) and coming (BNAT) technologies, it is almost possible to halve worldwide electricity demand for both, residential cold appliances and washing machines in comparison to this baseline in year 2030. In the efficiency scenario absolute reductions are possible for cold appliances in all regions, even in developing and emerging regions such as CPA with China, where the stock is expected at least to double within 20 years. One additional outcome of this study is that these electricity savings are cost-effective both for end-users and society.

However, this market transformation towards energy efficient appliances is unlikely to happen itself, therefore policy packages are needed. Within the bigEE-project a new theoretical and empirical foundation has been developed that shows what is a necessary and advisable package of policies for energy efficiency in appliances.

Measuring Electric Energy Efficiency in Portuguese Households: a tool for energy policy

Thomas Weyman-Jones[1]

School of Business and Economics, Loughborough University, UK

Júlia Mendonça Boucinha

Catarina Feteira Inácio

EDP Serviço Universal, Lisboa, Portugal

Abstract: There is a great interest in measuring the efficiency of energy use in households, and this is an area where EDP has done research in both data collection and methodology. This paper reports on a survey of electric energy use in Portuguese households, and reviews and extends the analysis of how efficiently households use electrical energy. In addition, we compare the stratified cross-section analysis with a time-series study to extend our understanding of how to measure energy efficiency.

It is relatively common to model energy efficiency in terms of an energy intensity or electricity intensity relationship with aggregate income or aggregate consumption. A new approach to this problem was suggested by Filippini and Hunt (Energy Economics 2012) [1] in which an econometric energy demand model was estimated to control for the exogenous variables determining the energy demand. The variation in energy efficiency over time and space could then be estimated by applying econometric efficiency analysis to determine the variation in energy efficiency. In this paper we apply this approach to the Portuguese electricity sector in particular. The analysis allows the identification of priority areas for the implementation of measures to enhance electricity efficiency. On the other hand, it is also possible to evaluate the success of the energy efficiency measures, which have been launched by Government and the Regulator, in the recent past.

Keywords: Electric Energy Efficiency, households, econometric efficiency analysis

Introduction and Contribution of this Paper

EDP Serviço Universal has carried out a structured interview and survey of about 3500 Portuguese households that asked about appliance ownership, family income and family size. The sample was stratified by region, subscribed demand categories (kVA) and actual electric energy consumption bands (kWh). The appliance ownership covered space heating/cooling, refrigeration, cooking and washing, and the survey applied to ownership levels in 2008, before the recent economic crisis dominated economic decision making, allowing the sample findings to be relevant to the long term. The survey complemented earlier surveys of the same variables. These data can be used to model the electric energy efficiency of the households in the Portuguese mainland.

The aim of this paper is to show the results from the application of an econometric approach to evaluate energy efficiency to this cross-section data set. The fact that the survey was conducted in 2008 means that the results are illustrative of the analysis that could now be updated with more recent surveys, as consumers' behaviour may have changed in the recent past. The same method

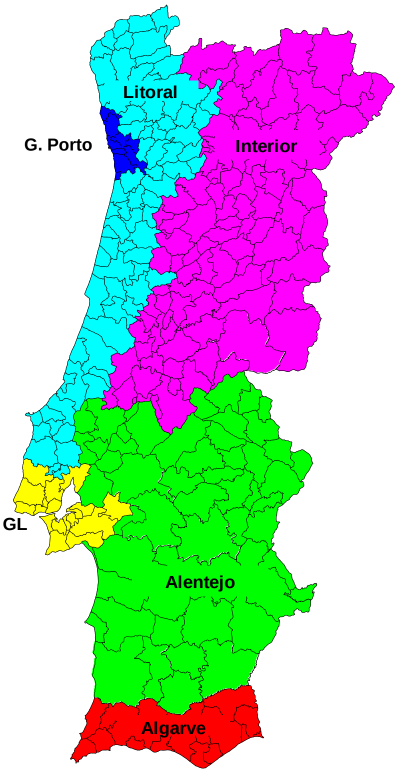
1 Corresponding author - T.G.Weyman-jones@lboro.ac.uk, School of Business and Economics, Loughborough University, Leicestershire LE11 3TU UK, Direct Line: +44 (0)1509 222710, Fax: +44 (0)1509 223910

was applied to a time series data set also collected by EDP on electric energy use in households in Portugal.

This new approach is based on a recent study by Filippini & Hunt (2012) [3] on energy efficiency within the European Union. The paper begins with a review of the datasets collected by EDP, and then moves on to the different ways in which these can be modelled to understand energy efficiency amongst households in Portugal, according to region and subscribed demand, and also over time.

Data sample 1: cross section study of EDP customers in 2008

The first cross section sample, which was collated from interviews with household customers, was based on EDP consumption data for 2006, and it was stratified by region, subscribed demand categories (kVA) and actual electric energy consumption bands (kWh). The following figure illustrates the sample distribution. Interviews took place during 2008.



Region	Subscribed demand kVA	Population Total	Population <500 kWh	Population >=500 <1500 kWh	Population >=1500 <3000 kWh	Population >=3000 kWh	Interviews

Figure 1: Overall number of customers (population) and sample stratification

The data collected includes information on appliance ownership per region and for each selected group of subscribed demand. The following graphs exhibit the same data broken down according to family income and family size. This information is relevant for demand forecasting purposes, as it gives an idea of the saturation levels for the ownership rates in the different appliances. In the case of dishwashing machines, for instance, the rate of ownership of the highest income class (84%) may be used as a proxy for the saturation level, whereas only 40% of the households in the highest income group have clothes´ driers; the comparison with the average (58% and 27%, respectively) shows the potential increase for these appliances. The data also shows that, despite the fact that bigger families tend to have more appliances, families with more than four persons have lower rates of ownership of appliances like the dishwahing machine or electric oven and stove, possibly due to income constraints. The opposite is true for freezers.

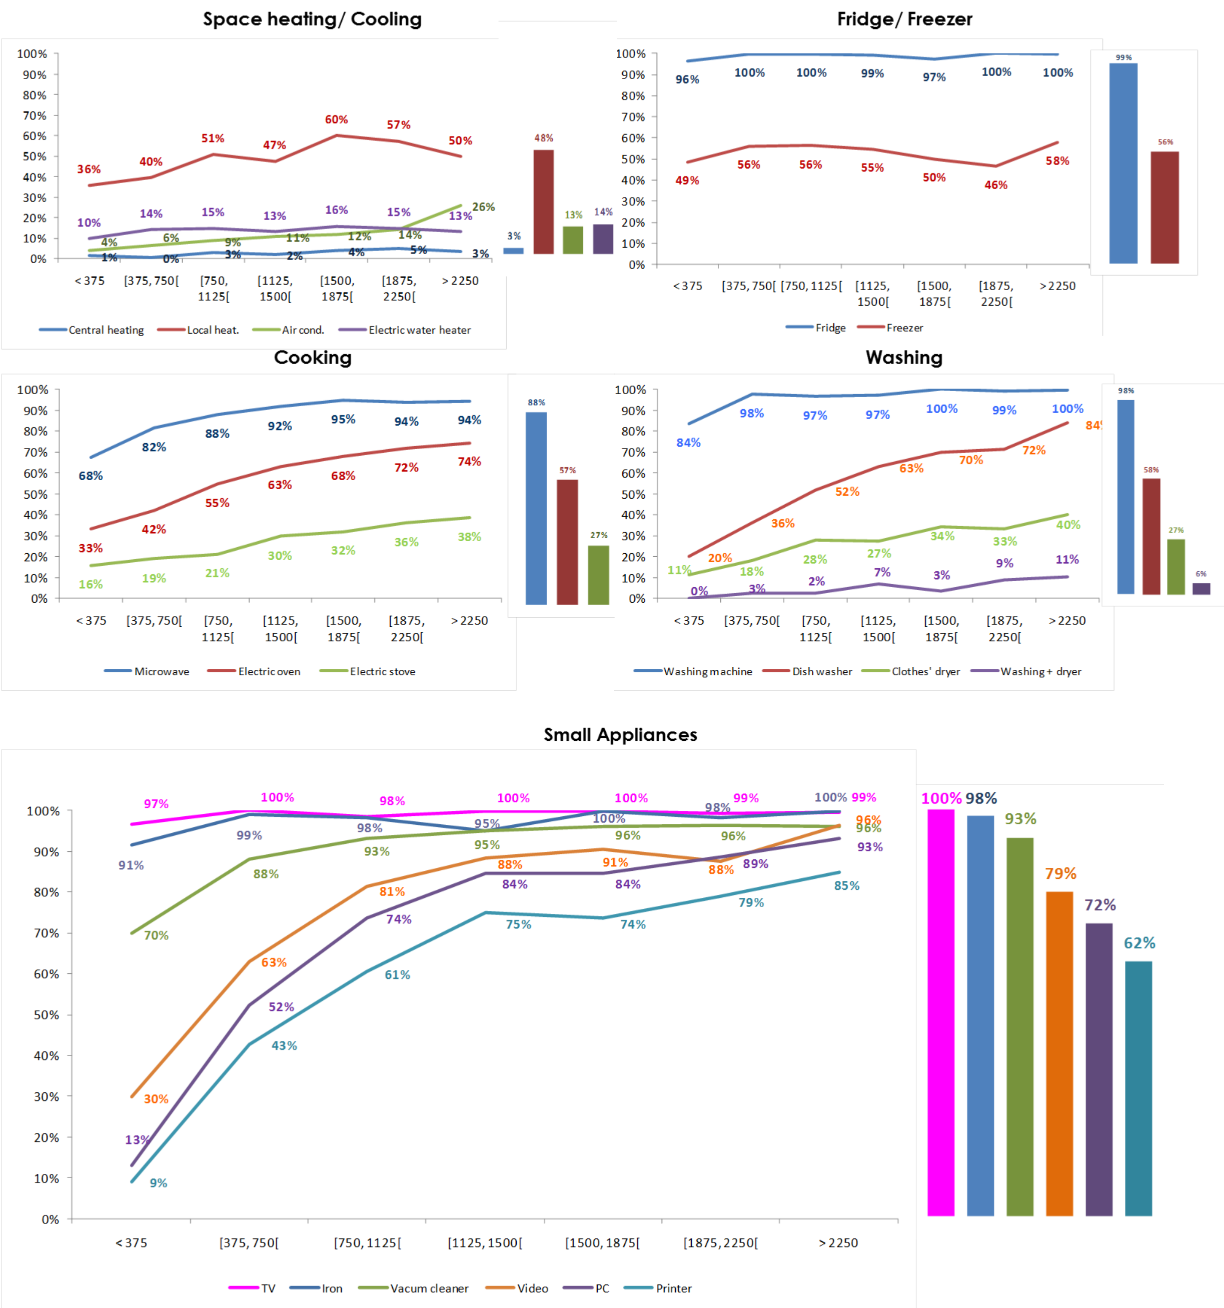

Figure 2: Ownership Rates vs. Family Income

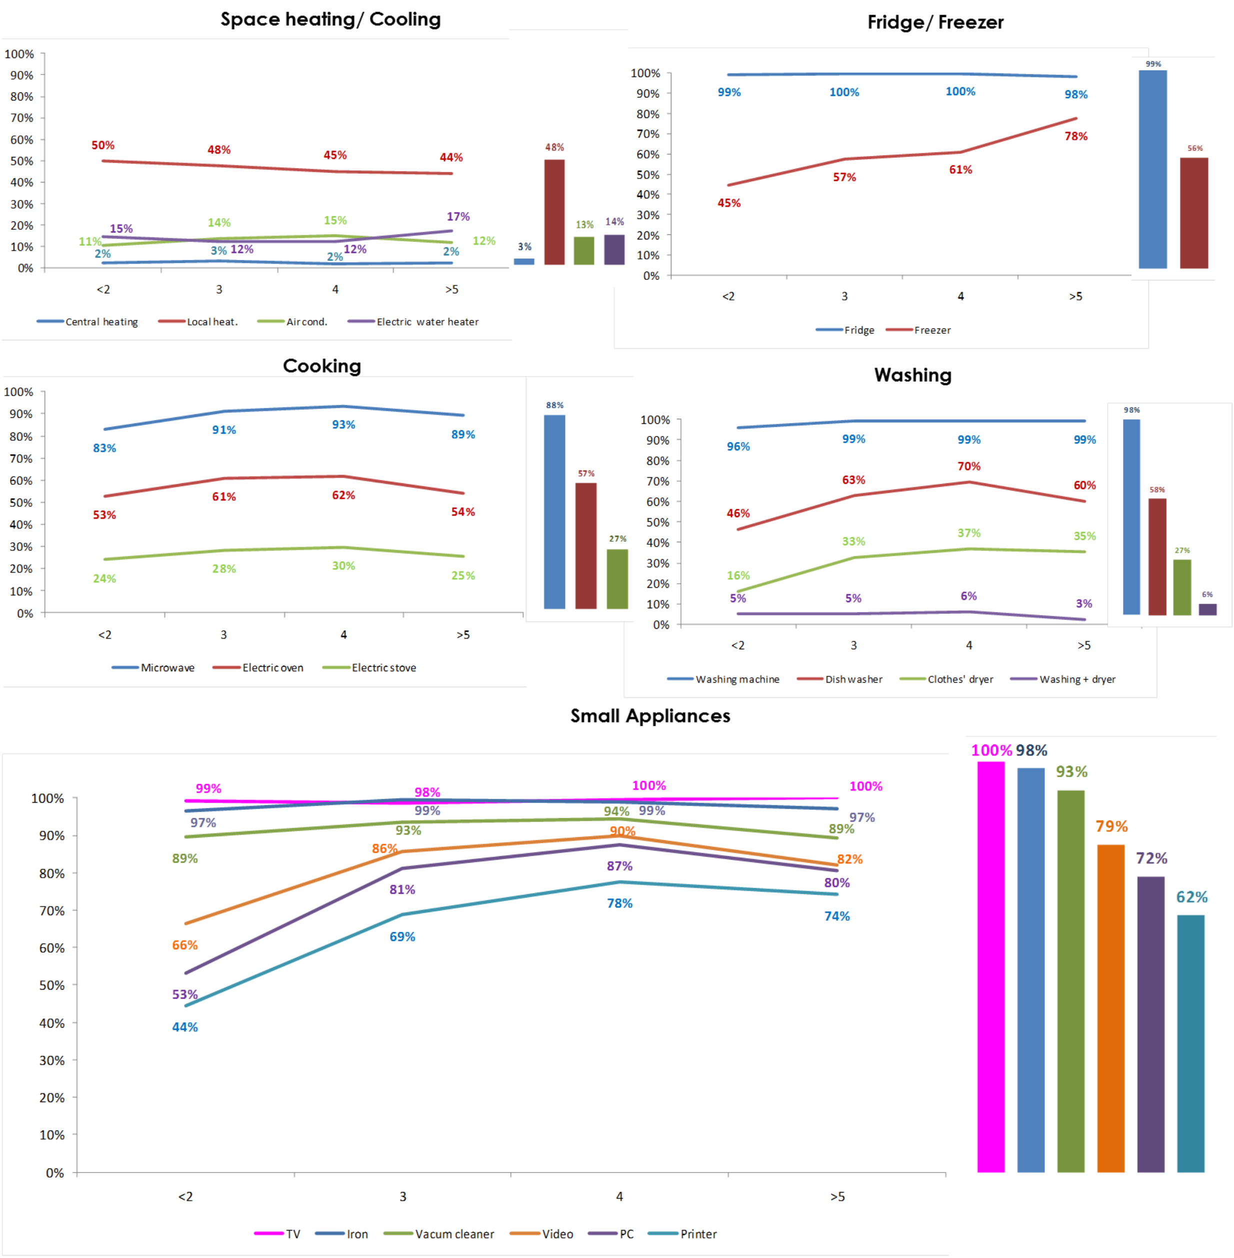

Figure 3: Ownership Rates According to Family Size

Turning now to the efficiency analysis, we have selected the following variables:

- Household Electricity Consumption (y);
- Clients (for electricity consumption), i. e. the number of customers (x_1);Family Income (x_2);
- Additional variable to explain inefficiency: electric Heating ownership/ electric water heating ownership

The following graphs illustrate how household electricity consumption varies across regions/ subscribed demand bands with the variation in clients and family income. Band 6, marked in red, exhibits a slightly different behaviour, as the number of consumers in this band is lower, but consumption is relatively higher; this fact is taken into account through a dummy variable (the intercept moves upwards):

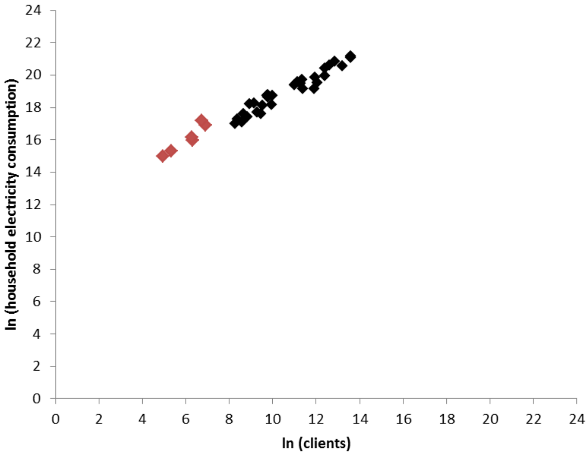

Figure 4: Household Electricity Consumption versus Clients

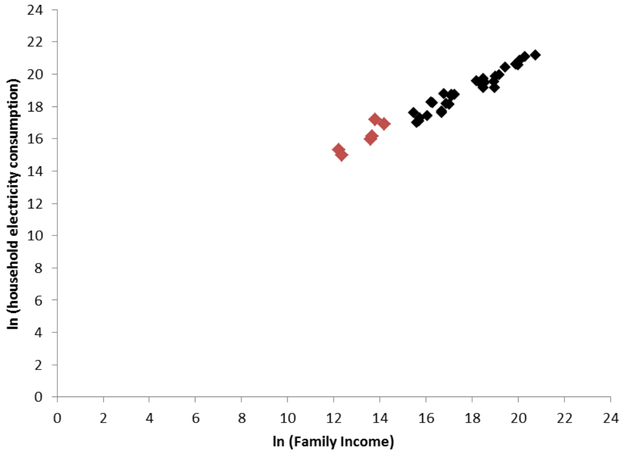

Figure 5: Household Electricity Consumption versus Family Income

Econometric Modelling of Energy Efficiency

It is relatively common to model energy efficiency in terms of an energy intensity or electricity intensity relationship with aggregate income or aggregate consumption. A new approach to this problem was suggested by Filippini and Hunt (*Energy Economics* 2012) [1] in which an econometric energy demand model was estimated to control for the exogenous variables determining the energy demand. The variation in energy efficiency over time and space could then be estimated by applying econometric efficiency analysis to determine the variation in energy efficiency.

Energy efficiency is conventionally measured by the ratio of energy consumption (E) to a measure of aggregate national income or expenditure (Y), i.e. energy intensity is:

E/Y = energy consumption relative to income

However, this measure is too simple because other variables (Z) and random errors impact on the measured intensity, and therefore the efficiency relationship itself varies over time:

E = f(Y, Z, efficiency, errors)

Filippini & Hunt (2012) [1] suggested a regression model (to be precise the model of stochastic frontier analysis, SFA) of this relationship which includes two components in the error term:

E = f(Y, Z) + u + v

In this relationship we identify two types of error:

- u = inefficiency;
- v = measurement, specification, sampling error

The kernel relationship: f(Y, Z) however must be specified parametrically.

Therefore we can measure a stochastic demand frontier to judge energy efficiency, and a schematic representation of this is given in the figure 6 below.

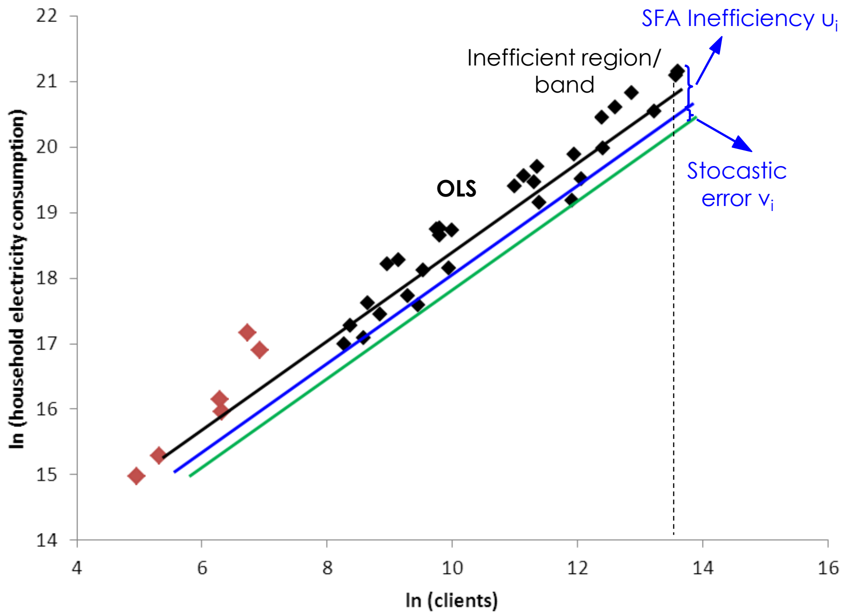

Figure 6: SFA model of energy intensity: inefficiency u_i stochastic error v_i

Formally, we write ln y_i as the dependent variable and we let X_i represent the explanatory variables. The remaining variation in the dependent variable is due to a composite error term comprising inefficiency (u_i) and idiosyncratic error (v_i).

SFA Model: $\ln y_i = a + bX_i + u_i + v_i$

Composite error term

A measure for the presence or contribution of inefficiency is then derived from the variances of the error components

$$\gamma = \frac{\sigma_u^2}{\sigma_u^2 + \sigma_v^2}$$

We can interpret this parameter as follows:

$\gamma = 0$: no inefficiency, while $\gamma = 1$: errors are exclusively related with inefficiency.

Having fitted the regression model, we identify three curves in figure 6. The highest curve represents the average relationship amongst the variables, while the lowest curve represents the efficient frontier that relates minimum household energy use to the number of clients. The lowest curve is the frontier if there is no stochastic error in our data. Allowing for a stochastic error component means the efficient frontier is the intermediate curve, and it is the distance to this curve which is used to measure efficiency of energy use. We begin our analysis therefore by fitting this model to the cross-section data on household consumption.

Electric Energy Efficiency in Households – cross-section sample

A Technical Effects model was adopted, in which additional variables are introduced as explanatory variables of the error term, and the distribution of inefficiency includes a constant (truncated) [4] [5].

Parametric kernel of the behavioural relationship: $\ln E_i = \alpha + \beta_1 \ln FI_i + \beta_2 NC_i + \beta_3 D + u_i + v_i$

Assumed probability distributions for the inefficiency and error terms: $u_i \sim \left|N\left(\mu_i, \sigma_u^2\right)\right| \; v_i \sim N\left(0, \sigma_v^2\right)$

Assumed model for how Z-variables affect the average inefficiency: $\mu_i = \delta_0 + \mathbf{Z}_i'\boldsymbol{\delta} \quad \forall\, i = 1 \ldots n$

Where:

E = Electricity Household Consumption

FI = family income;

NC = number of clients;

D = 1 for band 6 (subscribed demand > 20.7 kVA), D = 0 otherwise;

Z-variables = determinants of the inefficiency, including electric heating and electric water heating ownership

The results of fitting three different versions of this model which allow for different Z-variables to determine the inefficiency are shown in table 1 below with the significance codes for the probability-values associated with each coefficient.

Table 1: Results for the stochastic frontier analysis of electric energy consumption

	model 1		model 2		model 3	
Intercept	-0.791	****	-0.595		8.482	****
family income	0.762	****	0.762	****	0.356	*
clients					0.388	*
band 6 clients	0.627	***	0.538	**	0,577	*
Z-Intercept	0.256		0.444		-0,610	
Z-electric heating ownership	0.842				1.204	
Z-electric water heating ownership			0.155			
sigmaSq	0.120	****	0.117		0.097	***
gamma	1.000	****	0.712		0.008	
mean efficiency:	0.529		0.624		0.969	

Significance codes: 0 '****' 0.001 '***' 0.01 '**' 0.025 '*'

From these results, we conclude as follows: there is a strong positive relationship of energy consumption with family income and the relationship does shift for band 6 consumers. There is significant variation in energy efficiency in consumption patterns across the different regions averaging about 60 per cent. Electric heating and water heating increase the inefficiency but not in a statistically significant way.

Including also the number of clients as an explanatory variable, we find that the level of efficiency of the households shows a major improvement — mean efficiency increases to 96.9%. This result highlights the importance of using more than one explanatory variable to determine efficiency, which is one of the advantages of this method, in comparison with the simple energy intensity measurement, as referred above.

The Figures below illustrate the resulting measured performance of energy efficiency across region/ subscribed demand.

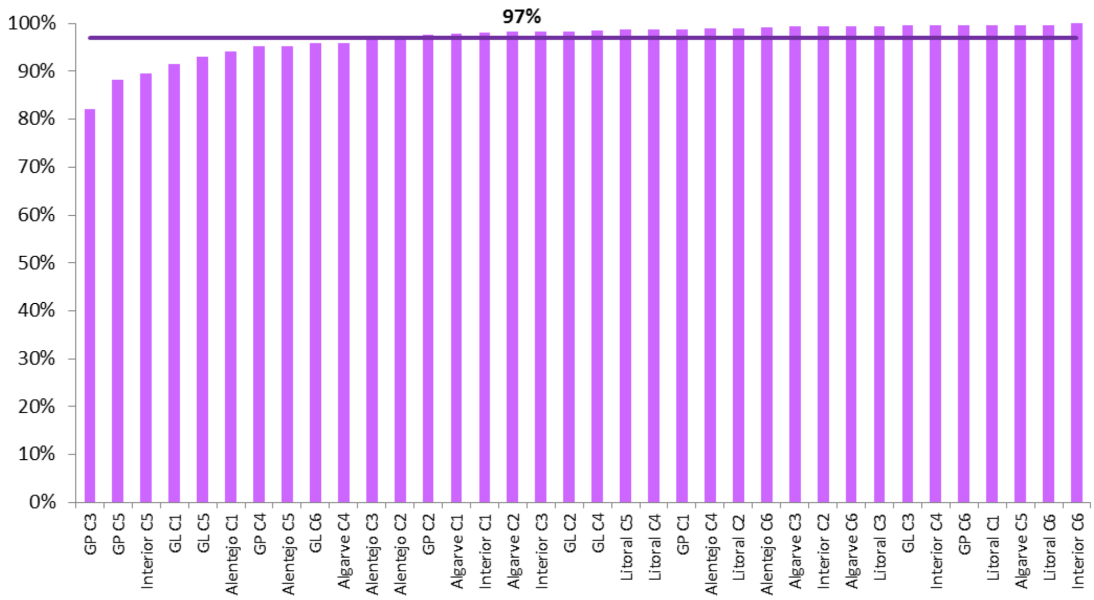

Figure 7: Electric Energy Efficiency Results

Dependent Variable: ln Household Electricity Consumption

Independent Variables: ln Family Income, ln Number of Clients, Dummy for band 6

Additional variable to explain inefficiency: Electric Heating ownership

In summary, the results from this survey lead to the conclusion that priority regions to reduce inefficiency in electricity consumption are Greater Porto, Greater Lisbon and Alentejo. Litoral is the most efficient region. The additional information included in figure 8, relating to consumption per client, shows that the regions with higher consumption per client are not necessarily the less efficient, reflecting the importance of the additional explanatory variables.

Residential clients included in the band between 13.8 and 20.7 kVA of subscribed demand should also be considered as the main target for the promotion of electric energy efficiency measures.

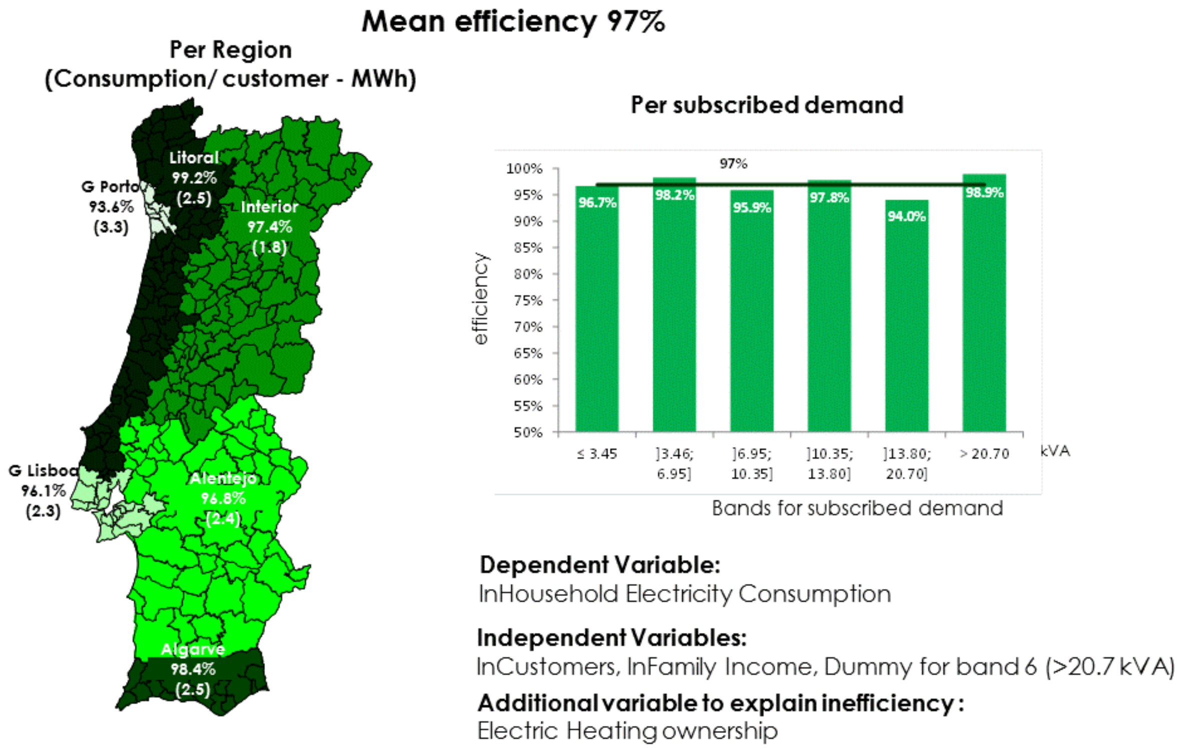

Figure 8: Electric Energy Efficiency per region according to 6 bands for subscribed demand

Extending the Data Set

Having established that energy efficiency does vary across different regions and population groups, we now consider how it has varied through time for the household sector in the whole of the Portuguese mainland. The data are for 1970-2011 and forecasts for 2012-2015 [3] [2].

From amongst these additional yearly data collected by EDP, we select for initial analysis the following variables, to which we fitted a stochastic frontier analysis as we did with the cross-section data:

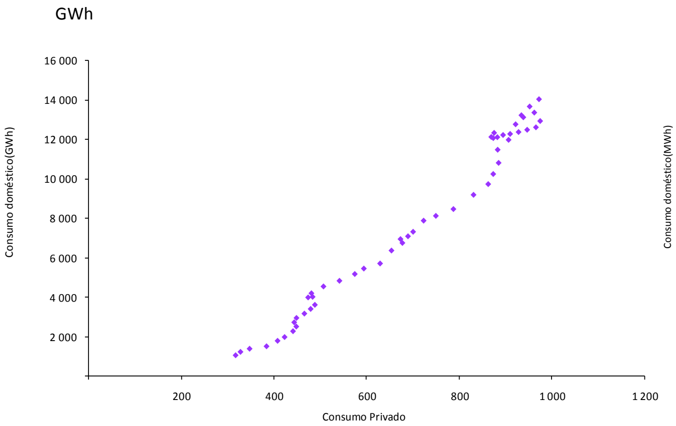
Household Electricity Consumption (y)

Private Consumption (of all goods and services) (x_1)

Consumers for electricity consumption (x_2)

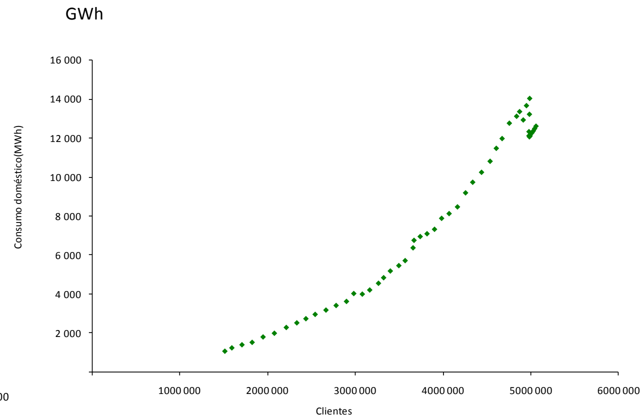
The following graphs, figures 9 and 10, illustrate how household electricity consumption varies over time with the variation in x_1 and x_2.

[2] Part of these results was presented at the 4th Workshop on Efficiency and Productivity Analysis, Porto, 29th of October 2012.



Private Consumption

Figure 9: Household Electricity Consumption versus Private Consumption



Consumers

Figure 10: Household Electricity Consumption versus Consumers

Source: Forecasts based on a model for Household electricity consumption developed by Pedro M. Martins and Júlia Boucinha (EDP).

Electric Energy Efficiency in Households – SFA model

The behavioural relationship is an Error Component function estimated through Maximum Likelihood as we illustrated previously for the cross section sample.

Dependent Variable: ln Household Electricity Consumption

Independent Variables: ln Private Consumption, ln Consumers

The sample consists of Aggregate residential electricity consumption in the Portuguese mainland over the period 1970-2011. Results are shown in the table below.

	coefficient	standard-error	t-ratio
constant	-11.30	0.42	-27.01
lnPrivate Consumption	0.69	0.05	12.96
lnConsumers	1.49	0.05	30.14
gamma	0.925	0.07	13.03
Log likelihood function	98.54		
LR	2.23		

Table 2: results for the stochastic frontier analysis of electric energy consumption

In the following figure we illustrate the resulting trend in the measured performance of energy efficiency over time, showing that electric energy efficiency in households has fallen in the recent past. The introduction of a weather correction in the last few years leads to an increase in the efficiency levels, except in 2007 and 2008, when the mild weather conditions led to a reduction in electricity demand, whereas in the remaining years, from 2003 onwards, the temperature effects led to an increase in electricity consumption and, hence, an apparent reduction in efficiency.

Current forecasts for household electricity consumption are consistent with an increase in efficiency (99% in 2014-2015).

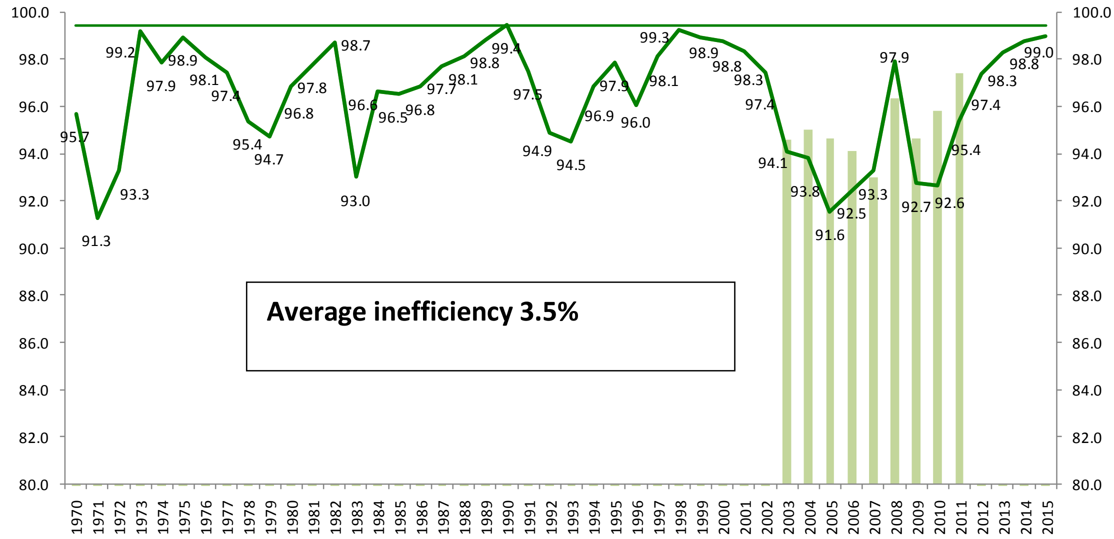


Figure 11: Electric Energy Efficiency Trend in Portuguese Households (%) - (1970-2015)

Dependent Variable: ln Household Electricity Consumption

Independent Variables: ln Consumers, ln Private Consumption

Corrected for weather effects: 2003-2008 REN; 2009-2011 – estimates by J. J. Domingos and J. Boucinha

According to our estimates for the period 2008-12, expected savings from energy efficiency initiatives, from the Ministry of Economy and from the Regulator, were fully accomplished, if we take temperature effects into account. This fact is illustrated in figure 12, which shows the reduction in electricity consumption which would be needed to eliminate inefficiency in 2008, in comparison with our estimates for 2012. According to the efficiency level given by our model for 2008, electricity consumption in 2008 should have been lower than the actual value by 269 GWh, for the efficiency frontier to be attained (this value is illustrated in the first column of the graph). If we take into account the fact that the mild temperature conditions led to a reduction of 205 GWh in consumption, for normal weather conditions consumption should have been reduced by 473 GWh. Applying the same analysis to our estimate for consumption in 2012, the corresponding reduction is only 321 GWh. Hence, we have an increase in efficiency of 152 GWh, given by the difference between the targets for the efficiency frontiers in the two years. These predicted efficiency changes are aligned closely with the official targets for energy efficiency savings (156 GWh).

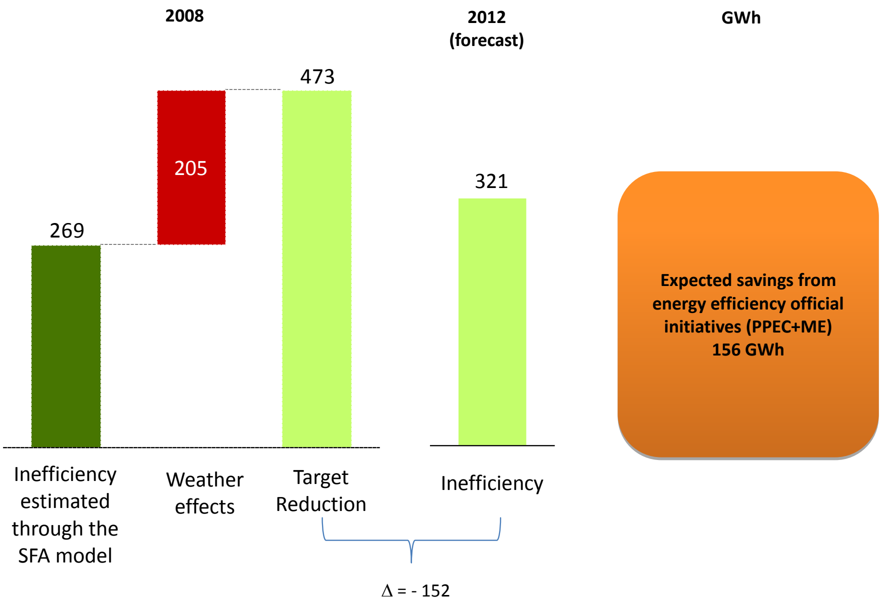

Figure 12: Estimated Targets for electricity savings derived from the efficiency model vs expected savings from official initiatives

13

Conclusions

In this paper we have outlined a new procedure for developing useful tools for modelling energy efficiency. These tools were successfully applied to electricity consumption in the Portuguese residential sector.

Through the application of an econometric model to a set of data collected from a survey launched to a sample of residential customers, we are able to identify priority regions and consumer bands to reduce inefficiency in electricity consumption. Hence, this approach may lead to the implementation of electricity saving measures in a more cost effective way.

Finally, through the application of the same method to a time-series data set, we related this efficiency measurement to policy developments in Portugal, concluding that the expected electricity savings from the efficiency measures introduced by the Government (essentially distribution of efficient light bulbs) and enhanced by the Regulator, through successive plans to promote efficiency in the use of electricity (PPEC – Planos de Promoção de Eficiência no Consumo), were fully realized. The corresponding savings, which amount to 150 GWh, represent 1.2% of household electricity consumption in 2012.

Lessons from a large scale energy consumption study in UK households

Chris Evans
Consumer Research Associates Ltd UK

ABSTRACT

Most authorities need to establish the types of data that can only be produced from household studies but are put off from commissioning them due to their anticipated cost and complexity. This paper demystifies these complexities and demonstrates a successful management structure that can be confidently adopted by any authority planning to commission such studies in future.

A study monitoring some consumer behaviour and the electricity consumption of all the domestic appliances in 250 households was completed in England in 2012. The results of the initial analyses and, uniquely, the entire 8Gb database have already been made publically available. Although this presentation will pick some headlines from the findings, its main theme is to identify the key features of the design and management processes that enabled this huge and complex research programme to be completed as specified, on time and on budget.

INTRODUCTION

There have been many small scale studies of energy consumption in households but few have been attempted on a national basis. Whilst the 250 households study reported here may seem large by comparison it is still small when compared to the 26million total of households in the UK.
(Note that the households monitored in this Study were all in England.)

The Study was commissioned by the authorities responsible for energy consumption and climate change policy in the UK. It was focussed on the consumption of electricity as additionally monitoring the consumption of gas and water would have more than doubled the cost of the planned programme.

There were two main needs that the study had to satisfy; one was identify what electrical products made the main contributions to consumption during the peak energy demand periods which, for the UK, occur during the coldest days of the winter. The other was to more reliably establish the average consumption for each of the major energy consuming products in domestic households. This data was needed for consumption projection modelling which, in the absence of any better data, would otherwise need to be based on assumptions about consumption patterns or on consumption data established in trials comprising just a few households. And, since the data from this study typically showed variations between the lowest and highest consuming households of some 500% for many of the different product types, it is clear that small scale household trials can yield very unreliable data due to the huge variation of household size, affluence and living patterns.

The purpose of this paper is not to discuss or share some of the findings of the study, remarkable though they were. Links to the reports of the findings are given at the end of this document. The purpose is to provide details of how this study was managed, what skills were needed to deliver it and what lessons were learnt that can be passed onto those undertaking their own large scale trials in the future.

THE ESSENTIALS

BUDGET
Undertaking a study to provide robust findings of national significance is likely to be a substantial undertaking. This study had a budget of €1million and an earlier, larger (400 households) study in Sweden is believed to have cost substantially more.

This UK Study was completed with an underspend of 5%.

TEAM MAKE-UP
The following roles each played an essential part in the delivery of the Study. All, except those making up the Governing Body, were contractors.

GOVERNING BODY
The Governing Body comprised of representatives of the commissioning Government departments. They initially drew up the specification of the Study and, following a competitive tendering exercise, appointed a consortium of contractors. All the bidders for the contract were consortia, this being a recognition that the variety of skills and experience required to deliver this Study do not normally exist within a single company.

The specification required the successful contractor to be responsible for all features of delivery i.e. the Government staff who commissioned the study would be left free to concentrate on its overall stewardship and so not be responsible for ensuring that specific parts of the programme were being delivered. All day-to-day management, all organisation, all problem solving etc. occurring within the Study being the responsibility of the contractors.

Once commissioned, the role of the Governing Body was to act as a Steering Group which met with the Managing Contractor (described below) every 3-4 months in order to monitor progress and to provide advice as needed. Over time, the Steering Group grew with additional members joining from the Government Departments that originally commissioned the Study. The diversity of steering group members represented a wide range of policy interests and this ensured the Study delivered data that could be used by several Government departments.

MANAGING CONTRACTOR
This Study required the delivery of a variety of technical solutions e.g. market research, installation of measuring equipment, data analysis etc. Put simply, it was the managing contractor’s job to ensure the smooth and successful integration of all these technical activities. The importance of this role should not be underestimated. There is a myriad of things that can (and do) go wrong in a study of this size and complexity. So there is a continuous need to develop and implement contingency plans and have problem solving expertise to hand. Importantly, the Managing Contractor for the Study was not responsible for providing any of the technical solutions, so was able to focus entirely on the overall management of the study without being distracted by the responsibilities of having to deliver one of the technical solutions too.

The Managing contractor thus developed and then monitored progress on the complex timing and activity plans to ensure each of the 250 households was recruited, interviewed, had instrumentation installed and later removed, maintained their activity diaries etc. This process worked very efficiently as the Managing Contractor assigned one person to manage the whole project. This ensured good project continuity but it did place that individual under considerable pressure at times.

This Study was completed on time.

TECHNICAL TEAM MEMBER (1) – MARKET RESEARCHER
It was known that locating suitable households was a task that organisers of studies often underestimate. In the case of this Study, the demographic profile of the householder sample needed to be a good match to the overall population in England in terms of:

- *Social grade* using a classification system enabling a household and all of its members to be classified according to the occupation of the Chief Income Earner
- *Number of people living in a household*
- *Life-stage*
- *Working status*
- *Property age*
- *Geographical region*

Thus a challenging task best undertaken by a professional market research company that already has this type of statistical data available and who has the recruiting capacity to locate not just 250 suitable households but also enough additional ones to act as a reserve in case some households drop out after volunteering. In the case of this Study, the drop-out rate was close to 30% - a strong indication of how challenging this aspect of the Study was.

Employing the skills of a professional market research company meant that attitudinal interviews could be undertaken at each household in the study. And, whilst there, the interviewer was able to conduct an initial audit survey to establish what electrical appliances were available for use in each household.

The interview ensured that data about social grade, household size, etc. was collected. The attitudinal survey covered pro-environmental behaviours segmentation, views towards climate change and energy saving. The appliance audit revealed that the average household had 41 appliances; the minimum found was 15, the maximum 85.

TECHNICAL TEAM MEMBER (2) – MEASURING INSTRUMENTATION SUPPLIER
The supplier (contractor) for the Study provided all the measuring instrumentation, data capture processes and data analysis. Having a single contractor to provide all the instrumentation, data capture and storage was attractive because it meant just one entity was responsible for a key part of the process which involved the interplay of several technologies. In the case of this Study, that contractor was also responsible for data analysis. This brought certain benefits but also some drawbacks – these elements are discussed in a later section of this paper.

One of the choices that needed to be made at the time of commissioning the Study was what measurement technologies were to be employed. Each of the consortia that tendered for the Study were required to make their own proposals and most chose to submit just one option rather than a choice. The options submitted varied. There were 3 main variations:

- Serial wattmeters for plug loads, combined with clamp-on meters used for individual circuits at the consumer unit – all measuring devices having some form of integrated data storage. The data being manually downloaded by a technician when visiting that household.
- Serial wattmeters for plug loads, combined with clamp-on meters used for individual circuits at the consumer unit – all measuring devices having some form of integrated data storage. The data being automatically downloaded and transmitted using ZigBee type technology.
- Plug load data capture using Radio-Frequency Identification (RFID) technology. The data being automatically downloaded and transmitted utilising the household's Wi-Fi router.

The choice made for the Study was to employ serial wattmeters for plug loads, combined with clamp-on meters used for individual circuits at the consumer unit with data being manually downloaded by a technician when visiting that household. The reason for making this choice was that it was based on well-proven technology of known reliability. The newer, higher technology options, though attractive as some were physically less intrusive for householders, did not have such a well-established reputation for reliability. Although remote monitoring meant that data streams could be checked in real time, the cost of dispatching a technician to make the necessary repairs could become very high.

One other important choice about the instrumentation was whether to purchase it or rent it. Rental was much less costly than purchase but it meant that the client departments would not have the instrumentation available for further studies once this Study had been completed. In this case, the equipment was rented.

Details of the instrumentation used for the Study are provided in the literature referenced at the end of this paper.

TECHNICAL TEAM MEMBER (3) – MEASURING INSTRUMENTATION FITTER
All households needed to be visited by a technician to fit the measuring instrumentation and again sometime later to remove it. During their return visit, these technicians also downloaded the captured data onto laptop computers for subsequent onward transmission for storage in the database and eventual analysis.

For the tasks they had to do, the technicians needed two key attributes. One was that they needed to be qualified electricians as minor dismantling of household electrical supplies was occasionally necessary in order to fit the measuring devices. Clearly, any such task had to be undertaken in a completely safe manner and in accordance with wiring regulations, so only certified electricians were employed for this task. The other attribute was not a technical one, for it required inter-personal skills. These were necessary as the electricians were, apart for the market researcher who made the initial recruitment visit to each household, the only person to person contact that the householders had with those running the Study. These electricians were also going to spend as much as one day in the household fitting the instrumentation and, because this meant them visiting every room in the house, could be rather intrusive at a personal level. Therefore, it was particularly important that these electricians had very good ”client management” skills i.e. were very polite, prepared to spend time with the householder to explain what they were doing, worked very tidily and were even attentive to small considerations such as removing their shoes when entering people’s homes.

This consideration might seem unnecessary but these “ambassadors” received excellent feedback from householders and on a few occasions were able to identify pre-existing safety faults in household wiring systems that they were able draw to the attention of the householder.

Prior to commencing their role in the Study the electricians (two small teams of electricians covered the whole of England) were provided with substantial training by the instrument suppliers.

TECHNICAL TEAM MEMBER (4) – DATA ANALYSER
Studies like this generate a huge amount of data (220 million lines of data in this Study) and those who commission them may not understand this aspect well – so can find themselves being offered advice about the provisioning of databases and analytical solutions that they do not fully understand the implications of. Some of this impacted this Study. The solution offered by the measuring instrument supplier, which was for them to also store the data in their preferred data base solution complete with their in-house analytical tools, was very convenient and produced elegant outputs in accordance with the wishes of the Steering Group.

In the short term, this provided a very satisfactory solution – the solution only being limited by the Steering Group themselves as they were required to produce a list of requested analyses. But this solution can impose limitations in the longer term as other parties begin to ask for analyses for which no solution can be provided other than through the inflexible and added-cost route of needing to request and pay the data base custodian (the Measuring instrument Supplier) to provide the required analyses.

The solution that was developed for this Study was to migrate all of the data into a MySQL database. MySQL was chosen as it is widely used open source software, so available to all would-be users. Such databases provide storage facilities only so need some additional features to enable users to access the data in suitable formats for their intended use. The following were developed for this Study:

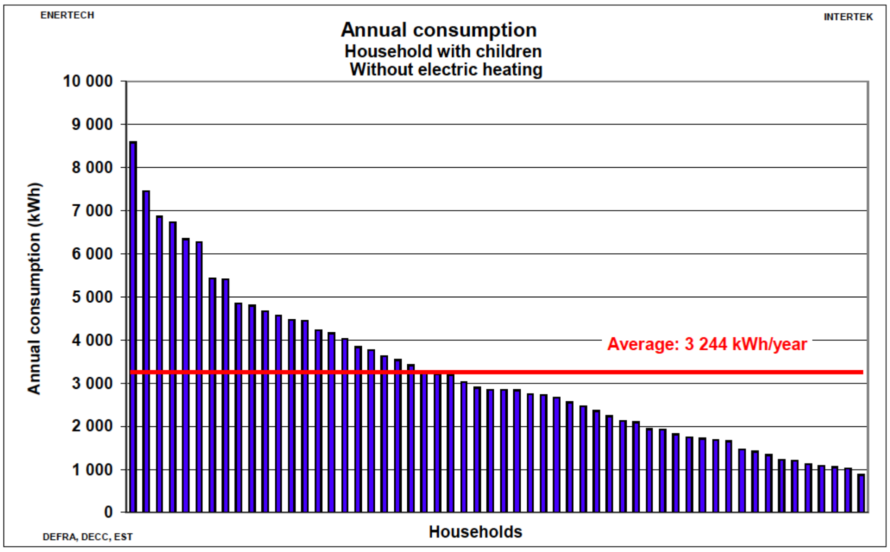
- WAMP database solution package with pre-defined queries (WAMP is a pre-packed set of programs that enable web based queries to be made of the MySQL database). This solution being designed to enable non-database base experts to run their own queries on the database.
- The MySQL database was given a Microsoft *Access* front end to allow users to design their own queries (users can use the core MySQL database and add their own front end). This solution being designed to suit those with some familiarity with databases, particularly the most common one MS *Access*,
- Or, for database experts, they would be able to export data files directly from the MySQL database.

SOME OTHER FACTORS

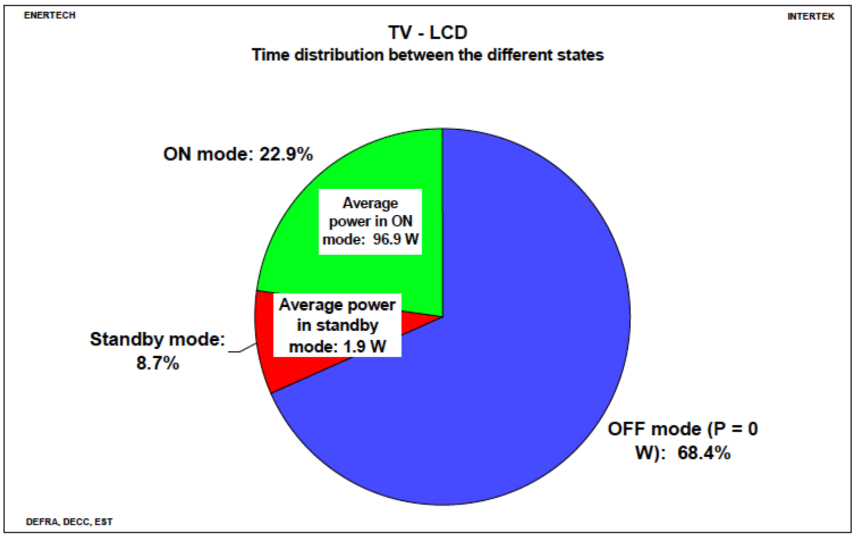
- All of the households in the Study were owner-occupied. It was not possible to recruit households from the social housing sector and rented sectors as the wiring needed to be modified to fit some of the measuring instruments and landlords were not expected to readily give permission for this.
- The most difficult household population to recruit was younger single occupiers. These were important to include as 29% of UK households are single person dwellings.
- Ownership of the intellectual property rights to the analytical tools required to analyse the database needs to be established at the outset.
- The detailed analyses that were required should be determined well in advance of completion of the study.
- Downloading of data during intensive (peak) periods could be intrusive for householders and should be done remotely where possible.
- Owning rather than renting the instrumentation may encourage the development of lower cost studies that can be used to refresh the data in future years.
- Only the data analyser could check the data as the project progressed and as much of this was done at the end it meant that problems with missing or corrupted date were not always spotted as early as they could have been.
- Appliances that are built into kitchen units in such a way that their power input plugs are inaccessible can be particularly difficult to monitor.
- Households that use portable electric heating to supplement a non-electrical main heating source need particularly close attention to ensure these extra heating sources are included in the monitoring programme.
- Studies such as this only provide a snapshot in time; so will eventually need to be repeated.

SOME EYE-CATCHING FINDINGS

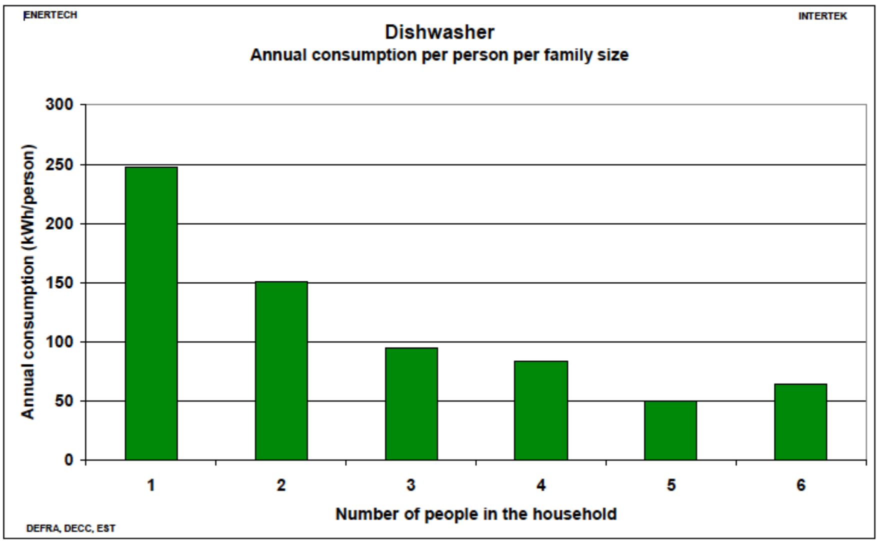
- The study found the total average annual electricity demand for all dwellings monitored in the survey (excluding electrically heated homes) to be >3200KWh.



- This average annual electricity consumption in the Study's households was 10% higher than the UK national average.
- Single person households were found to use as much, and sometimes more energy than typical families. This is particularly true of cooking and laundry activities.
- TV viewing is close to 6 hours in a typical day; the typical household having 2 TV sets…



- Although peak domestic electricity demand occurs at breakfast time and again in the evening, there remains a seemingly high baseline demand of 175-200 watts throughout the 01.00- 05.00 hours period.
- Excluding electric heating, the largest contributor to the average annual household demand is the combination of consumer electronics and ICT (20.5%), followed by cold appliances (16.2%) and lighting (15.4%). Cooking and wet appliances consume similar levels of energy at 13.8% and 13.6% respectively.
- UK households use much more energy to dry clothes (annual average 394 kWh), than to wash them (166 kWh) and they use more energy to wash dishes (294 kWh) than to wash clothes…



- Incandescent lamps accounted for the majority of lighting with close to 40% of all installed light bulbs. Halogens come next with 31%, demonstrating that CFL and LED technologies still have a huge market to penetrate and huge savings to potentially be made…

The Study that has formed the basis for the content of this paper was inspired by an earlier study of electricity in 400 households undertaken by the Swedish Energy Agency. The expert advice provided by Egil Öfverholm and Peter Bennich proved to be invaluable during the period when the specification for the UK study was being formulated.

Project ACHIEVE: promotion of practical and structural solutions that help Europeans to reduce fuel poverty

Marie Moisan, Lidija Živčič, Barbara Kalker

CLER – Réseau pour la transition énergétique,
Focus, Association for Sustainable Development,
Caritasverband Frankfurt e.V.

Abstract

With rising energy prices, more and more households across Europe are facing fuel poverty. Although the problem is a complex one, some solutions are simple and cost-effective. The paper presents ACHIEVE (*ACtions in low income Households to Improve energy efficiency through Visits and Energy diagnosis)*, a pan-European action with practical and structural solutions that helps Europeans to reduce fuel poverty.

ACHIEVE works towards uniting the various definitions of fuel poverty across Europe and sharing approaches to better identify fuel poor households. It is known that these households are often not well reached by energy saving awareness campaigns oriented towards the general public, and thus do not seek the help they might need to improve their situation.

In this action, long-term unemployed people are mobilized and trained to carry out home visits to fuel poor households, where energy use is monitored while families are recommended tailor-made measures. The households are stimulated to reduce their energy and water use through energy saving devices provided free of charge and behavioural adjustments. The action's important social innovation is that it contributes to social reintegration, both by empowering households and by engaging long-term unemployed people to fight fuel poverty. Visits also provide an opportunity to identify complementary long term measures for improving the buildings' energy performance.

The action also looks for structural solutions, from building retrofit to financing mechanisms for abating fuel poverty at micro and macro levels. Some of the structural solutions for fuel poverty need to be formed at EU level and for this reason international collaboration in tackling fuel poverty is needed.

Short introduction to fuel poverty

Definition of fuel poverty

Defining fuel poverty has and still is causing numerous debates, but as this is not the topic of this paper, the issue is addressed only briefly. Brenda Boardman [1] explains the challenge in the following manner: 'Now that the fuel poverty is politically accepted as a real problem, there are some difficult definitional issues to consider. All of these are compounded by the circular argument: who is fuel poor depends on the definition, but the definition depends on who you want to focus on and this involves political judgement.'

At the EU level, there is no common definition of what constitutes a fuel poor household. However, one way of defining it, which is used in practice, is that a household, which has twice the median fuel expenditure as a proportion of income, is facing fuel poverty [2]. Another commonly used definition is that any household that would need to spend more than 10% of its annual income on having adequate energy services is in fuel poverty [3].

For the purpose of the project ACHIEVE, the following definition of a fuel poor household emerged: a fuel poor household is one that has a difficulty, or sometimes inability, to be able to afford its basic energy needs [4]. Households in fuel poverty have energy costs, which are excessive, compared to overall household income.

Causes of the problem

Fuel poverty is mainly caused by the convergence of the following inter-related factors [5]:

• low income, which is often linked to general poverty

• high energy prices, including the use of relatively expensive fuel sources

• poor energy efficiency of a home, e.g. through low levels of insulation and old or inefficient heating systems.

Heating is the first item that strains the global energy bill for a household (around 70% of the annual energy consumption). However, the running of appliances and the energy used for hot water consumption are also important: appliances account for a growing proportion of households' energy budgets (low income households tend to use older and more inefficient appliances), and water consumption is showing a general tendency to increase (amongst all categories of households) [6].

Scale of the problem

Even though the European Union is one of the richest areas in the world, many EU citizens have such limited resources that they cannot afford the basics. Between 50 million and 125 million people (about 10 – 25 %) in Europe are estimated to be fuel poor [7]. The span of fuel poverty estimations is so large mostly because – as explained above – in many countries there is no definition that constitutes fuel poverty and since there is no definition, there are no statistics [8]. However, most of the evidence shows that the problem is inevitably deemed to increase in the future, in line with rising energy prices [9]. The problem is particularly expressed in the eastern European member states, where the energy liberalization strategies, which had to be put in place to access the EU, led many households from a situation with subsidized energy prices into a situation with market based energy prices, which meant (and still means) a major rise in costs for them [10].

Health impacts of fuel poverty

Fuel poverty has considerable physical and mental impacts. Living in a cold home exacerbates circulatory and respiratory conditions and accounts for around 40% of excess winter deaths. Around one third of excess winter deaths are due to respiratory illness [11]. Older people are more likely to be vulnerable to cold weather, partly because they are more likely to have existing medical conditions. However, other vulnerable groups include young children and people with long-term illness. Home energy improvements have proved to decrease school sickness absences by 80% in children with asthma or recurrent respiratory infections [12]. People living in homes with bedroom temperatures at 21 °C are 50% less likely to suffer depression and anxiety than those with temperatures of 15 °C [13].

Project ACHIEVE in a nutshell [14]

Project ACHIEVE is an Intelligent Energy Europe [15] supported pan-European action with practical and structural solutions that help Europeans reduce unnecessary energy and water use. The action reaches to low income households that are most vulnerable to fuel poverty and works with them to reduce their consumption. It links dispersed local actors into an EU-wide concerted effort to reduce fuel poverty and develops common tools and methodologies for addressing energy poverty at the European level.

Starting point of ACHIEVE in the covered countries

Although in some countries (UK, France and Germany) activities, similar to ACHIEVE, already exist, the programme is upgrading the existing activities. In France, several local initiatives have been in place for more than 15 years to implement actions against energy poverty, most of them relying on the housing solidarity fund, which helps people who have difficulties to pay their energy bills. Only recently an action started at a national level, the so called Grenelle Plan for Buildings. ACHIEVE in France builds on those initiatives. In the UK, UK fuel Poverty Strategy, the Climate Change Act and the Energy Act are the bases for fuel poverty action. Some local authorities have established Affordable Warmth strategies and partnerships, however there are many areas where activity is very limited and support is needed. ACHIEVE works with those, while also building on the results of initiatives to improve the insulation, such as Cavity Wall and Loft Insulation. In Germany, more specifically in Frankfurt, initiative “Energiesparservice” (energy saving service) has been in place since 2005. Unemployed people are being qualified as “Service Consultants for Energy and Water Saving Techniques”. With the necessary measuring and testing gear, informational brochures and sample equipment, the consulting teams go to low-income households and document the current usage of electricity, water and heat with the help of a comparison chart. ACHIEVE benefits from sharing the experiences of this initiative and transferring them to the other partner countries.

In Slovenia and Bulgaria the initiatives for abating fuel poverty are practically non-existent. In Slovenia there is an existing financing scheme for refurbishment investments of low-income households, while in Bulgaria grants are available through the National Programme for Refurbishment of Dwelling Buildings. The direct state subsidy amounts to 20% of the basic package of measures necessary for refurbishment of the buildings. There are many questions opened about the criteria related to the ways of supporting low income households.

Aim and objectives of the action

The aim of ACHIEVE is to contribute to practical and structural solutions for reduction of fuel poverty in Europe. The strategic objectives of this action are the following:

• Improve health and well being for households facing fuel poverty,

• Link dispersed local actors into an EU wide concerted effort to reduce fuel poverty, through common understanding, communication and networking,

• Reduce social exclusion and marginalisation of households that suffer fuel poverty

• Develop a methodological and economical concept for addressing energy poverty at the European level

Activities of the project

Basing its approach on the best practices throughout Europe, ACHIEVE identifies households that are most vulnerable to fuel poverty and works with them to implement suitable steps to reduce unnecessary energy use and of course, costs.

Indeed, private households do often not take up or know the solutions they can mobilise to decrease their energy consumptions and bills. The information available often does not fit their specific situation. In addition, this target group lacks the financial resources to make energy efficiency investments in their homes A proper understanding of their situation, through a socio-technical diagnosis during a home visit, is the very first step to be able to help them further and orientate them towards existing solutions and support.

In ACHIEVE, long-term unemployed people, volunteers or students are mobilized and trained to develop a large-scale campaign of home visits to households who have hitherto not had access to help and support, and who are facing difficulties with paying their energy bills.

The service is based on home visits, with the main purpose to identify on a case-by-case basis the everyday actions that can have a real impact on their energy consumption. Visits focus on the following points:

• to understand vulnerable consumers' energy consumption, bills and habits, and to check their appliances with a set of reporting/analysing tools;

• to distribute and install a set of energy-efficient and water-saving devices (such as light bulbs, power strips, tap aerators…), which are free of charge for the households, and give advice to the households on how to implement further practical measures for saving energy;

• to analyse which longer term solutions can be introduced to improve the households' situation, by linking local actors into a concerted local action plan.

Fuel poverty and long-term unemployment are often linked with social marginalisation. ACHIEVE's important social innovation is that it contributes to social reintegration, both by empowering households to fight fuel poverty by improving understanding of their energy use, and by engaging people who have been unemployed long-term to raise awareness on fuel poverty.

A crucial programme activity is to trigger building improvement when thermal improvement works are needed: by better connecting tenants and landlords, informing, motivating and orientating them with easy to understand and tailored documents and methods. To do this, project partners cooperate closely with tenants, home owners, landlords, social services, consumer protection agencies and other relevant actors.

Expected results and impacts of the project

ACHIEVE runs from May 2011 until April 2014. It is expected that ACHIEVE will result in:
• changing energy using behaviour,
• introducing energy efficiency measures at the level of individual households,
• reducing overall energy consumption and thus reduce the risk of energy poverty in target households, energy savings and
• a reduction in CO_2 emissions in each household visited,
• developing competences and job opportunities for those energy advisors carrying out the visits, and thereby
• reintegrating them into the labour market,
• improving health and well being for households facing fuel poverty,

• linking dispersed local actors into a EU-wide concerted effort,
• reducing fuel poverty, through common understanding, communication and networking,
• reducing social exclusion and marginalisation of households that suffer from fuel poverty and
• developing a concept for addressing energy poverty at the European level.

2600 visits are planned to be implemented within the frame of the ACHIEVE in 2012 – 2014 (300 to 500 visits in each of the 6 target areas of the project). Each ACHIEVE visit targets the following reductions, depending on the countries and the saving devices offered:
• 400 to 500 kWh decrease / household /year
• 150 to 300 kg / CO2/ household / year
• 20 to 30 m^3 of water / household / year

These figures are based only on the calculation of the direct savings generated by the installation of energy and water saving devices at the households. They don't take into account the potential savings generated by the application, by the family, of the advice and tips given during the visits. To monitor the achievements of the project, evaluation will be a separate step in the process. Evaluation of the success will be done through interviews with the visited households.

The ACHIEVE concept is based on the idea of promoting climate-friendly behaviour, together with money savings considerations, - specifically for low-income households. Developing and replicating ACHIEVE methodology in Europe would definitely contribute to meet the 2020 EU target consisting in a 20% reduction in EU greenhouse gas emissions.

Target groups of the project

The key target group consists of households that have difficulties in affording basic energy needs. Through diagnostic visits and the installation of free energy saving devices they can save energy and money by better controlling their energy consumption. The visits show them where and how they can save energy and water and help them to decide what behavioural changes to introduce.

This implies working with any other local actor that might be able to identify the targeted households and be relevant to proposing longer-term and durable aid or solutions to the households, after the visit.

Other target groups are:

• *Local authorities* with access to information on how to reduce fuel poverty. They can support housing schemes and housing renovations that secure sustainable energy consumption and improve well-being of occupants. They can support the households through their technical or legal services.

• *Owners of buildings* in which fuel poverty situations are concentrated: by learning how to improve energy performance of the building they can improve the living conditions in their buildings and improve the value of their property.

• *Local actors* (such as local housing associations, tenants' associations, health, energy or social actors, for whom addressing poverty challenges are at the core of their mission) can both benefit from and take part in implementing the project through networking and shared competences.

• *People* who have the right basic skills to be trained to give energy advice to low income households, such as volunteers, people who are long-term unemployed or students that wish to gain work experience.

Partners of the action

ACHIEVE project partners are
• **CLER** - Réseau pour la transition énergétique (Coordinator; France)
• **CARITAS** - Energiesparservice Caritasverband Frankfurt e.V. (Germany)
• **EAP** - Energy Agency of Plovdiv (Bulgaria)

• **FOCUS -** društvo za sonaraven razvoj (Slovenia)
• **GERES** - Groupe Energies Renouvelables, Environnement et Solidarités (France)
• **IDEMU** - Institut de l'Ecologie en Milieu Urbain (France)
• **Severn Wye** - Severn Wye Energy Agency (UK)

Local circumstances in countries, covered by the action

This chapter describes the situation in each of the countries where ACHIEVE is trying to make an impact. This is to describe the backdrop against which the activities of the project are set [16].

France

In France, it is assumed that between 4 and 5 million households face fuel poverty. Either because they spend more than 10% of their income on energy costs, or because they impose self- limitations on their energy consumption and suffer from cold homes. Despite a national plan and funding scheme starting in 2010, (aiming to help 300,000 tenants with low-incomes to improve the energy performances of their home by 2017) visits remain the first step for any action, whether it is on occupant behaviour or actual energy efficiency upgrades to the building itself. If visits are not clearly organised, they are not implemented at all. The success of the national plan depends on the local actors and authorities to find a way to identify the concerned households in their territory, and to organise and finance these mass visits. Several local initiatives are being implemented in France to fight energy poverty, similar to ACHIEVE activities. Within the framework of ACHIEVE, the French partners have set up a national task force to build a range of structures for carrying out these type of projects that offer visits. Partners include local authorities, enterprises that work on the integration of immigrants, and non-profit organizations. This task force aims to exchange and share each structure's experience, and to push forward the need and opportunities for public authorities to participate in such type of actions. The final aim of the task force meets the ACHIEVE goal: to develop an economical and organisational pattern for mass visits.

Bulgaria

The term fuel poverty has no concrete definition in Bulgarian legislation. For the purposes of the project, we define a fuel poor household as one that applies for social aid to cover heating costs during the winter. The Social Ministry in Bulgaria grants aid for heating during winter to selected households. The target group of ACHIEVE consists of/includes households applying for this kind of aid. An important target group is households that use coal for heating. As part of the project Energy Agency Plovdiv will co-operate with the Ministry of Environment and Water and the Ministry of Labour and Social Policy to propose and implement changes in the current legislation, so that the use of inefficient and polluting coal in heating is discontinued and, instead, use of modern sources of biomass is encouraged.

Slovenia

Due to growing prices of energy, fuel poverty is becoming an alarming issue in Slovenia. Approximately one third of the households in Slovenia suffer fuel poverty (as specified by the UK definition). However, energy prices are not the only contributing factor. The poor condition of buildings is also relevant. 44.5% of low income families and 28% of families with higher incomes live in humid and poorly maintained buildings (leaking roof, humid foundations, floor or walls, shattered windows). This means that in Slovenia fuel poverty could be widespread also in households that are not strictly poor, as poorly maintained buildings cause high energy consumption and hence high costs to the residents. In the municipality of Ljubljana, where the Slovene ACHIEVE activities take place, more than half of the buildings date between 1945 and 1990, which characterizes the flats as energy inefficient. Yet, there are many unresolved questions as how to identify the households in need of support.

Germany

In Germany, there is neither an official definition for fuel poverty nor is there statistical data about people who live in fuel poverty. The German consumer protection association estimates that more than 800,000 households (2%) are cut off from their power supply each year because they are not able to pay their bills. The energy prices in Germany have gone up continuously over the past few years. After liberalisation of the electricity market in 1998, the average price for electricity has risen from 15 cents to 24 cents per kWh in 2011. At the same time, households lack control of their energy usage because they only get a bill once a year, based on their yearly consumption. This leads to significant problems for low-income households whenever they have to manage additional payments at the end of the year. For people with low income, e.g. people who receive social welfare or long-term unemployment benefits, the costs for heating, water and water heating are paid by the municipality. Thus the main problem is how to pay for the electricity consumption for cooking, washing and cooling. Only 5 % of the German households use electricity also for heating.

United Kingdom

Project ACHIEVE comes at a time when an unfavourable economic climate and rising energy prices have impacted those groups who both traditionally and recently are considered to be at risk of energy poverty. In 2009, the number of fuel poor households in the UK was estimated at around 5.5 million. In the UK, project ACHIEVE is based in the county of Wiltshire, in the western region of the county which statistically has a higher propensity towards energy poverty. Wiltshire has been working towards creating training and employment opportunities for its residents; a policy designed to mitigate the impact of the economic recession. ACHIEVE will work to address the training needs of residents in line with the ‘Green Deal’ a flagship energy efficiency policy for the domestic sector based on a ‘Pay as you save’ model. The government expects around 250,000 new jobs to be created as a result of this policy. Project ACHIEVE hopes to help advisors on the road to employment within this sector and to develop a local, skilled workforce.

Transferring experiences and know-how

ACHIEVE covers some countries where advising households on how to abate fuel poverty is already ongoing (Germany, UK and France) and others where fuel poverty is hardly tackled at all (Slovenia and Bulgaria). For this reason the first step of the programme was to present to partners from all the participating countries how energy efficiency measures and equipment are being introduced in German households.

Caritas Frankfurt has been running a programme for empowering households to act on fuel poverty since 2005. The programme, called Energiesparservice, was developed jointly by Rhein-Main Energy Supplier and the Department of Social Services of the city of Frankfurt am Main, JobCenter Frankfurt am Main and Caritas Association Frankfurt. The programme started with 12 advisors who were long-term unemployed and has now developed into a national initiative called “Stromspar-Check” in over 100 cities and communities in Germany [17].

The programme empowers households by two visits of energy efficiency advisors. During the first visit, the advisors check the household’s equipment and energy bills. Based on the check, calculations are made on where to save energy most efficiently. A set of recommendations is made and during the second visit, the experts install easy-to-use energy saving devices like efficient bulbs, tap aerators or power strips. They also provide advice on changes in behaviour to further save energy and water. Practical experience from the programme so far shows that annual savings for households can run up to 140 EUR yearly and more than 1100 EUR in long-term-savings [18].

As this programme has been successfully running since 2005, it was selected to be the starting point of ACHIEVE. The project partners visited Caritas in Frankfurt in May 2011 to see how the visits are implemented in practice. Apart from the visit, the partners also translated Caritas’ “Guidelines

Introducing Advisory Services on How to Save Energy in Low-income Households" [19], which describe the concept of service of Caritas Frankfurt, called Cariteam Energy Saving Service, and the procedure of introducing and implementing the project step by step. To provide material for trainings of energy advisors, Caritas also developed a "Curriculum for Specialized Training on Saving Energy and Water" [20]. The curriculum covers topics such as general introduction to energy, detecting fuel poverty situations, showing a concept of thermal comfort and heat loss, procedure and data documentation, evaluation and installation of devices or communication training. For each chapter, a corresponding module has been developed – contents, tips about the method of presentation (exercises, group work, role playing, homework, etc.), and time frame. This curriculum was taken as a general basis for defining, designing and developing training modules and exercises for all ACHIEVE partners.

Equipped with the materials, the partners implemented trainings for energy advisors. Each partner decided to use a different approach to identifying and training energy advisors (see Table 1).

Table 1: Approaches to identifying and training energy advisors in project Achieve

Partner	Used approaches
IDEMU	4 people in an integration programme have been recruited for 6 months and trained by IDEMU. The recruitment was done by IDEMU, in cooperation with key recruitment offices. An information event was organized in January 2012 to present the project and the mission to the applicants, followed by individual interviews.
GERES	GERES works with people in an integration programme. GERES decided to work with EVOLIO, an NGO implementing integration programmes. The recruitment was organized by EVOLIO in close cooperation with centre for unemployed and a youth organization.
SWEA	Advisors are people who have been long term unemployed. Advisors were recruited through Job Centre Plus. Their training will form part of a national initiative to remove barriers to work- the Sector Based Work Academy
CARITAS	Caritas works with long-term unemployed people, people in an integration programme and volunteers. People for the integration programme are pre-selected by the job centre. Volunteers are recruited through PR activities.
FOCUS	Focus works mainly with unemployed people (some long-term unemployed) and some recently graduated young people, who seek experience. The recruitment was done through promotion (leaflet, mailing lists, news and social networks) and presentation at the Office for Employment. 12 advisors were selected and trained.
EAP	EAP works with students from professional schools. Agreements with two professional schools (for household technology and for electric technology) have been signed. The training served as an addition to the students' curriculum. The visits that they implement give a chance to put their knowledge and skills into practice.

Source: First project report

Detecting fuel poor households

Fuel poverty is not a term that households will apply spontaneously to themselves, hence they often need to be detected. They can be identified through a number of relevant indicators including [21]:

• The inability to pay energy bills,
• Cold damp living conditions,
• Disconnection from energy supply,
• Self-disconnection (in some countries),
• Debts owed to the energy supplier,

• Health impacts associated with poor living conditions,
• Homes with low energy performance

Thus, the first challenge for ACHIEVE when setting up local action plans to tackle fuel poverty was to identify those households that are facing problems in affording their basic energy needs. This challenge was tackled by exchanging experience between partners/countries: - looking to identify fuel poor households, - implementing site-tailored discussions and interviews with key actors and affected households - elaborating reports on the findings [22]. Based on the analyses and consultations, the partners decided on their target group – households that were identified to be the most prone to fuel poverty, as described in Table 2.

Table 2: Parameters for identifying fuel poor households

Location	**Used parameters for identifying fuel poor households**
Frankfurt, Germany	Results of the evaluation of the programme Energiesparservice, which offers visits to fuel poor households, show that 32 % of the households have a migration background, 66 % are unemployed and 20 % receive social welfare because of other problems. 35 % are single households, 18 % are single parent families and in 26 % of the households there are four or more members. The main problem for these households was their inability to pay their electricity costs. In Germany, there is neither an official definition for fuel poverty nor is there statistical data. There are only some indicators for fuel poverty: very low income or social benefit, problems to pay the bill, cutting off from power supply. More than 8 million people (thus about 10 %) in Germany use social support. The consumer protection association estimates that each year more than 800,000 households (that equals 2 %) are cut off from their power supply because they are not able to pay their bills.
Plaine Commune, France	Given the problems of private housing and socio-economic characteristics of the population, Plaine Commune appears to be particularly vulnerable to fuel poverty. The area is very exposed to poverty, with 30% of people living under the poverty threshold, compared to 13.6 % at a national level. In 2009, 21,546 people were in receipt of income benefits, and 4,649 households received financial aid to pay energy bills. This aid is proposed in the case of severe fuel debt and with the intervention of social services. There is no specific data or statistics to estimate the number of people in situation of fuel poverty. The tenants from private housing seem to be particularly vulnerable to fuel poverty in Plaine Commune: 78% of them live in a building built before 1975 (71,5% for owners, 69% for tenants of social housing). 53% of the buildings are heated by electricity, which is the most expensive type of energy in France (23 % for owners, 18% for tenants of social housing).
Marseille, France	Households in this region are extremely poor: between 50 and 70% of the population live below the poverty line. 20% of the population is unemployed and 30 % have part time jobs. The majority of the households benefit from social welfare (70% receive financial support for housing, 30% support for health security). Around 60% of the households benefiting from social welfare are families with children, including around 16% of families with more than 2 children and 25% of single parent families. In general, the thermal performance of the buildings' stock is very low in line with the age of the buildings' stock. Hence a significant part of the population is at high risk of energy poverty.

Ljubljana, Slovenia	The unemployment rate is currently slightly under national average – 9,9 % compared to the national 11,5 %. More than half of the buildings date between 1945 and 1990; this characterizes the housing stock as an energy inefficient one. Structure of social welfare does not allow bills to be paid by the welfare organization; they are paid by the individual regardless of circumstances. 11 % out of 813,531 households nationally are low income households. Thus they live below the poverty threshold. But if we take the numbers for fuel poverty, the percentage rises to 30 % of persons in Slovenia (British definition of fuel poverty). Target group are households on social benefit or receiving less than 300 EUR/month/person (as those often fall just short out of the social benefit system).
Plovdiv, Bulgaria	In 2010, 9,056 households applied for the Winter Supplement Programme and 7,138 of them received funding. The Winter Supplement Programme provides partial funding for households' heating bills. To receive funding from the programme a household has to meet certain criteria such as: income level, dwelling size, health or other conditions, etc. In the city of Plovdiv approximately 36% use wood or coal for heating, 23% use electric energy, 21% use district heating, and 20% of the homes are unheated. About 60% of the buildings are 30 years old or older, many of them constructed from prefabricated panels and are categorized as highly energy inefficient. The analysis showed that the target group are people who apply for funding through the Winter Supplement Programme and especially of people who are using inefficient ways of heating (for example, low-quality coal and electricity).
County of Wiltshire, UK	In 2010, 8.8% of Wiltshire (39,100 people) was classified as low income. Social welfare benefits include paying for rent, council tax relief, child care vouchers and winter fuel payments. In Wiltshire, 26,650 were claiming benefits in May 2011, 9.3% of the working age group (15-64). In 2011, 1% of Wiltshire's population (99,510) were of retirement age and older. This group is set to be the fastest growing group in all population. The Building Research Establishment estimates that around 12% - or 19,777 – of households in Wiltshire are in fuel poverty. The target group should, besides active recipients of benefits, also include households earning £15,000 per year or less. The elderly is also a growing target group.

Source: Achieve. *Report on the specific areas targeted in ACHIEVE.* 2012. http://www.achieve-project.eu/index.php?option=com_phocadownload&view=category&download=49%3Adescription-of-the-areas-targeted-in-achieve-d23aeu-version&id=1%3Aeu-targetareas&Itemid=6&lang=eeu

Reaching out to households

An important element of the ACHIEVE approach was developing a methodology for accessing the target households. The decision on methodology was based on learning from various projects, which showed that: there is a need for being proactive in approaching households, community engagement (neighbourhood events for example) demonstrates success, opportunities for co-promotion with partner organisations working with the target group should be sought after, promotion of the service through local media is useful and advisors could explore the possibility of promoting the scheme in ways that the community responds to: for example, by activities such as door-to-door canvassing to reach hard to reach households [23].

Bearing this in mind, the partners developed a variety of communication campaign approaches and tools to reach target households. The information about the project was given to target households by a variety of local actors, such as welfare associations / non-profit associations, municipalities and local authorities, utility providers, presentations in newspapers, unions of low-income, disadvantaged people, employment offices, social housing providers, social landlords, and community foundations

[24]. Communicating with agencies who work with families is important to gain access to the households. Additionally, German and UK projects have found that in order to empower households to make real lasting changes to the way that they use energy other agencies who interact with clients need also to be informed about the project: its aims and possibly key messages can help to keep households motivated [25].

There are many projects that have aimed to provide energy advice to households with the overarching aim of reducing household energy expenditures. A running theme of much of the partners' research demonstrated that web-based support tools can be very effective in communicating energy advice messages both to households and also to stakeholders [26]. Another approach, which turned out to be successful, is joining households together in a neighbourhood to help them to work together to save energy as a community competing against other such communities [27]. Also children may be a key agent of change as they are well versed in current discourses around environmental issues [28]. This learning could be incorporated into tailored energy advice reports to help motivate behaviour change in the whole household. Other examples put forward by partners suggest that a competition element with the prospect of prizes can help to stimulate households. Again, this may be an area where partners can explore the possibility of directing clients to such initiatives on a case-by-case basis [29].

The key messages communicated to the target households were shaped based on the inputs of focus groups and interviews, which showed that the emphasis should be on reduction of costs (not environmental matters), on the fact that it is a free offer (no long term engagement), free-of-charge devices, neutrality of the advisors and the structures managing them [30].

Implementation of the visits in households

Identifying the devices to be given to households

In order to manage energy and water consumption well, one has to have the appropriate knowledge as well as access to various devices in order to be able to reduce energy and water consumption. Due to their general financial situation, households facing fuel poverty are often the same as those who have less opportunity to purchase energy and water saving devices [31], or even simply have less or no information about their existence. The devices can be efficient light bulbs, appliances, and consumer electronics, thermometers and thermostats, weather stripping for windows and doors, transparent insulation foil for simple-glazing, tap aerators, dual-flow flush mechanisms, and even shower timers. One way to alleviate fuel poverty is to make these devices more accessible for households at risk, either by providing them, or by installing them. The impact of these devices can be easily measured in kWh or litres of water, which are easy to convert into monetary units [32].

The first step in deciding which devices to offer free of charge to households was to gather a list of possible energy and water saving devices and estimate their savings potentials, costs and ease of installation. The scope of devices was developed jointly by the partners, with the assistance of CARITAS experience. This resulted in a list of 26 devices to be potentially used [33]. It showed the devices that appear to offer the highest savings are those related to space and water heating. However, some appliances in this field (often those with the highest savings) will require more skill and time to install. The partners made their device packages and decisions based on the following aspects [34]:

• Time and skill needed to install the devices (e.g. drought proofing is really efficient, but it can take a lot of time and skill),

• Devices must fit to the household's situation: some devices may be systematically distributed (thermometers, CFLs, etc.), but some devices will be installed only when relevant (e.g. transparent thermo cover insulation foil for windows - only where single glazing is currently available),

• Availability and costs of each of the devices on the respective national markets (linked to the willingness of transferability and reproducibility of the project activities),

• Targets on energy savings and CO_2 reductions,

• Quality of the devices - people need to accept the material (user-friendly) and to be able to count on its efficiency for a long time (quality).

Advising the households

On the basis of the information and documents CARITAS brought to the consortium through its experience in Energiesparservice, the implementation of the household visits was prepared. The first step was organizing an Excel tool to gather and analyze data, and define the devices/tips to be given in priority. Next step was to organize the corresponding data collection sheets to report information about energy and water consumptions/habits of the households during the visits. Each partner adapted the final tools to its country context (language, energy prices and emission factors, heating systems, currency, devices used, etc.) [35].

Another step was to define the format of the visits. Generally, the following approach is used [36]:

• Procedure before visits: getting in touch with the household (appointment and first contact);

• First visit: analysis of water and energy consumption and habits;

• Second visit: installation of the most relevant devices according to previous observations and calculations from the first visit, likely to generate the best savings for the households; delivery of report and tips for behaviour change;

• Third contact (minimum 6 months later): this contact is made over phone to help evaluate the effects of the visit (currently a questionnaire is being finished).

Experience showed that a minimum of 8 hours is necessary for each household visit: travel, presence in the households (1-2 hours x2 visits), analysis of data collected at the household, and evaluation of impacts [37]. The number of energy advisors to visit a household varies in the countries, depending on the feedback received from focus groups and interviews at the beginning of the project, as presented in Table 3.

Table 3: Number of energy advisors for visiting households in project ACHIEVE

Partner	Number of advisors
IDEMU	The 1st visit is made in teams of 2 advisors, and the 2nd one by a single advisor.
GERES	The visits are implemented by two advisors at the start of the project. Then, if the energy advisors feel more self-confident, they may do the visits alone.
SWEA	2 advisors per visit for at least the first 5 visits. After this advisors will be expected to operate alone.
CARITAS	Two advisors, one with more experience, one with less, are to visit the households
FOCUS	First 1 – 2 visits of each advisor are done in pair with a supervisor, the next visits are done by one advisor.
EAP	At the beginning there will be 2 advisors per visit, later this could be changed to 1 per visit, depending on the feedback.

Source: Achieve Project Report 1.

The energy and water saving devices that are installed have two main advantages:

• The devices support/initiate a general talk about how the households can improve their energy and water use in their everyday life, as well as the importance of taking care of their consumptions. As such, they generate more savings than just those linked to the installation of devices (i.e. savings linked to behavioural changes, which are, however, difficult to assess);

• The devices make it easier to get into the homes. The devices are seen like a present by the families. The visit is essential to be able to make a first analysis of the situation (socioeconomic situation of the household, technical situation of the dwelling), and then find structural solutions that will allow more ambitious and more sustainable savings, through an intervention on the building envelope itself or on the appliances (including heating systems). Often, poor households are not aware that financial or legal support exists and could help them retrofit their home or find the assistance they need.

Home visits implemented through ACHIEVE are a starting point to detect and understand critical situations. However, it is essential to find a way to link this type of local projects to national schemes or even European regulations, and make sure that the proper level of action is activated when and where necessary. All materials developed or adapted for the purpose of ACHIEVE home visits service (and notably training modules and saving calculation software) are dedicated to be utilized by any organization willing to implement such a service.

Developing structural solutions

As much as the household visits are designed to make a lasting impact, they cannot bridge the structural components of the fuel poverty problem: they cannot improve energy efficiency of the whole building, they cannot guarantee financial support needed for large investments in fuel poor households, they cannot reduce the general level of energy prices, nor increase the income level of the households. Hence one of the objectives of ACHIEVE is to coordinate key actors into a concerted effort for formulating long-term solutions and develop a network for implementing the long-term solutions. The project seeks to develop a concept for addressing energy poverty at the European level, through a set of tested and assessed structural solutions and a widely transferable set of tools, so as to launch similar experiences elsewhere [38].

One key field to look into is social housing, where the majority of fuel poor families live. Social housing is organized very differently in the targeted countries. Table 4 shows the most critical barriers to energy renovations in the owner groups. In most countries, either high initial costs or (more frequently) long payback times represent a critical barrier. The landlord-tenant dilemma is another fairly widespread barrier [39].

Table 4: The most critical barriers to improving energy efficiency of the social/professionally owned rental housing in several EU countries

Source: Entranze. *Working paper: Literature review of key stakeholders, users and investors.* 2012.

Large scale efficiency retrofit is one key element of developing structural solutions for addressing fuel poverty [40]. Financial aspects are the key barrier in triggering energy retrofits (long pay-back time, access to funds). Currently there is a lack of understanding of the process, the costs and results of energy renovations among owners. ACHIEVE will help to inform them by providing reference data bases. Information should encourage owners to undertake such works [41]. For landlords and owner occupiers, ACHIEVE will provide information tools about retrofitting measures (costs, interests) and local/national existing financial mechanisms. These tools will provide clear guidance on whom to contact to receive further information and advice.

Another structural solution is to provide pedagogical tools for the households visited, to link the often already existing but dispersed information (about energy or water consumption, prices, contracts, payments, social, economical, health, etc.) and to give insight into bills, selection of suppliers, availability of financial assistance, etc.

Evaluating the results [42]

To properly monitor the effects of the household visits and advising, an evaluation of the results will be conducted in the second half of 2013. The aim of the evaluation is to monitor the success of the project and the measures developed, to identify potential problems and find solutions to improve the programme. To do this, the evaluation is divided in 2 general parts:

• an impact evaluation to analyse qualitative and quantitative effects of the project, and

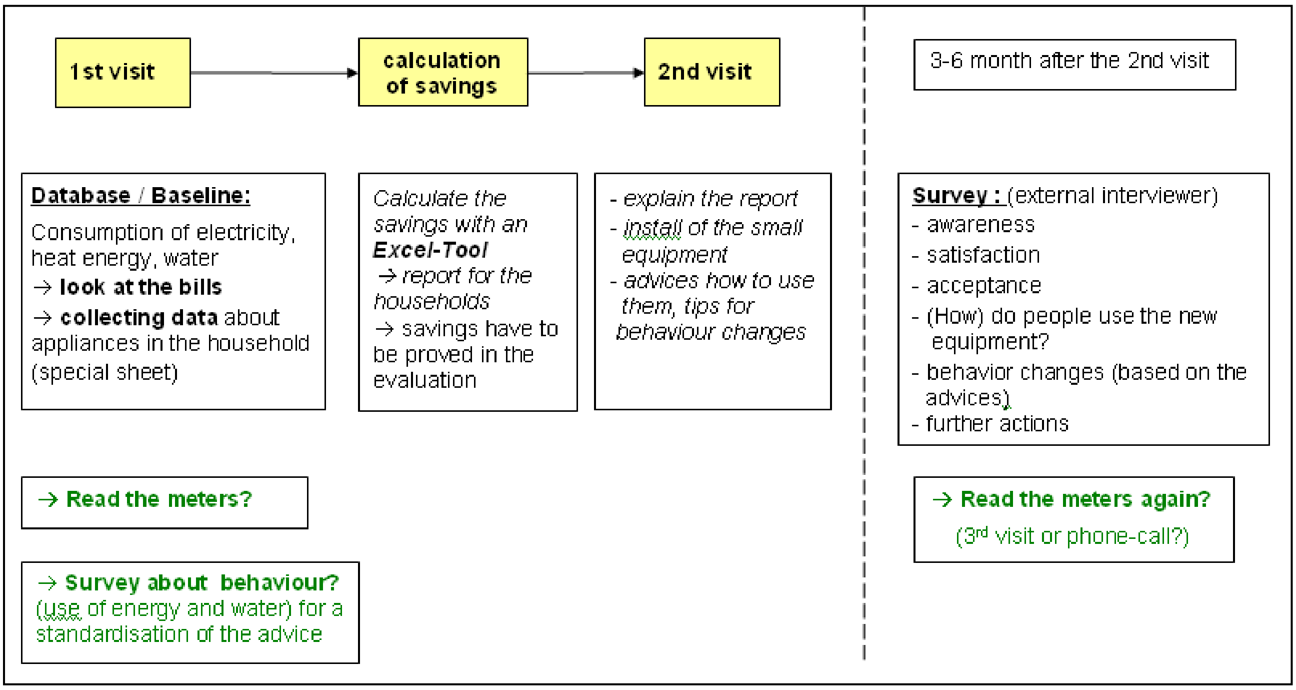
• a process evaluation to monitor the strategies set up within the project duration and the transferability of the methodologies and results.

The impact evaluation concerns the impacts that the actions undertaken by the partners have, for instance on environmental issues, social and security aspects, economic and comfort improvements for the households etc. This is based on quantified indicators and measurements defined in the initial evaluation plan, and précised in the interim evaluation report. Possible indicators include:
• The implementation of the advice (e.g. the number of mobilized local structures (associations, organisations etc.), management of financial support)
• The quality and quantity of the advice and savings (e.g. number of visits, the amount of savings, satisfaction of the households) and the cost-benefit-ratio
• The level of public awareness (e.g. total number of people reached by the dissemination of the project, participation to external /national / international events)
• The (re)integration of advisors into the labour market
• The number of landlords and owner-occupiers contacted and provided with targeted information on retrofitting measures.

The evaluation framework for the ACHIEVE-project is based on the experience of the evaluation of the Cariteam-Energiesparservice in Frankfurt 2009. It was adapted to the situation in the different countries. The concept of the development of structural solutions was added to the evaluation. The data-collection methodology is based around a mix of attitude and awareness surveys with specific target groups appropriate to the situation in each participating location.

The following chart shows the concept of the evaluation of the visits. At the first visit, a huge amount of data for the baseline-evaluation is collected. The savings from the installed devices and from the recommendations given start at the day of the second visit. Usually there is a period of 1-2 weeks between the visits. At least 6 months after the second visit, the conditions of the devices installed and the implementation of the recommendations are checked by a survey.

Table 5: Concept of the impact evaluation



Source: Achieve Interim Evaluation Report

Data collected at the first visit:
• Data about the actual consumption and cost of electricity, heat energy and water
• Data about the situation of the household (number of people, family situation, time spent at home every day, etc.)
• Data about the flat/house (size, age, energy standard, etc.), appliances used and water installations
• Data about the behaviour related to energy and water uses (e.g. way of ventilating the room, number and duration of showers, number of washes a week, etc.)

All the data is typed into an EXCEL-TOOL that was developed for the purpose of the project, based on the calculation tool of the Energiesparservice Frankfurt. The tool is used to calculate the savings generated by the visits and to collect data for the baseline-evaluation. That means that the baseline-evaluation is also a full part of the visit. The collection of these data can generally help to learn more about the situation of low-income households. On the other hand, it supports the visits and makes tailor-made advises and devices to the households possible. With the EXCEL-TOOL of ACHIEVE, a first calculation of the savings generated is possible. There are three different kinds of savings of energy and water:
• Savings based on the devices installed: These savings will be reached whenever people use the devices installed correctly (e.g. keep the CFL, always switch off the switchable power strip, etc.). In a report delivered to each visited household (during the second visit), people are given information about the potential amount of savings (in kWh, m³ and €) they can expect if they use the devices correctly.
• Possible savings by adapting behaviour: These savings will be reached if people follow the additional advices.
• Possible savings by own investment: These savings will be reached if people could buy new energy efficient appliances by own investment. They are given information about these possible savings (in kWh, m³ and €) in the report they are delivered.

A further possibility to check the savings is to read the meter several times. This is usually possible for electricity and/or water (if there is an individual meter for the flat). The consumption of heat energy, if it can be metered, is largely influenced by the weather and does not help to prove the savings. Special fields are foreseen in the EXCEL-TOOL to insert data read from the meter for electricity and water.

The questionnaire survey is the main part of the impact evaluation. It will be administered by telephone, and analyses the qualitative and quantitative effects of the advice. The survey will be organized by each partner / WP leader by themselves, by using the evaluation framework and a commonly agreed questionnaire. External support can be used by subcontracting.

For the evaluation, a minimum of 200 households visited in each local target area is necessary. Visits can be evaluated three month or later after the second visit at the earliest: households need some time to get experience in using the devices and to adapt their behaviour depending on the advise they receive (do they intend to make it an experimental behaviour or a new habitual behaviour, lasting in the long run?). They also need some time to buy new appliances by own investment if they wish to do so (like energy/water efficient fridges, washing machines etc.). Visits are planned not only during the heating period, to be able to reach the maximum clients within the 3 years of the project. The surveys should start in autumn 2013.

For the scientific validation of the analyses, a minimum of 100 feedbacks per target area or 50% of the visited households is necessary. People have to agree to be contacted again for the evaluation. It is thus necessary to ask whether a household would volunteer to participate in an interview at the first or second visit, and to complete a list of households that accepted to be contacted again for evaluation purpose. Individual survey results will be used to conduct an overall quantitative and qualitative assessment of the impacts of the project. It is recommended that an external interviewer asks the questions, to avoid socially desired answers. If the same people or even the same institution that the one offering the advice ask the questions, people could feel controlled.

The survey includes the following groups of questions:

• Acceptance and satisfaction: Awareness of the availability of the offer, reasons for using the advice, use of the energy saving products, satisfaction with the advice and the advisors

• Learning effects: Behaviour changes based on the advice, new appliances by own investment

• Multiplier Effects: Recommendation of the audits, public awareness of the project / of the issue

• Quantitative Effects: Savings of energy and water, CO_2, cost

• Further aspects: comfort, health, poverty etc.

• Socio-demographic items: sex, age, education, income, size of family, etc.

Some of these items, like family size, are already asked during the first visit. With the survey, it can be checked whether the number of persons has changed (could have an influence on the consumption of energy and water).

In addition to the questionnaire survey, some of the partners (precise) will organise face-to-face interviews with 10-20 households. The above described questionnaire will constitute the basis of the face-to-face interviews' process. This method will allow an extensive exploration of the level of satisfaction of the respondents regarding to the service proposed, giving them the opportunity to formulate recommendations. This way of data collection also minimizes non-response and maximizes the quality of the data collected.

The savings generated through the service have to be calculated by each partner. The savings are calculated for yearly savings and long-term savings (multiplying the yearly savings by the average lifetime of the devices and actions). A reduction is applied if the devices are not used correctly, especially for switchable power strips. People have to be asked questions about their behaviour changes in a very sensitive way, so that they do not feel controlled (e.g. "We would like to know if the devices fit for you or if we should improve the service. Here you can help us. How often could you switch out the power strip?"). There is another reduction of savings if devices are not used anymore. The experience of the Energiesparservice Frankfurt shows that some reasons can lead people to remove the devices they were given. For example, it can be people who did not like the colour of the light of the CFL, or dissatisfaction regarding the flow of water running from the tap, or malfunctioning of the water heater after installing the tap aerator, etc. It is helpful to ask for these reasons, to be able to improve the quality of the devices or the training of the energy advisors installing the devices. In addition to the savings that can be calculated in a precise way, some further savings from specific devices cannot be calculated exactly: it is savings generated thanks to the thermometer, thermo-hygrometer, key for the radiator, thermometer for the fridge or shower timer). On the other hand these devices are very important to support behaviour changes. Other effects, such as multiplier effects or further learning effects, cannot be counted in kWh at all. The savings will be taken to calculate a cost-benefit-ratio. For the transferability of the project it is necessary to know whether it runs cost-effectively. To calculate the cost-benefit-ratio, two groups of items should be compared: total costs of the project and total effects of the project.

ACHIEVEd so far

ACHIEVE's energy advisors have been visiting households in five European countries for more than a year now. The first results are therefore already visible (see Table 5). Please, bear in mind that the presented figures are not to be compared directly between countries as each of the covered countries applies a different approach to working with households (e.g. the devices given to households vary between countries hence also the savings are different). The presented figures are meant to show the first effects of the project.

So far, ACHIEVE partners have [43]:

• Designed and developed training content and modules for people recruited to perform the visits

• Designed and developed tools to be used by the advisors for the implementation of the visits (a guide on how to prepare and implement a visit, data collection sheets to collect data during a visit, a "software" to automatically calculate the savings generated by the energy and water saving devices distributed and installed...)

• Summarised, for organisations willing to develop such a service, the procedure and materials needed

• Designed materials to communicate on the service locally

• Reached a total of about 1000 households that received a visit,

• Trained 94 people to become advisors (among them, 57 students, and 37 volunteers/unemployed people).

Table 5: Estimated average savings from household visits of ACHIEVE

Country	No. of visited hh*	Avg. investment (€/hh)	Electricity savings (kWh/ hh/a)	Heating savings (kWh/ hh/a)	Water savings (m3/ hh/a)	Energy savings (%/ hh/a)	Water savings (%/hh /a)	CO2 savings (per site kg /a)	EUR savings/ hh/a

Key findings and lessons learned

As the project is still ongoing at the time of preparing this contribution, it is hard to draw final conclusions and lessons learned from the experience. However, some insights of what worked well and what mistakes can be avoided in the future are already available and presented in this chapter. The chapter is based on feedback provided by project partners during a project meeting [44] and interim report [45]

The first lessons from the project are oriented to the training modules for advisors. It was discovered that during training it is necessary to emphasize knowledge about social issues, so that the advisors are able to identify social problems (involve social workers in the training sessions so that advisors know how to identify social issues too, not only technical issues). It is also important to train communication requirements. The last important aspect is to clearly define the limits of the mission during the training in order to limit frustration among advisors and households (in practice it often happens that the household expects more than an advisor is able to give, as well as that advisors attempt to provide support for which they are not qualified to provide). In relation to this, it is important to better inform the advisors about possible solutions they can propose to households at the end of the visit (orientate them towards the proper structures).

In regard to selecting and training energy advisors several important findings came to light. The most important is that when recruiting energy advisors to be trained, a particular focus should be put on their social and communication skills: even if a large part of the work around the visits is technical (assessment and calculation of the main possible energy and water savings, advice given to households to reduce their consumptions…), the visits are also largely about “human” contact. Technical capacities can be strengthened, but this is not necessary the case with the ability to speak and listen to people. It is also suggested that visits are performed by two advisors, one of whom has an emphasis on technical skills, and the other has an emphasis on social skills or else one of whom is an experienced advisor and one a new advisor.

Another relevant finding is that people who wish to become energy advisors might have different expectations and the job does not necessarily suit them. To avoid disappointment when starting energy advising in practice it is suggested that the potential advisors do one visit before they get fully involved in the project, or have a movie to present the content of the mission – the aim is to clarify expectations before training. It is also advisable to work closely with the job agencies and employment centres in order to define the competences needed for energy advising.

When working with long-term unemployed people or volunteers, it is very likely that those who are trained to perform the visits will leave the programme when they find another job opportunity This means one has to plan regular new training sessions to train newcomers to the programme that replace the leaving advisors. Time dedicated to training activities should not be underestimated. This is the same for time dedicated to supervise/follow the advisors before they can be fully operational on their own (especially if the “turnover” of advisors is high). Training activities and general supervision of the visits are thus highly time consuming for project managers willing to implement a home visits service. It is a full time job for project managers. As a lot of support is needed to help advisors in the management of their own time, to plan the visits for them, to check the quality of the work and results that they are producing, it is advisable to receive some support from professional organizations when possible.

When dealing with households, it is of utmost importance to pay attention to their circumstances. Fuel poverty closely coincides with general poverty, which means that some of the households are very sensitive to their situation and are reserved in asking for support. It is advisable to have advising teams of one man and one woman, as it seems more acceptable for the households (in some cases it will even only be women who are accepted by the households). When working in areas where many immigrants are settled, it is preferable to work with advisors who are familiar with the languages of the immigrants.

Visits are a good occasion to get in touch with households who sometimes have not received any visits from “external” parties for a long time. As a consequence, the time needed for one visit can be much higher than expected, as people might have a lot to say to advisors (not necessarily strictly linked to the core purpose of the visit – this calls for social skills, as mentioned above). Also a lot of critical situations linked to unsanitary / inadequate housing or extreme poverty situations call for the need to organise, from the very beginning of the project, appropriate responses and procedures when such situations are needed. This means systematically linking with tenant/landlords mediation structures, sanitary services of the municipality, etc.

In regard to the local networks, the lessons learned are that creating and maintaining these networks (with social/health services mainly) is time consuming and it must be done regularly. One time contacts do not deliver long-term results. There can be barriers when working with social/health services. A possible solution could be sending a report on the results of visits (anonymous) to them to show and explain clearly the benefit of the visits.

Community based social marketing and energy efficiency – an evaluation of engagement strategies and domestic retrofit policies.

Aaron Gillich, Minna Sunikka-Blank

Department of Architecture, University of Cambridge

Abstract

It is widely acknowledged that efforts to reduce carbon emissions must consider strategies to improve the energy efficiency of existing building stock. A considerable number of policy options have been enacted to address barriers to energy efficiency improvements in the domestic sector. The Better Buildings Neighborhood Program in the United States has awarded competitive grants to state and local programs designed to transform the market for domestic retrofits. Therefore national level policy objectives are used to guide the creation of state and local programs and strategies that are specifically calibrated to their individual communities. These programs make use of similar but differing approaches to retrofit financing and end user engagement allowing for a comparative analysis amongst them. Many programs employ innovative methods of engagement with end users including community based social marketing strategies. This work examines case studies from two Better Buildings programs using a common methodology. This unique group of programs targeting similar objectives allows the opportunity to study the indicators for engagement mechanisms that most effectively translate policy theory into successful energy savings for the end user. In addition, it offers a discussion of community based social marketing in end user engagement strategies and policy design.

Introduction

This paper explores the issue of outreach in driving domestic energy efficiency retrofits. A number of barriers exist that limit the effectiveness of retrofit programs. This work explores some of these barriers and the past policy responses that have been used to address them. Furthermore, it argues that the community based social marketing (CBSM) methodology presents numerous advantages in reaching out to homeowners and driving participation in retrofit programs. Using two case studies from the Better Buildings Neighborhood Program in the United States, this work presents a methodology through which to approximate the quantitative impact of various outreach strategies as well as qualitatively explore the themes that deliver successful outreach for retrofit programs and better address the barriers present.

Barriers to Energy Efficiency Retrofits

The past several decades has seen considerable academic and policy focus directed at the topic of barriers to energy efficiency in the built environment [1][2][3][4][5][6]. Among these barriers, the low priority of energy issues, lack of information, upfront cost barriers, and split incentives have been highlighted as limiting the potential for retrofits in existing dwellings [7][8][9].

For the purposes of this work, the principal barriers to domestic retrofits can be summarized in three categories: upfront cost, information, and trust. The upfront cost barrier, or access to capital, is a self-evident barrier that often receives the majority of attention in policy solutions. Information is a slightly more complex barrier, as customers frequently indicated having either too much, or too little information upon which to make an informed decision. The barrier might be better described as a lack of time, as customers report rarely having the time required to filter the available information into what is useful. Additionally, the time required to plan and allow for the work itself is often cited as a barrier. Finally the barrier of trust can be disassembled into a collection of issues. Customers frequently report a lack of trust in the contractor, the program operation, or the promised savings. [10][11]

It is widely acknowledged that these barriers are pervasive and will not be addressed by any single policy mechanism or financial instrument [8]. Policies to incentivize domestic retrofits have tended to focus on specific technologies and often costly giveaways and rebates. Despite much positive progress, a significant energy efficiency gap remains [8].

An alternate behaviour model

Much recent work has highlighted the potential for behavioural economics to provide new perspectives on policy design [12]. However, historically, policies commonly rely on rational behaviour models to influence our energy use decision making and drive behaviour change.

The attitude behaviour model states that the provision of information will drive behaviour change, while the economic self-interest model assumes that individuals will change behaviour in order to maximize their own utility [10]. While these directly address the cost and information barriers discussed above, they have consistently underperformed against expectations. Both theory and practice have demonstrated that the provision of information and financing are necessary but insufficient drivers to encourage widespread adoption of energy efficiency measures [13].

CBSM builds on these theories and offers a clearer path towards enhancing communication between program designers and participants in two critical ways. It allows the delivery of targeted messaging that caters more directly to a given audience, and also enables a more interactive form of discussion that engages the end user rather simply disseminating information in a one sided manner [10]. CBSM is a methodology, not a particular outreach strategy or action. This methodology is described by Douglas McKenzie-Mohr [14]:

1. Targeted behaviour is selected.
2. Barriers and benefits associated with this behaviour are identified.
3. A strategy is designed using behaviour change tools to address these barriers and benefits.
4. The strategy is employed at the community level.
5. Program impacts are evaluated.

While these five steps describe a fairly intuitive process that is akin to improving outreach simply by reaching out to more people, the CBSM methodology accomplishes this using some less intuitive principles that draw on insights from psychology to enhance the persuasive power of the messaging. Principal among these is the idea of using social norms to reinforce group solidarity and reduce barriers to new ideas as a collective [10]. Social norms are useful because people value social relationships and therefore orient their behaviour in line with what they perceive is socially desired [15]. CBSM incorporates this idea into an outreach strategy in a fundamental way by targeting barriers at the level of social group rather than the individual [10]. It does this using the principle of the trusted messenger and the identification of leaders and authority figures within a social group. The next section will describe examples of this methodology and describe why it is particularly well suited to addressing barriers to domestic retrofits.

A new generation of retrofit programs

The CBSM methodology has been applied to a diverse range of social outreach and behaviour change campaigns. A number of studies have documented the effectiveness of CBSM towards fostering behaviour change [16] [17], as well as noted its potential applications to energy efficiency programs [18]. The application of CBSM to retrofit policies is a relatively recent, but increasingly popular trend.

The principle of establishing a program simply around the provision of information and financing faces several shortcomings. There is an accepted wisdom to the use of personalized information, relevant role-models, and personal service when engaging the behavioural aspects of energy use [19]. Some studies have indicated that the marketing and implementation of the program may even be more important than the size of the incentive [20]. It is important to note that CBSM is not a behaviour change campaign in the usual sense. Behaviour change programs typically centre on the provision of information or feedback, whereas CBSM uses these ideas to help define a more comprehensive methodology for outreach and engagement.

Financial incentives have historically targeted specific and isolated measures over more comprehensive whole-house solutions. In a national survey (n=505), people overestimated the impacts of small savings like changing light bulbs but drastically underestimated the savings realized through deeper retrofit measures such replacing appliances and HVAC equipment [21]. As this work will show, the use of CBSM can be effective at improving customer service and encouraging homeowners to take a comprehensive look at energy efficiency.

While providing giveaways and rebates are indisputably popular, they neglect to motivate those with non-financial barriers to retrofit actions. A number of behavioural studies suggest that a population is likely made up of groups with very differing, sometimes mutually exclusive motivations for pursuing retrofits, and furthermore, will have varying types of messaging and outreach to which they will be responsive [22].

It is well accepted that barriers are pervasive and must be addressed with a range of solutions [8]. Deeper retrofits require the engagement of homeowners with new feedback mechanisms, operation of new devices, adoption of new habits, and making long-term investments in their homes. All of these actions may be invisible, intangible, and grossly undervalued by the real estate industry [10]. CBSM offers a method of enhancing a programs engagement with the end user and addressing the barriers of upfront cost, information and time, and trust, more comprehensively.

Method

This work proposes to assess the application of CBSM to domestic retrofit programs on both a qualitative and quantitative basis. This will be done using two case studies from Vermont and Maine that form part of the Better Buildings Neighborhood Program.

The qualitative component of this work will explore the ways in which each program markets their services and reaches out to homeowners. This will focus on the ways in which these methods are calibrated to the specific barriers discussed in the previous section, with the aim of extracting principles that have broader applications for retrofit policy design.

The next element of this discussion seeks to define an outreach rate and an upgrade rate that will quantify the effectiveness of the marketing and outreach methods employed by each program. The outreach rate will be defined in terms of the percentage of initial program participants per household in the targeted area. The retrofit rate is defined as the percentage of program participants that proceed past the application stage and implement the recommended upgrade measures. The exact products and services included in both the initial program outreach stage and the retrofit upgrade stage varies by program and will be discussed in detail for each case study.

This work will consider the number of potential participants in the program to be the number of households in the targeted geographic region according to the most recent available census data from the US Department of Commerce [25]. The Fuller [18] review of 18 financing programs in North America employed similar criteria for potential participants, noting that this is a much larger pool than the actual potential customers. Ideally one would only include those eligible customers who could qualify for the loan and had not participated already [18]. However, the size of this smaller pool is unknown.

This work will strive to compare the outreach and retrofit rates of these two case study programs, however noting that methodological differences between them prevent a perfect like for like comparison. This is a frequent hurdle in program evaluation; however, the selection of two case studies that exist under the same Better Buildings policy umbrella allows for enough structural similarities that meaningful trends can still be extracted.

Better Buildings Neighborhood Program

Before describing the case studies with which this work explores the topic of CBSM, this section will briefly describe the policy environment within which the two presented case studies are set. The United States Department of Energy (DOE) and the office of Energy Efficiency and Renewable Energy (EERE) created the Better Buildings Neighborhood Program to improve domestic energy efficiency and drive the transformation of the retrofit market. [33]

A funding block of $508 Million USD primarily through the American Recovery and Reinvestment Act (ARRA) was awarded as competitive grants to 41 separate programs around the country. In each case, the programs applying for the ARRA funding fit into an established system of state programs already in operation. The Better Buildings portions of these programs run from September 2010 to the end of 2013[23]. This offers opportunities for comparisons across communities due to the federally determined framework and objectives set out by the DOE. This gives consistencies across program design, implementation, measurement, and evaluation [24]. This paper will consider case studies from two of these 41 programs: the Vermont NeighborWorks Program and the Efficiency Maine Trust. Before detailing the program descriptions and analysis, Table 1 gives a brief comparison of the outreach strategies employed by each program. Note that many of the outreach strategies overlap. This work will detail the differences in their implementation.

Table 1: Outreach strategies employed by Vermont NeighborWorks and Efficiency Maine.

Vermont NeighborWorks - CBSM	Efficiency Maine – Traditional marketing
-collaborating with existing NeighborWorks community group -traditional outreach: tv, radio, newspapers -earned newspaper publicity (unpaid) -town meetings -bill inserts/brochures/newsletters -events/energy parties -online/social media -phonathons -word of mouth referrals	Statewide -print media, newspapers -television, radio advertising -online/social media Local -word of mouth referrals -collaborations with contractors -collaborations with established community groups

Case Study #1 – NeighborWorks of Western Vermont

Program Description

NeighborWorks of Western Vermont is a non-profit organization founded in 1985. They are a community based social service agency created to engage homeowners in making health and safety repairs to their homes. Over the past decade they have gradually incorporated energy efficiency into part of their work scope. In 2009 they were awarded USD$4.5 million in funding from the DOE's Better Buildings grant program with the target of delivering energy efficiency retrofits to 1000 in homes in Rutland County, Vermont [26]. Rutland County has a total of 33,837 housing units [25].

The Better Buildings funding was used to establish the HEAT Squad, which is a specialized group within NeighborWorks dedicated to identifying and circumnavigating the barriers to retrofits in local groups using the community based social marketing methodology. NeighborWorks began the program with a staff of 12 people, 5 of which are now dedicated to the HEAT Squad energy efficiency program. The project hypothesized that one-on-one information sharing and greater attention to customer service could reduce or replace the need for cash incentives to drive the uptake of energy saving measures in homes [27].

The Better Buildings funding is used to create and deliver the HEAT Squad marketing, outreach, monitoring, and customer services. The Better Buildings grant is therefore not used for direct lending or rebates, but rather to drive participation in programs such as the state-wide Home Performance with EnergySTAR Program, which is separately funded through Efficiency Vermont and offers rebates on energy measures that are undertaken.

Program Process

The HEAT Squad has created a range of events and outreach activities specific to the communities in which they are operating. A HEAT Squad staff member typically guides the homeowner through the entire program process, including the selection of an appropriate contractor to carry out the work. Any follow-ups that the customer has are carried out with the same individual from the initial home audit to the final loan application process. A customer satisfaction survey (n=108) indicated that 98% of respondents were ‘very satisfied’ (84%) or ‘satisfied’ (14%) with the HEAT Squad customer service [27].

Typically, when a homeowner approaches NeighborWorks, a HEAT Squad representative will help them contact a contractor certified by the Building Performance Institute (BPI) and arrange a home energy audit. The audit is a 4-5 hour survey of the property that includes a blower door test, thermal imaging scans, and inspections of the insulation, heating, and ventilation systems. The audit identifies potential areas for improvement but does not offer any direct install measures such as weatherization or light-bulb replacements. The contractor will then issue a report with their recommendations, the potential savings, and the likely cost of the measures. Typical upgrade measures include insulation and weatherization, and heating system replacements. Should the homeowner decide to proceed with any of the upgrade measures, they will likely be eligible for a rebate offered through Efficiency Vermont. The average rebate offered by this incentive is approximately USD$1,200, and is funded via the state program, not the Better Buildings grant.[28]

While the NeighborWorks program and Better Buildings funding are not used to directly subsidize any of these measures, they have used their collective bargaining power to reduce the prices of the energy audit and thus reduce the upfront cost barrier to undertaking retrofits. Contractors typically charge USD$350-$500 for the initial energy audit. NeighborWorks have encouraged them to reduce this upfront cost to USD$100. If customers do proceed with the work the contractor will receive USD$200 in additional payment out of the USD$1,200 rebate offered by Efficiency Vermont. If customers do not proceed with any work, the contractor bears the loss for offering the audit at a reduced price; however, they typically deem this a worthwhile risk due to the increased workflow they receive through their relationship with NeighborWorks[28]. Contractors generally felt that NeighborWorks was a more trusted messenger than they could be on their own [11].

The increased workflow has resulted in the creation of 62 new contracting jobs in Rutland County. However, contractors have been cautious about the risk of taking on full time workers, so in addition, the HEAT Squad created the LaborWorks with NeighborWorks Program as an employment service with 9 further part-time contractors that can be called upon when needed.[28]

Analysis

This section will now consider the outreach rate and the retrofit rate for the NeighborWorks Program. Table 2 gives the results from the previous year using the most recent statistics available at the time of writing, as well as the total rates for the program to date.

Table 2: Outreach rates for NeighborWorks of Western Vermont in Rutland County, Vermont

Rutland County - Vermont	Past Year	Program to Date
Total Households	33837	33837
Data Period	Mar 2012 - Feb 2013	Feb 2011 - Feb 2013
Total Audits	487	1509
Total Upgrades (including in process)	195	627
Outreach Rate - Audits per Household	1.4%	4.5%
Upgrade Rate - Upgrades per Household	0.6%	1.9%

The results in Figure 1 show that the program has delivered consistent results since its debut in February 2011.

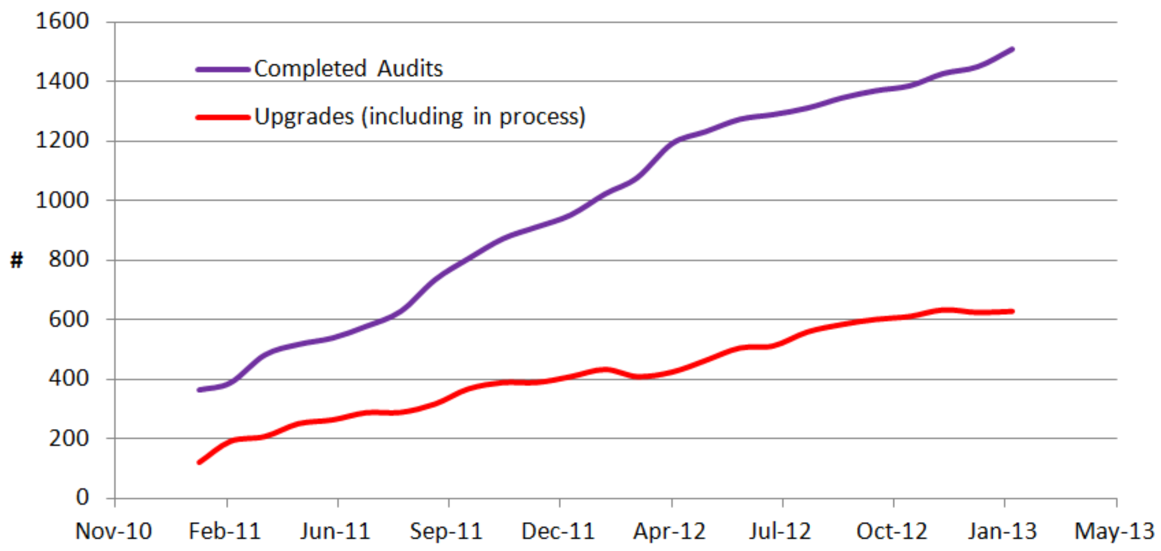

Figure 1: Audits and Upgrades under NeighborWorks program. [28]

As noted, the NeighborWorks program exists alongside the Efficiency Vermont Home Performance with EnergySTAR program. A report commissioned by the independent Cadmus Group [11] reviewed the success of the NeighborWorks program thus far. They compared the uptake of retrofit measures in Rutland County under the CBSM outreach program to those of the state-wide Efficiency Vermont program that relies on traditional outreach and media. They conclude that customers receiving the NeighborWorks messaging are 46% more likely to install measures. This was even more notable for lower income households (those earning below 80% of the average median income), where those that received outreach from NeighborWorks were 146% more likely to install measures [11].

The Cadmus evaluation also highlighted the fact that participants, including those that did not proceed from an audit to an upgrade, report a high likelihood of installing further energy-efficiency measures in the future.

Despite the fact that NeighborWorks and HEAT Squad use their Better Buildings funding for outreach and not to directly subsidize energy saving measures, the Cadmus report concludes the program delivers sufficient savings to be cost-effective on its own, with a net present value benefit to cost ratio of 1.72[11].

Case Study #2 – Efficiency Maine

Program Description

In June 2010, the DOE awarded the Efficiency Maine Trust a funding block of USD $30 million through the Better Buildings Neighborhood Program. The Better Buildings funding application was based on the funds primarily being used to finance Property Assessed Clean Energy (PACE) loans [29]. In April 2012, Efficiency Maine introduced the PowerSaver Loan Program and the Residential Direct Install Program to drive up signup rates. The programs serve a total of 725,577 housing units state-wide [25].

The program officially relies primarily on traditional outreach such as television, radio, web, and print advertising for their state-wide marketing strategy. They do however include some fundamental principles of CBSM in their local outreach when possible through collaborations with contractors or already established community groups.

Efficiency Maine commissioned an independent interim review of the ongoing PACE program [30]. From the USD$30 million ARRA Better Buildings funding, USD$20.4 million USD was used for the PACE revolving loans. PACE loans differ from typical financing by tying the value of the loan to the property not the individual. As of February 2013, a total of 158 Maine municipalities had passed PACE ordinances and entered into an agreement with Efficiency Maine to administer the loan program on their behalf, accounting for 74% of the state population. PACE loans are available in 5, 10, or 15 year terms at a fixed interest rate of 4.99%APR. Participants may borrow from USD$6,500 to $15,000, up to 100% of their home equity.

The average loan value under PACE is USD$12,898, with 50% of loans receiving the maximum USD$15,000 available [30]. Most participants were those in the top 35% of income by household. Projects below USD$7,500 are typically financed directly by the homeowner.

The suggestions in the interim program review included bundling loans with rebates, and subsidising the upfront cost of energy assessments needed for PACE loan applications [30]. These suggestions were taken onboard when Efficiency Maine introduced the PowerSaver Loan Program and the Residential Direct Install Program (RDI) in spring 2012 to expand the eligible participants. Both programs are also funded by the ARRA Better Buildings grant [30]. The PowerSaver Program covers the same home energy improvements as PACE, but offers a wider range of loan amounts, is available state-wide, and has slightly different eligibility criteria. The RDI program initially offered a USD$300 rebate towards air sealing and insulation work. In September 2012, the rebate was increased to USD$600 or six hours of work. The aim is for this to overcome the upfront cost barrier for homeowners considering retrofits. [31]

Program Process

There are two separate processes for the RDI program and the PACE/PowerSaver loan program. Customers approaching the RDI program receive a rebate for up to 6 hours of work towards direct install measures carried out by BPI certified contractors. The measures include a blower door test, thermal imaging, combustion safety testing, and air sealing and weatherisation measures. The homeowner must pay any costs out of pocket that exceed the USD$600 subsidy.

The retrofit measures targeted by the RDI program are meant to be direct install options with little follow-up or long term planning. The PACE/PowerSaver loans on the other hand begin with an energy audit that takes a more long term view at the potential retrofit measures. A BPI certified contractor will perform a survey of the possible measures including the generation of a thermal model that simulates the potential savings and payback periods. The proposed measures must demonstrate a minimum savings of 20% to be eligible for the loan.

The audit typically costs around USD$500 and is part of the loan application procedure, but does not include any on the spot improvements. The program designers hoped that customers would use the RDI direct install program as a stepping stone to the deeper retrofit measures of the PACE/PowerSaver loans. To incentivise this, homeowners may count their RDI measures as meeting the 20% energy savings threshold required for the loan, thus removing a barrier to the application process. [31]

Analysis

This section will discuss the outreach and retrofit rates for the RDI and PACE/PowerSaver loan programs. While there may be some overlap in the customer base between the two programs, these statistics are not presently available.

Table 3: Outreach rates for RDI Program

	Maine RDI
Total Households	725577
Data Period	Apr 2012 - Feb 2013
Total Outreach	2752
Outreach Rate per Household	0.4%

Table 3 gives the outreach rate for the RDI program. Since there are no follow on steps for the process, the outreach rate is simply the percentage of RDI customers per household. Note that the RDI program was introduced partway through the Better Buildings grant period to help drive further turnout. The cumulative total of RDI completions since the program’s introduction, as shown in Figure 2, demonstrates the rapidly increasing popularity of the program, particularly since the benefit was raised from USD$300 to USD$600 in September 2012. The trend suggests that the outreach rate indicated in Table 3 will increase significantly before the program's completion.

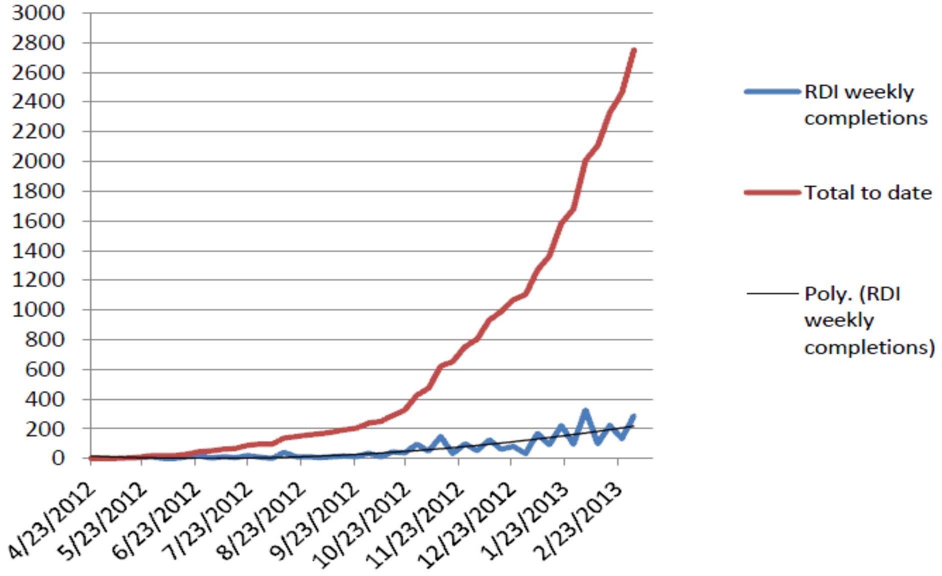

Figure 2: Number of RDI Completions.[31]

The outreach rates for the PACE/PowerSaver loan programs can be calculated in the same way as that of the Vermont program. Since the energy audit typically costs USD$500, customers seldom undertake it unless they plan to make the following step of completing the loan application. As such the completion rate from audit to application is very high and for the purposes of this calculation the outreach rate can effectively be taken as the number of loan applications per eligible household. The decrease from the number of applications to the number of upgrades is due primarily to loan applications being rejected or customers withdrawing from the process.

Table 3: Outreach rates for PACE & PowerSaver Loan Programs

Maine PACE & PowerSaver Loans	**Past Year**	**Program to Date**
Total Households	725577	725577
Data Period	Mar 2012 - Feb 2013	Jun 2011 - Feb 2013
Total Applications	1253	2003
Total Upgrades (including in process)	358	488
Outreach Rate - Applications per Household	0.2%	0.3%
Upgrade Rate - Upgrades per Household	0.05%	0.07%

With an average loan value of USD$12,838, the PACE and PowerSaver programs have closed loans totaling a value of USD$4,993,806 as of 02/10/2013.

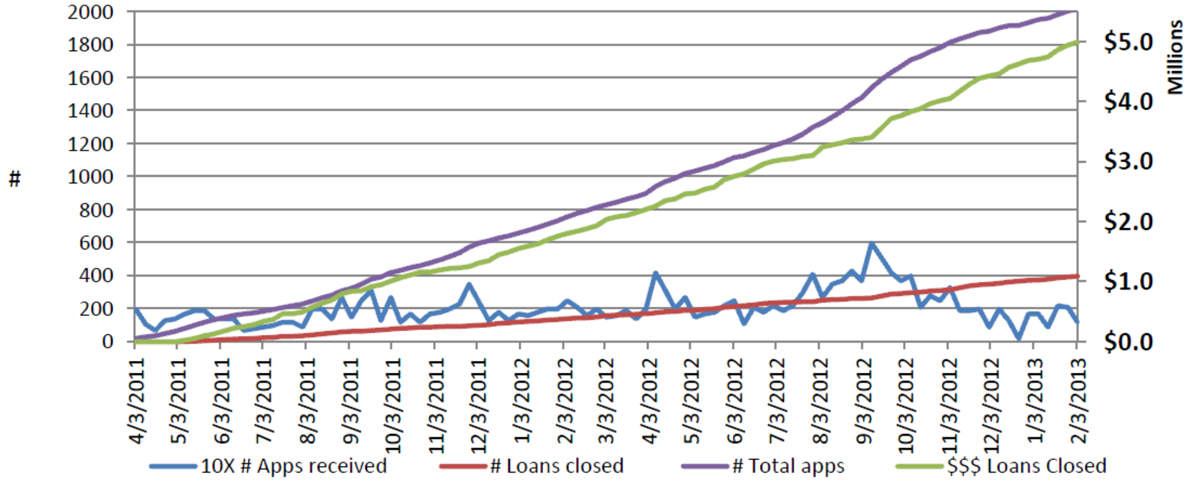

Figure 3: PACE and PowerSaver Loan Tracker.[31]

The very recent downturn in the application rate is presently unexplained. Program organizers theorize that it is perhaps due to the rapid escalation in RDI completions, and the limited resources of contractors to meet the demands of both programs simultaneously. This further suggests that if customers are using the RDI measures as a stepping stone to the deeper retrofits, then the program will likely see an imminent increase in PACE/PowerSaver loan applications.

Findings

The two case studies highlight several key ideas about the application of CBSM to domestic retrofit programs. The available data set does not permit a thorough investigation of customer motivations or a detailed analysis of free-ridership and spillover effects from other initiatives. While such methodological constraints and operational differences between programs will always cloud the potential for direct comparisons, there are some trends that can still be gleaned from the available data. Several such comparisons will now be explored in turn.

Fuller's review of 18 financing programs in North America found that on average most upgrade less than 0.05% of their potential customers in a year [18]. By this measure, both the Vermont and Maine loan programs have therefore reached more homeowners in the past year than an average loan program. Furthermore, based on the increasing outreach rates shown in Figures 1, 2, and 3, it is highly probable that the outreach rates will only improve as the programs move towards their conclusions at the end of 2013.

The NeighborWorks Vermont program utilized a CBSM approach and achieved outreach rates and upgrade rates roughly an order of magnitude higher than the Efficiency Maine PACE/PowerSaver Loan program, which relied on a traditional marketing strategy state-wide and employed CBSM principles where possible. The NeighborWorks CBSM program even delivers comparable outreach rates to the RDI direct install rebate program, which offers a higher financial incentive. Note that the link between the outreach rate and the CBSM strategy as calculated in this work demonstrates a correlation, and not a causal relationship. Nonetheless, the correlation supports the idea that CBSM is a useful tool in overcoming barriers to retrofits.

The Cadmus Report [11] included an analysis of participant motivation that was able to assign a causal relationship by comparing the results of the NeighborWorks CBSM program to the state-wide Efficiency Vermont program. They conclude that customers receiving the NeighborWorks messaging were 46% more likely to install measures and lower income households were 146% more likely to install measures [11].

The Efficiency Maine PACE/PowerSaver loan program possesses several features that enable it deliver favourable outreach rates compared to most loan programs. A significant tool is its tie-ins with the RDI direct install subsidy which lowers the upfront cost barrier. Additionally, while the program does not officially use a CBSM approach, it does incorporate several of the principles of CBSM into its marketing. The Opinion Dynamics interim report [30] observed the effective use of contractor networks and word of mouth in generating awareness of the program as well as enabling contractors to be the trusted messenger on the program's behalf.

Efficiency Maine holds monthly webinars in which it relays program information as well as training items regarding customer service and sales. This not only improves relationships with clients, but helps organize a cohesive narrative between contractors and gives unity to the Efficiency Maine brand. There are over 100 contracting firms around Maine, over half of which work with the RDI and PACE/PowerSaver programs. Over half of these participating contractors consistently attend the monthly webinars. [31]

It is noted in other behaviour change campaigns that as the sample size increases, the effect size decreases [32]. The results in this work agree with this principle. The Vermont program has roughly 5% the target population of the Efficiency Maine program and yet a similar number of total staff members. Smaller programs within tightly-knit communities have evident advantages over larger populations in delivering local and personal customer service. The success of Efficiency Maine's outreach therefore offers some useful insights in how to bring such programs to scale.

Efficiency Maine began by trying to artificially implant a community outreach structure into different community groups around the state. It created field offices and sent staff members door to door to generate interest in the program. They encountered disinterest and even resistance, and realized that their groups were outsiders and thus not suitably trusted messengers.

They therefore adopted the more traditional outreach strategy described in this paper, and turned to contractors as the focus of their community outreach. Additionally, where possible they seek collaborations with local groups that already have an established presence in their communities. Fostering these connections then allows their community presence to grow organically via the established trusted messengers, allowing them very high outreach rates in some communities. [31]

The NeighborWorks experience supports this idea, having held an established community presence for over a decade before directing their efforts to energy efficiency in recent years.

Conclusions

This work attempted to explore the application of the CBSM outreach methodology to energy efficiency retrofit programs and comment on the utility of a CBSM approach in addressing particular barriers to retrofits. It did this using two case studies of ongoing programs under the Better Buildings Neighborhood Program in the United States. These case studies were used to demonstrate qualitatively the benefits of a CBSM approach at addressing the barriers of upfront cost, time and information, and trust. Where the data permitted, the study also attempted to draw quantitative correlations between program outreach rates.

This work showed a positive correlation between the use of CBSM and increasing outreach rates, as the NeighborWorks Vermont program achieved higher outreach rates than the Efficiency Maine PACE/PowerSaver Loan program, and rates comparable to those of the RDI program which had higher financial incentives.

The Cadmus analysis of participant motivation was able to assign a causal link between the CBSM messaging of NeighborWorks and found a 46% increase in the installation of retrofit measures compared to state-wide rates. Among lower income households the CBSM outreach corresponded to a 146% increase suggesting that CBSM is particularly well suited to expanding the available audience for retrofit programs.

The Efficiency Maine PACE/PowerSaver program still achieved high outreach rates for a loan program, and the trends suggest this will only increase as the program continues to the end of 2013. The higher outreach rates of NeighborWorks Vermont enjoy the advantages of having a smaller target audience, and higher number of employees per potential customers. The Efficiency Maine program therefore offers a useful example of how to expand the principles of a CBSM strategy to a larger scale, while maintaining a state-wide outreach based on traditional marketing strategies. They did this by fostering strong relationships with the workforce and using the contractors themselves to drive community outreach. They also allowed partnerships with existing community groups to grow organically, encouraging them to be the trusted messengers, rather than trying to artificially implant a CBSM structure into a community.

This work gave examples of how the use of CBSM strategies can more directly address the barriers of upfront cost, time and information, and trust. Vermont was able to address the upfront cost barrier by collaborating with another program and using collective negotiation to create a mutually beneficial arrangement with contractors that both reduced the upfront cost for homeowners and provided additional business and created jobs for local contractors. The barrier of information and time is also better addressed with CBSM as evidenced with the high customer satisfaction rates of the HEAT Squad team compared to the state-wide results of Efficiency Vermont [11]. The barrier of trust is addressed almost by definition when employing the use of trusted messengers to deliver program information as demonstrated by Maine’s strategy in allowing relationships with trusted messengers to grow organically.

In evaluating the utility of CBSM strategies for addressing barriers to energy efficiency retrofits, one must consider many factors that were beyond the scope of this paper. Factors such as cost effectiveness, and the overall energy savings achieved are obviously critical to an energy efficiency program’s success. Furthermore, the downstream effects of different marketing strategies should be explored. Customers exposed to CBSM strategies expressed a strong willingness to undertake future retrofit work, and this effect should be investigated. The application of CBSM to retrofit programs is a relatively new development and many of the programs are still ongoing. While the long-term success of CBSM as a tool to overcome barriers to retrofits remains to be proven, the present results show much promise. Future work should attempt to break down the cost structures of various approaches to outreach and engagement and assess the implementation costs of the different programmes.

Do we know the way now? Using international comparison to confirm a policy package that can deliver energy savings from appliances

Lena Tholen, Wuppertal Institute for Climate, Environment and Energy

Stefan Thomas, Wuppertal Institute for Climate, Environment and Energy

Thomas Adisorn, Wuppertal Institute for Climate, Environment and Energy

Abstract

What are effective packages of policies and measures to stimulate energy efficiency from appliances? In the project "bigEE – Bridging the Information Gap on Energy Efficiency in Buildings", we have addressed the question in a systematic way – by combining theoretical evidence on what policy support markets need, and an international comparison on which packages of policies have worked well. The project develops an international internet-based knowledge platform for energy efficiency in buildings (www.bigee.net). Hence, it must provide evidence-based information.

On the theoretical side, presented in earlier papers, the analysis starts with the barriers but also market-inherent incentives that the different types of market participants face. This enables to identify, which regulatory, economic and other policies and measures need to be combined to overcome barriers and strengthen incentives. On the empirical side, model examples of good practice for policy packages have been collected and their design and impact compared. Finally, the model examples, lessons learned, and the preconditions for their transferability are used to validate the generic policy package identified in the theoretical analysis.

In this way, we were able to support the well-known recommendable policy package for appliances, combining MEPS, mandatory energy labelling, and information of consumers and training of sales staff, financial incentives where appropriate, and measures to stimulate innovation and market introduction such as award competitions and public or co-operative procurement, with fresh evidence. The paper will present the recommended package as well as a comparison of existing national policy packages from Brazil, China, Japan and California (USA) and what we learned from it for effective packages and implementation.

Introduction

Policy-makers worldwide have increasingly recognised energy efficiency as a key factor to reduce the energy consumption and to realise a sustainable energy future. In this context, appliances, as a major source of energy use should be a focus to control the energy consumption and to reduce greenhouse gas emissions. The most energy-efficient appliances available today can save between 60% and 85% of energy compared to inefficient models that are still on sale in many countries [19]. The energy efficiency efforts do not only achieve high energy saving potentials. CO_2 emissions can also be reduced cost-effectively from a life-cycle perspective and thus provide economic benefits. Furthermore, a policy package that concentrates on the whole life-cycle of the product can address other sustainability aspects like other resources and health aspects and realise several co-benefits like an increased competitiveness. By offering innovative products this can open up new (niche) markets, which will likely have a positive effect on the economy as a whole [8].

Yet, at least as many papers have concluded that in spite of their cost-effectiveness, these savings are not going to be realised by market forces alone (e.g., [11]; [15]). This lack of market uptake results from a large variety of barriers and market failures that hinder market actors to manufacture, sell or buy energy efficient products [18].

Therefore, the challenge remains to reach all relevant target groups and to transform the appliance sector in a way that efficient solutions will no longer be an exception but become the standard choice of market actors. We have to abandon the prevailing ‘as-fast-and-cheap-as-possible’ construction approach, because it systematically ignores lifecycle costs and creates appliances that will be wasting enormous amounts of energy and money throughout their whole lifetime [15].

To reach this goal, actor-specific and well-designed packages of policies are required. Policy-makers should be encouraged and informed to combine a selection of instruments tackling the most important market barriers.

The web-based platform “bigEE.net - Your guide to energy efficiency in buildings” was developed to make structured information easily available and to enable policy-makers to make well-considered decisions. The demonstration of the practicability of different policy approaches and the successful implementation can be a key motivation for policy makers to transfer a similar policy or to improve existing ones. The project seeks to address this problem by summarising knowledge and presenting comprehensive, independent and high-quality information on energy efficiency in buildings and appliances on its international website. In particular, the project aims to make the information about existing policies and technologies throughout the world comparable and present it in a targeted way so as to support investors and policy makers in making the right – energy-efficient – choices.

Many studies (e.g. [7]; [15]; [17]) have argued that different types of policies – most notably regulation, financial incentives and information, or “the sticks, the carrots, and the tambourines” – need to be combined into packages in order for them to be effective and make energy efficiency easy and attractive for market actors. However, we are not aware of a systematic and comprehensive analysis to underpin and derive what kind of policies and measures the packages should consist of, and how they need to interact.

To develop the evidence-based information required for bigee.net, we addressed in a different way than usual the question of how policy can support improved appliance energy efficiency most effectively: We combined (1) a theoretical, actor-centred analysis of market-inherent barriers and incentives for all actors in the supply and use chain of (energy-efficient) appliances to derive a recommended package combining the types of policies and measures the actors need to overcome all these barriers, with (2) empirical evidence on model examples of good practice policy packages to check if pro-active countries have indeed used the combination of policies we derived from the actor-centred analysis. While the actor-centred analysis has been presented during the EEDAL conference 2011, this paper focuses on the empirical evidence.

In the paper, we will therefore briefly describe the bigEE project to illustrate the project background and its scope. Next, the methodological approach to developing the recommended policy packages for energy efficiency in appliances will be presented. Then follows the resulting strategic package approach to energy efficiency policy for energy efficient appliances, proven in practice by a comparison of the existing national policy packages from California (USA), China, Japan, and Brazil.

bigEE – Your guide to energy efficiency

bigEE

Your guide to energy efficiency in buildings.

“bigEE – bridging the information gap on energy efficiency in buildings” is a project by the Wuppertal Institute, with financial support from the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU). Within the project, the international internet-based knowledge platform “bigEE – Your guide to energy efficiency in buildings was developed (see: www.bigee.net). Three comprehensive guides – for building design and technologies, for appliance energy efficiency and for policy implementation present detailed information about how to increase energy efficiency and how policy can support this development. Apart from information universally applicable for policy makers and investors from all over the world, up to five partner countries will be addressed, starting with China and South Africa and possibly soon Mexico.

A central task for bigEE is collecting and updating information on the best available technologies (BAT) on a comparable basis, as well as the gathering of possible energy saving potentials (depending on different scenarios and market developments) and their net economic benefits, and the demonstration of successful implemented good practice policies. To achieve the required quality of information, the bigEE team collaborates with scientific institutes and with existing initiatives (international and in partner countries) including the United Nations Environment Programme (UNEP) and the International Energy Agency (IEA). Furthermore, bigEE engages in the active dissemination of information relevant for policy-makers in the partner countries.

Methodology[1]

Different steps are needed to derive an 'ideal' policy package, which increases the energy efficiency of appliances and which assist the various actors in overcoming their specific barriers and strengthening their incentives. Experience from pro-active countries and an analysis of market barriers show that several instruments will need to interact and reinforce each other in a comprehensive policy package. The question we have to answer then is which specific policies and measures should be combined in strategic policy packages to address the barriers and incentives, and how they need to interact. We used a two-step approach combining (1) an actor-centred theoretical analysis with (2) an empirical proof.

The methodological approach we use on the theoretical side is based on and seeking to extend and refine the theory-based policy evaluation approach, which goes back to experiences with energy efficiency policy evaluation in the USA (e.g., [2]) and was applied and developed further more recently within the EU project AID-EE (cf. www.aid-ee.org). Originally, the theory-based approach was developed for ex-post evaluation of existing policies. It aims at understanding how policies work and the factors of success or failure by defining for each step of implementation a theory on the implementation mechanism or strategy of the step and indicators to measure success of the step and the instrument overall. It can be used both for process evaluation and for theoretically explaining the reasons for the impact achieved – success or failure. The AID-EE project has pointed out that this can also be used to examine ex ante whether policies are expected to be successful, and therefore guide policy design. In bigEE, we developed this further to analyse, which implementation strategies and policies need to be combined to a package to achieve success in realising energy efficiency.

The actor-centred theoretical analysis starts with the identification of all relevant market actors along the value chain of the national market for the type of appliance concerned. In order to be able to adequately design and implement energy efficiency policies and measures, political decision makers must have good knowledge of the concerned market actors and thoroughly analyse the specific incentives and barriers faced by each of them. These market actors are for instance manufactures, whole sales, retailers, investors and users. All of these actors make decisions that can influence the energy performance of appliances in question.

After identifying the relevant actors in the appliances market, it is necessary to put the focus on the actor-specific barriers and incentives. All actors have some inherent incentives to develop, offer, demand or invest in energy-efficient solutions, but are on the other hand facing strong barriers that prevent them from choosing energy efficiency [6]. The challenge is to identify the reasons that cause actors to be inclined towards or to refrain from choosing low-energy appliances - these barriers are the major reason why there is a gap between potential and realised energy savings. Each actor group has its own characteristics and therefore every policy has to pay attention to these. By knowing the barriers and incentives the policy package can be adapted to guarantee desired results and achieve the greatest possible success [15]. Barriers are for example the lack of knowledge and motivation, the high search and transaction costs, the uncertainty about the related monetary and other benefits,

---

[1] The actor-centred analysis was already published during the EEDAL conference 2011 (see [14]). For a detailed analysis of this theoretical approach please refer to this paper of visit www.bigee.net

capital constraints, the investor-user barrier or technical barriers. In comparison to these actor-specific barriers several incentives can be identified like saved energy costs, the increased (re-sale) value of the appliance or the contribution to environmental protection. The relevance of some of these barriers and incentives may differ from country to country depending on national circumstances [6]. Two questions remains:

- How can the immanent incentives that market actors have be strengthened?
- How can the specific barriers that market actors face be overcome?

In this context policy is needed to overcome the respective barriers and to exploit the existing potentials. For policy makers it is essential to identify the different barriers and incentives and to develop appropriate remedies in the form of tailored policy packages, which aim to remove the barriers and strengthen the incentives identified [6]. The overall goal for policy makers should be to move the market towards to the best available technology and to the best not yet available technology (BNAT) with very high energy efficiency levels. There are a number of direct ways to target the barriers and incentives. This ways can be called implementation strategies. By way of addressing the actor-specific incentives and barriers, these strategies aim to make energy efficiency feasible, easy, and attractive, and eventually even the default (i.e., the behavioural norm or even the legal standard). An implementation strategy may act on several incentives and barriers. Some examples for these implementation strategies are:

- Bring down the first costs of energy-efficient appliances via market transformation or economics of scale
- Increasing motivation by making it as easy as possible to choose the energy efficient option – make appliance energy consumption and quality visible and comparable; use social marketing tools
- Improve access to capital, e.g. subsidize purchase of energy- efficient appliances, establish innovative financing mechanisms

As a next step, political decision makers but also non-governmental actors such as energy service companies must take concrete measures and enact actual policies in order to put the implementation strategies to work. For each of the implementation strategies, a package of policies and measures is needed to make it work, and since also a combination of implementation strategies is necessary to tackle the manifold barriers, these targeted policy packages must then be merged into a consolidated overall package, which is ultimately capable of kick-starting a real market transformation in the appliance market. It is essential to have a look at the technology and the product-specific potential and to demonstrate the best way to increase energy efficiency with a package of different but coordinated instruments. Some instruments are alternative to each other, but usually several instruments should be coordinated in an adequate policy package to establish synergy effects and realise the implementation strategy.

The strategic policy package to deliver energy efficiency in appliances

According to international research and experience, a package of several types of consistent and technology-specific and actor-specific policy instruments is useful to be most successful. Instead of a single instrument, a package offers the opportunity to achieve synergies between single instruments, and to reach all market actors [15]. The ideal policy package consists of consumer-oriented instruments and instruments for manufacturers (to build a “push and pull strategy” to push consumers and manufacturers away from energy intensive practices and to pull them towards energy efficient ones). Each policy is tailored to overcome one or a few certain market barriers and to strengthen the actor-specific incentives, but none can address all of these barriers and incentives. Therefore, the impact of well-combined policies is often larger than the sum of the individual expected impact [7].

Different policies addressing the demand-and supply-side actors of markets should consequently be properly combined according to national circumstances. This does not mean that governments seeking to improve the energy efficiency of appliances have to implement all possible policies in order to be successful, but they should combine a selection of instruments tackling the most important market barriers.

As our analysis has concluded and successful countries have demonstrated (cf. also Table 1 below), a comprehensive and coherent policy package for energy efficiency in appliances will usually provide a sound balance between clear mandatory measures, incentives, information and capacity building. It also needs a governance framework to enable implementation of these policies.

The presentation starts with this overarching governance framework for energy efficiency that is general to appliances. Afterwards, the specific parts of the package with concrete policies and measures for energy efficiency in appliances follow suit.

The governance framework for energy efficiency

In the bigEE recommended policy packages, the general governance framework serves to guide and enable implementation of the sector-specific policies, as well as to remove price distortions in energy markets that would make energy efficiency improvements appear less cost-effective than they are.

A Policy Roadmap with a clear timetable and targets will guide policy-making and signal to the market a reliable political support for energy efficiency. The targets should be: Prepare markets for mainstreaming highest energy efficiency levels.

The administrative infrastructure and the funding for the other policy elements need to be in place. This includes (1) an energy agency or similar institution for co-ordinating activities. To ensure (2) stable funding, government energy efficiency funds and/or energy companies with the task to achieve energy savings via energy efficiency programmes are also required.

Energy prices should ‘tell the economic and ecological truth’. In addition, they must also consider social issues and should encourage energy sufficiency. It is essential that subsidies for energy production or on energy prices be gradually removed - governments are advised to rather use the budget saved to fund energy efficiency schemes for low-income households, so as to keep energy bills affordable instead of keeping energy prices artificially low. In addition to removing energy subsidies, energy or CO_2 taxes will finally internalise environmental damage and threats to health into final energy prices.

How the specific policies and measures for energy efficiency in appliances interact

For energy efficiency in appliances, the appliance-specific instruments can be packaged as follows:

- Mandatory minimum energy performance standards (MEPS) are the most important policy for energy efficiency in appliances. They should be created by law and then strengthened step by step every three to five years, to finally require energy efficiency levels equivalent to very energy-efficient appliances. MEPS reduce transaction costs as well as the landlord-tenant and buyer-user dilemma by removing the least energy-efficient models from the market. They should, however, always be at least as stringent as the energy performance level leading to least life-cycle costs. In a transition period before a law can make MEPS mandatory, a voluntary standard may help. Preferably, other statutory requirements, such as individual metering, would complement the legal framework.

- Energy labelling works together perfectly with energy performance standards. MEPS usually eliminate the worst products from the market but do not harness additional energy-saving potentials. Energy labels present the best products on the market and are primarily made for buyers and end-users. They are, thus, one element of the package to “reach the energy efficiency top”, like the others that follow here. Mandatory energy labelling schemes mostly compare the products on a classification scale to show the best but also the worst products on the market. Such classification labels are, however, useful only if there is a large enough spread of energy efficiency levels between the models of a type of appliance offered in a market. Where that is not the case, an endorsement label for the most energy-efficient models only may be an alternative. Furthermore, an information campaign is needed in order to promote the label and to raise the consumers' awareness towards energy efficiency.

- The market should, furthermore, be prepared for the next step(s) of MEPS regulation towards very efficient appliances through policies tackling the substantial information deficits and financing barriers. This includes the already mentioned energy labels, but also advice, easy-to-use product choice and life-cycle cost calculation tools. Policies for consumers should be designed to address specific actor groups but also the broad public. Highly consumer oriented approaches can bring energy efficiency on the agenda for many actors like end-users and investors (e.g. by TV spots or included in the school curriculum). Such programmes can address the rebound effect. These effects occur when consumers buy bigger and bigger appliances, such as large televisions of refrigerators or when they improve their desired thermal comfort (e.g. higher indoor temperatures in cold seasons). Policymakers should try to limit these rebound effects e.g. through motivation and information campaigns on energy-efficient user behaviour.
  Financial incentives - such as rebates, grants and tax incentives – can guarantee a broad market introduction of energy-efficient appliances. The latter are more costly than other instruments, so they will be particularly useful if there is a very large spread of energy efficiencies in the market and, hence, large energy cost savings are possible. In addition, they can often be limited to a certain time period (e.g., two or three years) until the market offer and demand has switched to the energy-efficient models. For low-income households, financing support may be needed to purchase very energy-efficient appliances that have a higher upfront price but pay back over their lifetime through lower energy bills.
  Policies, which can be perfectly combined with education and financial instruments, are policies addressing the life-cycle of the product including other sustainability aspects like resources, recycling and health. It is mainly for such information and financial programmes that energy efficiency funds or energy companies must contribute.

- Education and training of professionals (manufacturers, sales staff, and other relevant market actors) should prepare introduction and further strengthening of MEPS regulation. Certification of successful participation to the training can make it more attractive for both the qualified market actors and their customers.

- Once a certain market share of (highly) energy-efficient appliances is reached, the professionals are trained and used to selling the energy-efficient models, and the cost-effectiveness of the next step is proven, then this level can then be mandated by the regulation to become the new MEPS level.

- Future steps of MEPS regulation towards very energy-efficient appliances should be prepared by innovation support through R&D funding, award competitions, and maybe also already by financial incentives for broad market introduction. The public sector should lead by example through energy-efficient public procurement, thereby paving the way for the other sectors to follow. To push the market further towards energy-efficient appliances and create first markets for them, co-operative procurement programmes can make an important contribution towards very efficient products due to the high purchasing power. Voluntary agreements with large buyers to purchase more energy efficiently than required by MEPS may also support market introduction.

The following figure illustrates exemplarily a comprehensive policy package for appliances and describes the interactions between minimum energy performance standards, energy labels, financial incentives, energy-efficient procurement, RD&D (Research, development and demonstration) promotion as well as education and training programmes.

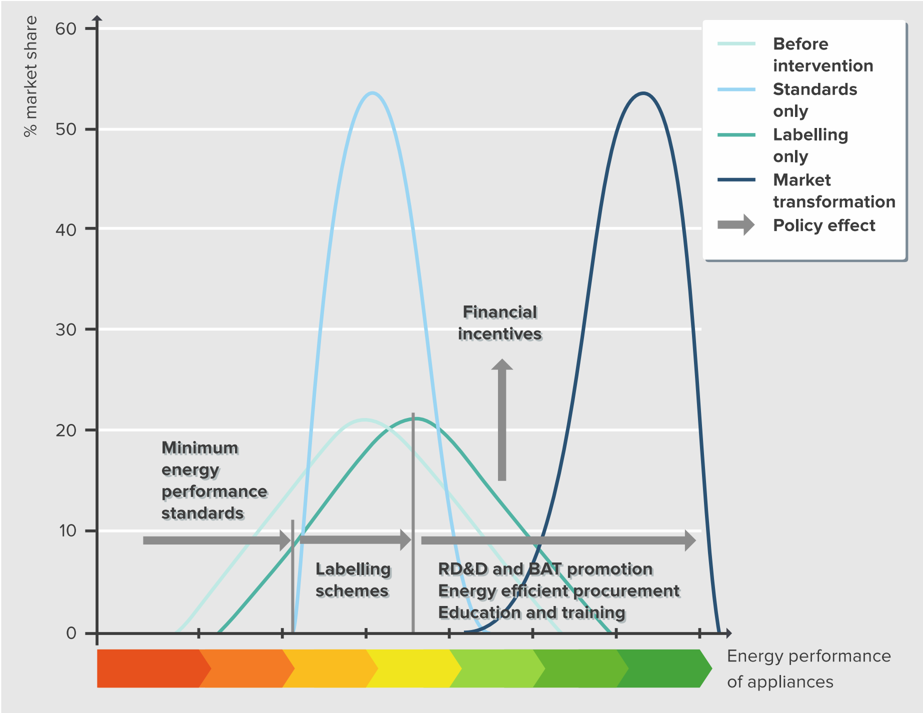

Figure 1: The interaction of policy instruments for energy efficiency in appliances

Model examples of good practice policy packages

The next step of our above mentioned methodology was to find out whether the results of our theoretical analysis are consistent with actually implemented examples of successfully operating policy packages. Consequently, we had to search for empirical evidence of good practice packages in pro-active countries. This next step was therefore the analysis of the policy packages that a number of countries have actually implemented to provide the empirical proof. Therefore the country analysis was to check whether the main elements of the theoretically adequate policy package can indeed be found in real life in the policy packages of advanced countries, so as to confirm the composition of the package. However, this does not yet include an assessment of whether all of the policy elements these countries have combined to their package are good practice for themselves.

This search started from a number of publicly available databases (such as International Energy Agency, World Energy Council, the EU project ODYSSEE-MURE[2]) and was continued with in-depth literature review on candidates identified by the team and international experts we approached for advice.

As some pro-active countries show (cf. Table 1), the policy package that we derived from our actor-centred analysis is exactly what these countries have introduced to approach very high levels of energy efficiency in appliances. These can be considered good practice for the consistent packaging of policies; however, more research is needed to analyse whether each element is a "good practice" policy of its kind and which country has achieved the biggest progress towards very energy-efficient appliances. The table can thus not be read as giving any statement on these further questions.

Table 1: Comparing the recommended policy package with good practice from four countries

Category of policies and measures	Subcategory of policies and measures	Implementation in California, USA	Implementation in China	Implementation in Brazil	Implementation in Japan
Governance framework					

[2] www.iea.org/policiesandmeasures/energyefficiency/ ; www.wec-poliicies.enerdata.eu ; www.odyssee-indicators.org

Energy efficiency targets and planning	Policy roadmap and targets for very efficient appliances	Assembly Bill 32, Climate Change Scoping Plan and Long Term Energy Efficiency Strategic Plan (Updated 2011)	China has a programme for mandatory minimum efficiency standards	National energy plan 2030, the Energy Efficiency Act	Basic Energy Plan, Energy Conservation Law
	International cooperation	California is part of the Western Climate Initiative, Co-operation with the Province of Jiangsu in China	China cooperates with the US Environmental Agency and with the Energy Management Corporation of South Korea	International organisations helped raise the profile of energy efficiency, substantial contributions from other countries	Japan is member of the IPEEC, EMAK, GSEP, Green Purchasing Network, JICA organises several activities
Infra-structure and funding for energy efficiency programmes and policy	Energy agencies	State level: California Energy Commission and California Public Utilities Commission; Federal level: Environmental Protection Agency, Department of Energy	National Development and Reform Commission (NDRC)	National Electrical Agency	Agency for Natural Resources and Energy (ANRE) Energy Conservation Centre of Japan (ECCJ)
	Overall co-ordination and financing	Each utility company must provide energy efficiency programmes and services: Energy Efficiency Portfolios and Budgets approved by the California Public Utilities Commission; Public Goods Charge	The Ministry of Finance is the key player in terms of funding; NDRC, CNIS and CSC are also instrumental for implementation	There are different financing schemes: Funding comes from the Public Benefits Funds, ELECTROBAS, the ANEEL Energy Efficiency Programme, PROESCO and other programmes to support energy efficiency	ANRE, ECCJ, NEDO agencies and budget by METI
Eliminating distortions	Removal/reduction of subsidies on end-user energy prices and on energy supply (if they exist); Energy/ CO_2 taxation and emissions trading	The electricity rate is divided into tiers	China plans to gradually implement a carbon trading system from 2013 on		There are some energy taxes but not a emission trading or a carbon tax
	Regulation of energy companies	Cost recovery of energy efficiency programme costs plus performance-based incentives; Decoupling of energy company profits from sales;		Regulatory supervision of the use of the Public Benefits Funds;	
Specific policies and measures					
Regulation	Minimum energy performance standards (MEPS)	MEPS were implemented in 1977; currently "2010 Appliance Efficiency Regulation"	China has a programme for mandatory minimum efficiency standards	Federal Law 10.295 MEPS	
	Other legal requirements				Top Runner Program, Home Appliance Recycling Law, Agreement to reduce stand-by power consumption
Information	Mandatory labelling scheme	Energy Guide	Energy Information Label	Mandatory A-G labelling scheme, Energy Standard Information System	Uniform Energy Saving Label

				(ESIS)	
	Voluntary labelling scheme	ENERGY STAR	Voluntary Energy Efficiency Endorsement Label	Voluntary labelling scheme PROCEL	Energy labelling programme; ENERGY STAR for office equipment
	Provision of targeted information	Product database for customers ENERGY STAR programmes, Flex your power	EE Information week, consumer education programme, online appliance databases	PROCEL provides relevant information on experiences and success	School programmes, training courses, up-to-date information, "Energy efficient household appliance forum", product database
	Feedback and other measures targeting user behaviour	Opower			Energy Conservation Navi Smart Life
Financial incentives and financing	Financial incentives	Financial incentives are given by both private and public energy companies. For example, SCE offers a rebate on refrigerators if an ENERGY STAR product is purchased, Energy Management Assistance Program	There are plans to subsidise the purchase of energy-saving refrigerators and other appliances	Refrigerator replacement programme	Eco-Point Scheme
	Financing instruments (e.g. soft loans)				
Capacity building & networking	Education & training for supply chain actors	Training of retail sales staff (ENERGY STAR – Retailer Resources)	GEF Project: Chinese manufacturers participated in design training workshops, study tours, and expert technical assistance	PROCEL offers training courses, seminars and conferences	Energy education in schools; Training of retail sales staff by retailers under the Energy Efficient Product Retailer Assessment Program
Promotion: Research, Development & Demo and Best Available Technology	Public sector programmes ('Lead-by-example', energy-efficient public procurement)	FEMP - EEPP	In 2006 the legal requirement „Energy Efficient Products For Government Procurement" came into force	Targets for the public sector	Green Procurement Law
	Research and development funding	Public Interest Energy Research programme		The Ministry co-ordinates research and development projects	NEDO is the largest R&D management organisation, METI has some R&D programmes
	Competition and awards	SERP, Super-efficient Refrigerator Program	The GEF project introduced the „principal award" The programme also included a lottery-style purchaser award		Energy Efficient Product Retailer Assessment Program

Note: the table only shows the priority types of policies in the bigEE recommended policy package

Discussion: What the countries do vs. bigEE's recommended policy package

A look through the table confirms that the empirical evidence proves the composition of policy package developed with the actor-centred theoretical analysis and presented above to be the right combination of policies and measures.

The governance framework for energy efficiency

Although all four countries have designed a roadmap facilitating the efficient use of energy, there are some notable differences. California stands out because of its long-term commitment to decrease GHG emissions by 80% of 1990 levels by 2050 set out in the Climate Change Scoping Plan (CCSP), which together with the Long Term Energy Efficiency Strategic Plan signals reliable political support for energy efficiency. Expanding and strengthening appliance standards are considered "key elements" [12]. For the medium-term, Assembly Bill 32 legislates GHG reductions by 2020. Similarly, China has been legislating energy intensity targets since its 11th Five-Year-Plan, established 2005, which is supported by Medium and Long-Term Energy Conservation Plan. This plan, however, does not go beyond 2020. Brazil's and Japan's strategic plans cover a period until 2030.

In Brazil and China, the Ministry of Mines and Energy and National Development and Reform Commission, respectively, pave the way towards an energy-efficient future. However, at least for Brazil, there is much room more for improvement in terms of allocating financial and human resource. California's Energy Commission (CEC) was, among other things, established to promote energy efficiency through appliance standards. Together with the Utility Commission, closely supervising privately owned energy companies, CEC designs energy efficiency measures. In Japan, the Agency for Natural Resources and Energy (which is under the Ministry of Economic, Trade and Industry) and the Energy Conservation Centre of Japan are the most important actors for increasing energy efficiency.

Brazil, California, China as well as Japan have realised that market distortions negatively affect rational energy consumption. However, different approaches have been pursuit. In California utilities are required to promote energy efficiency programmes to end-users funded through the Public Goods Charge. Moreover, energy companies are obliged to participate in a cap-and-trade programme on GHG emissions, which incentivises them even more to engage in energy-efficiency measures for end-users (e.g. refrigerator rebates). Because the less energy their clients consume, the less emission certificates need to be bought. The Chinese government plans to gradually implement emissions trading system nationwide and Japan introduced the Carbon Tax in 2012, whose funds are used for energy efficiency and renewable energy measures. Through this scheme, end-users are to use energy more rationally due to increasing energy costs. Brazil's government legislated utilities to invest 0.5% of their annual net revenues in end-user programmes aimed at increasing energy efficiency. Half of that sum must be spend on low-income households

Specific policies and measures for energy efficiency in appliances

Minimum energy performance for appliances is a key issue for all four governments, stressing its significance within an appliance package. While a comparison of the country-specific standard-setting processes would go beyond the scope of this paper, a brief description of Japan's innovative Top-Runner approach seems to be appropriate. Simply put, the Top-Runner programme identifies the most efficient appliances (or the top runners) of an appliance category on the market. Their energy efficiency value is applied as a future minimum energy efficiency standard to be achieved after a transition period of three to twelve years. This period is determined by taking into account technological development forecast and the development period of products. "Because the standard is based upon data from existing products, it can be said that the standard is market driven, i.e. no standard is set that is not (yet) available in a product on the market" [10].

Each of the four governments utilises mandatory and voluntary labels in order to accelerate market transformation by providing consumers with transparent and comparable information about the energy consumption of appliances. In Japan, the most energy efficient appliances can reach five stars. Only Japan's voluntary label, which can be incorporated into the mandatory one, shows a) whether a products meets the respective standard, b) in how far (in %) the device performs better or worse than its standard and c) how much energy a given product consumes. China's label classifies appliances into five different categories, from class one (highly efficient) to class five. Similarly, Brazil scales devices from class A (highly efficient) to class G. Both are reminiscent of the EU Energy Label and also make use of a voluntary label. The U.S. stands out because it does not incorporate a classic classification scheme. It rather focuses on the estimated annual operating costs. This suggests that the U.S. Government considers the lack of consumer information regarding the operating costs of devices a main barrier towards market transformation. On the upper end are operating costs for highly efficient devices and energy-inefficient devices (available on the market) constitute the scale's lower end. In terms of worldwide implementation, the voluntary label of the USA, the Energy Star, can be considered a huge success. Japan, the EU and other countries have made use of the Energy Star for a broad range of appliances, for office equipment, in particular. However, the Energy Star label is not very ambitious and the requirements are not based on the best products on the market. The label is also used for the public procurement in the USA but the function is mainly to set minimum energy performance standards. By this, it only cuts the most inefficient products from the market.

In order to make consumers more fully aware of energy-efficient appliances, all four governments provide information through different information campaigns. Feedback measures such as the Energy Conservation Navi in Japan or the Home Energy Report, offered by Opower in California (and other U.S. regions and countries), are to inform the end-users more comprehensively about their energy use and can be considered an asset for both cases. California, China and Brazil support or supported the purchase of some energy-efficient appliances. Particularly in Brazil, low-income households are focused on. The Japanese Eco-Points programme is like the Top-Runner approach a very innovative measure. Eco-points can be received for the purchase of appliances that, at least, score four stars on Japans mandatory energy label.

Education and Training programmes for supply chain actors are implemented in each of the four cases. However, capacity building measures in China, which were supported by the Global Environment Facility, can have a very positive effect. First, China's sales figures for the domestic market rise constantly (Fridley 2008, p.5). Second, increasing energy efficiency in products made in China, will improve energy performance of devices worldwide.

All governments also seem to acknowledge the usefulness of public sector programmes. Whereas California, China and Japan introduced public procurement law, Brazil's commitment to only "consider" energy efficiency in the procurement process appears to be a less ambitious. Research and development funding programmes are implemented in all cases but China. Regarding competition and awards, Brazil poses an exception. China, again, benefits from the GEF project, which, among other things, announced a reward of USD 1 million to the manufacturer achieving the greatest total energy savings.

Discussion: What are the achievements?

As noted before, the comparison between these four cases served as an empirical proof for the composition of the recommended policy packages for energy efficiency in appliances. Still, one question remains. Can these four cases also be considered successful in terms of energy saved? And what has been the contribution of policy packages? Unfortunately, information that would make the countries' achievements comparable is not easily available, if at all. To compare the four governments the following impact analysis focuses on cold appliances.

- Between 1977, when the USA fired the starting gun for energy-efficient policy measures, and 2001 the maximum allowed energy consumption of a typical fridge-freezer has dropped from 1,546 to 476 kWh/year. Further reductions are expected. An indicator showing the success of the policy package may also be the stabilisation of electricity consumption (per capita) at around 7,000 KWh since 1978. This stagnation contradicts electricity consumption of the USA in general (1978: ~9,000 kWh/capita, 2008: 12,000 kWh/capita) [3].

- With regard to China, the bigEE-analysis focused on refrigerators, freezers and combinations of the two. Sales figures rose from 360,000 devices in 1999 to 46 million in 2008. Between 2008 and 2010 the market share of Grade 1 appliances increased dramatically from below 10% to 77%. As far as China's mandatory energy label is concerned, it is estimated to have the potential to save more than 16 TWh by 2020 alone [5]. Due to continuous economic growth, that may become more inclusive in the near future, sales figures for appliances are likely to rise, which makes a comprehensive policy package aimed at reducing energy consumption of appliances even more important.

- The Brazilian government achieved to reduce the average energy consumption of new refrigerators from 491.3 kWh/yr to 270.4 kWh/yr between 1990 and 2005 [1]. Moreover, regarding the Brazil's voluntary label, PROCEL, established in 1993, saved 22 billion KWh by mid-2008 [9].

- With the Top Runner Program, Japan achieved an energy efficiency improvement rate of 55.2% from fiscal year (FY) 1998 (647.3kWh/yr) till FY 2004 (290.3 kWh/yr) for electric refrigerators. The expected average energy consumption for the target year for refrigerators was 449.7 kWh/yr [13]. For 2010, a study expected further energy savings of 21% for refrigerators and 12.7% for freezers compared to 2005 levels. Actual efficiency improvement is 43.0% from FY 2005 (572kwh/yr) to FY2010 (326kwh/yr) especially for large refrigerators and 24.9% for freezers.

Information on impacts resulting from energy-efficient policies and policy packages, in particular, are highly diverse. However, the cases discussed have implemented a broad range of policy instruments that are necessary to overcome barriers and strengthen incentives to achieve an energy-efficient appliance stock. As has been shown, developed and developing countries can make such important steps. However, more needs to be done and, hopefully, bigee.net can guide future measures for an energy efficient future.

Conclusion

With the two-pillar approach to policy analysis used here, we have been able to add new foundation, both theoretical and empirical, to the conclusion about what is a necessary and advisable package of policies to effectively advance high energy efficiency improvements in appliance:

As the first pillar, the actor-centred approach to policy analysis has confirmed our presumption that there is not one silver bullet that will kick-start a real energy efficiency transformation in the appliance sector. What is urgently needed are consistent packages of policies and measures, carefully tailored to the needs and incentive structures of all actors in the appliance value chain. Our theoretical analysis along this value chain has given us good insight as to which implementation strategies can successfully tackle the many existing barriers and which combinations of policies are needed to put these strategies into practice. The first important result is thus the policy packages we now recommend on bigee.net. There are sometimes alternative policies for one strategy, so the final composition of the package will depend on the circumstances in a specific country.

As a secondary result, we have also advanced the methodology that governments and consultants can use to assess given appliance markets and the policy support that all relevant actors need to harness energy efficiency.

As the second pillar, we also ascertained that the main elements of the theoretically adequate policy package could indeed be found in real life in the policy packages of advanced countries. This does not yet include an assessment of whether all of the policy elements these countries have combined to their package are good practice for themselves. But it confirms the composition of the package.

During our research on such model examples, we found, however, that the lack of thoroughly documented and evaluated policies and measures (both for single policies and for sectoral policy packages) makes the search for good practice quite difficult. Accordingly, resulting from our analysis there are two key messages for policy makers planning to implement a new policy or measure: it is crucial already in the policy design phase to bear in mind both the actors concerned and the data needs and other requirements in terms of monitoring and evaluation of the impacts, costs and benefits as well as for compliance with the policy, in order to ensure its effectiveness.

The Practical Scope for Reducing Air Conditioning Energy Consumption in Europe: Policy Opportunities and Priorities

Roger Hitchin, Christine Pout, David Butler

Building Research Establishment, UK

Abstract

For a variety of reasons, market penetration of air conditioning and consequently demand for cooling in Europe continues to increase and on a "business as usual" basis would increase by over 50% by 2020, although recent economic events may result in a somewhat smaller increase.

This paper summarises the results of an extensive "Study to assess barriers and opportunities to improving energy efficiency in cooling appliances/systems" carried out by the Building Research Establishment and funded by CLASP. The purpose of the study was to contribute to the development of relevant policy by identifying and quantifying the potential impact of possible measures to reduce the energy consumption of air conditioning in Europe over a ten year period, relative to a business as usual case.

Many of the policy measures relate to the performance of products and equipment, but there is also considerable potential in the areas of load reduction and more effective operation and management of systems. The analysis focuses on quantified realisable savings that reflect technically feasible measures whose rate of introduction is constrained by the replacement rate of air conditioning systems and appliances, refurbishment rates of buildings and different levels of ambition for performance regulations placed on air conditioning equipment and systems. It is disaggregated by country, but this paper concentrates on results for Europe as a whole.

The measures that offer the largest realisable savings formed the basis for recommendations for policy measures, often using existing policy instruments. These measures fall into two groups relating, on the one hand, to policies that impact directly on technical requirements for systems and products and, on the other hand, to those that do not. The second group includes policy measures to incentivize effective operation of buildings and systems, and to influence take-up rates for high-efficiency products.

Additional recommendations relate to the application of policy: consistency of approach between instruments; choice of application at national or European level. The report also identifies areas where further work is needed to improve the robustness of studies similar to this one.

More detailed results and information about the study can be found at
http://www.bre.co.uk/searchresults.jsp?category=5&q=energy+management

Introduction

This paper assesses the realisable potential for reducing energy consumption in Europe over a ten-year period by analysing a number of idealised cases which represent different types of possible measure applied with different ambition levels. The cases which yield the largest potential savings are identified, routes to implementation are discussed and recommendations to support implementation are offered.

The market for air-conditioning in European building is immature in the sense that ownership in most countries is considerably lower than in equivalent climates in North America or the Far East. (see, for example [1] This is reflected in the fact that most sales are for first-time installations in new or existing buildings with relatively few replacement sales. [2] This is very different from the markets for most other forms of building services, such as heating or lighting, where most sales are replacements.

The empirical evidence is that market penetration has increased fairly steadily over several decades with only a few signs of saturation [2] [3]. In consequence, consumer demand for cooling is likely to increase and, other things being equal, so is the associated demand for mainly electrical energy. However, there are many opportunities for reducing demand and improving the efficiency of use. For example, in a growing market, the impact of high-efficiency products is more immediate than in a market where the penetration of efficient products is constrained entirely by the replacement rate. In the study underpinning this paper we have also sought to engage with a wide range of policy options for constraining the growth of air conditioning energy consumption, including minimum performance requirements placed on products, on systems and on whole buildings and their systems. This broad perspective implies a more integrated approach to the development of policy, mobilising in a more deliberate way a comprehensive set of policy elements to form an integrated policy package.

The European market for air conditioning products and systems is far from being homogeneous. Consequently, the same is true of the installed stock of systems. Cooling demand varies with climate and with building type. New building may have higher (or lower) cooling requirements than existing ones. Different types of air conditioning system are more convenient to install in new or existing buildings, and for use in simple or complex buildings.

Categories of Systems

European product policy reflects the recognition that air conditioning systems designed to provide comfort in buildings can be divided broadly into three categories, with different principal applications and supply chains.

- Moveable units: These are appliances bought over the counter or on-line and do not generally require any installation expertise. These appliances are mostly used in dwellings and small commercial buildings.

- Room air conditioners/Packaged systems: These are series-produced self-contained units or systems comprising a unit that conditions a single room. They should generally be installed professionally. These systems are used in both commercial buildings and dwellings.

- Central systems: These are larger systems that serve more than one room (often large numbers of rooms or an entire building). They are generally bespoke systems designed for specific buildings, but are largely composed of standardised component products. In Europe they are predominantly used in non-residential buildings. There are a number of different types of central system, each with particular areas of applicability. For example some types of system are difficult to install in existing buildings.

Categories of Energy Saving Measures

There is no shortage of opportunities for reducing the energy used for air conditioning. Energy saving measures fall into three general categories: reduced loads, higher technical efficiency and improved operation.

- ***Reduction of cooling loads*** through improved building design and construction, and through the use of more efficient appliances and lighting systems.
  - The range of economically feasible measures relating to building design is more limited in existing buildings than in new designs. Some measures can only be practicably applied to existing buildings as part of major refurbishment works.
  - Cooling demand reductions from more efficient appliances and lighting often result from energy-efficiency measures specifically directed at those products.

- Improve the ***technical efficiency of air conditioning systems.***
  - Moveable units and room air conditioners are series-produced products to which performance tests and minimum requirements can be applied in a similar way to other energy-using products.
  - It is more difficult to devise practicable performance metrics for central systems, which are essentially bespoke. Such metrics can be applied in principle to specific components, but in-use energy use is often dependent on the design of the system as a whole. For example, energy use for air movement is often substantial in central systems and is, to a large extent dependent on the design of the air distribution

system. Component replacement is more frequent than complete system replacement

- ***Reduce wasteful operation*** of air conditioning systems.
  - In principle, this category of measure is immediately and universally applicable. In practice its application is often constrained by a shortage of easily assimilated information and pressure on building managers to prioritise other operational problems.

Policy Instruments

There are a variety of policy instruments that can be deployed to reduce the consumption of energy for air conditioning, including mandatory minimum performance requirements applied to products, systems or buildings; information provision, including energy labelling; financial incentives and energy pricing. Different instruments bear on different types of system, and on different categories of measures. Some instruments can only be practically applied at a Member State (or region or municipality) level while others are more suitable for a European level of application. The mapping of policies onto the most important cases is discussed later in this paper.

Realisable Savings

Realistic objectives for energy saving must take account of a range of practical constraints, not least the relatively long lifetime of air conditioning products and systems and the long time interval between major refurbishment of buildings. This study assessed “realisable savings” that would accrue over a ten-year period relative to a business as usual base case.

A ten-year period is sufficiently long to include the growth rates of the markets for: new systems in existing buildings; new systems on new buildings; replacement systems; product and system turnover rates; and building refurbishment rates. It is sufficiently short to constrain uncertainties due to long-term market projections; changes in policy priority; and changes in technology and pricing. During a ten-year period most of the initial stock of room air conditioners and moveable air conditioners will have been replaced, but a significant proportion of the original energy-using components of central systems will remain in place at the end of the period. In addition, many buildings will not have undergone major refurbishment during this period. In consequence there is considerable remaining potential for savings from building-related load reductions and from the complete replacement of central systems as part of major refurbishments.

Analysis Approach and Data Sources

General approach

This section of the paper provides an overview of the modelling process and data sources.

The core of the analysis is explicit, disaggregated modelling of energy consumption for a range of different assumptions, denoted “cases”. The modelling takes into account the replacement rate of air conditioning systems and appliances, refurbishment rates of buildings and rates of market growth. Levels of realisable savings were estimated for different levels of ambition for performance regulations placed on air conditioning equipment and systems, for practicable load reductions, and for improvements to operational efficiency.

We have calculated savings as if policy instruments were introduced instantaneously at the start of the period (the base year for the modelling is 2010.) This is obviously not realistic, but provides directly comparable estimates and avoids the complication of assessing the timescale for policy to be agreed and implemented. In addition, national data were sparse for some countries with smaller market potential and it was necessary to make estimates based on parallels with other apparently similar countries. For example, the figures for Norway are derived from market statistics for Sweden, scaled for population. The realisable savings are therefore to be viewed as idealised indicators of the scale of savings that are possible within the 10-year time frame.

The model generates estimates of annual energy consumption for the cooling and air movement functions of air conditioning systems. The calculation is disaggregated in a number of ways:

- Country
  - In order to capture the different national market dynamics, climates and national energy requirements for air conditioning, each of the EU-27 Member States and the EEA countries was separately modelled.
  - This paper, however, focuses on the EU-wide results.
- System type
  - The three broad categories described above were further disaggregated into 14 specific system types.
- Building type
  - Buildings of different age and use have different cooling demand levels. It was not practicable to include all building types and ages.
  - The stock was disaggregated into the three types of building that market research revealed to represent the largest shares of equipment cooling capacity: dwellings, offices and retail buildings. Each of these was represented in both a new-build and existing building form.

Air conditioning system energy consumption was calculated for a ten-year period for each combination of country, system type and building type, based on the aggregate installed cooling power, the aggregate air conditioning system efficiency characteristics, and the climatic and building design features were specific to each combination. This was repeated for both a base case and a number of variant cases which included energy-saving measures.

28 different combinations of plant (system energy performance), fabric and equipment energy saving measures were modelled, representing different energy saving measures and levels of ambition (for minimum performance requirements for example). Some cases represented combinations of measures since the combined impacts are not simply additive. These cases represented typical operating practice: the impact of more effective system operation and management was then explored as variations to these "technical" cases. A separate analysis explored the theoretical scope for savings if less-efficient types of existing central systems were replaced by more efficient alternatives (separately from simply replacing components).

Methodology overview and data sources

Stock and sales

The existing and future stock of air conditioning systems drew on previous studies by the authors [2] [3], The general approach was to obtain historical sales figures from market research sources, and by a process of fitting these to a market diffusion equation for each country and comparing reported proportions of sales in to new buildings, first-time sales into existing buildings and replacement sales, to build up sales trajectories and levels of installed cooling capacity. Aggregate floor areas of cooled space were not explicitly estimated, as suitable data sources are extremely limited. However, the resulting base case estimates of total energy use for air conditioning are consistent with published assessments based on floor area estimates which are summarised in the "results" section below).

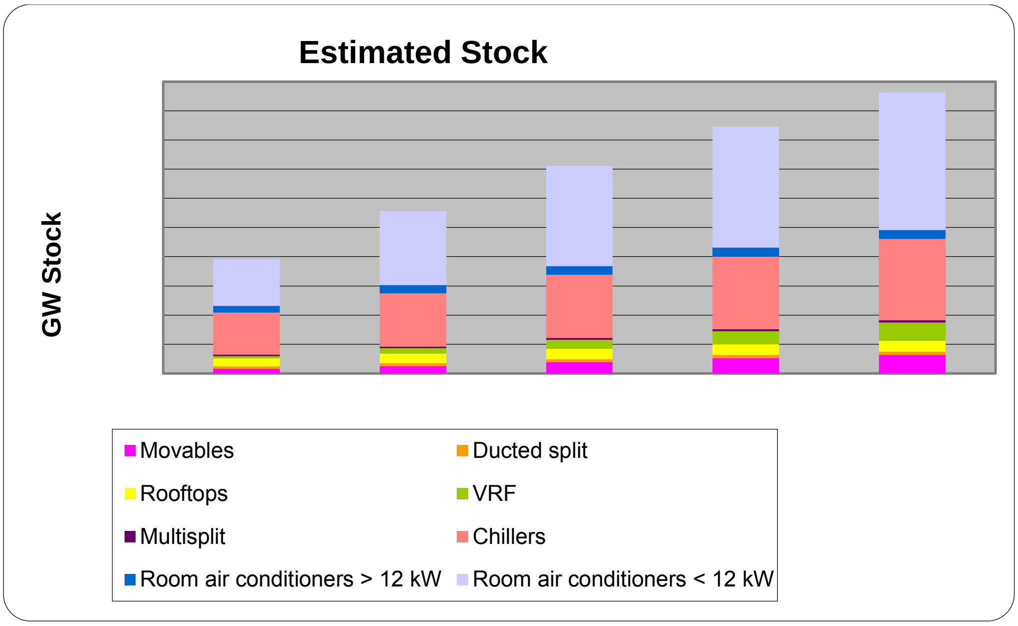

Figure 1. Installed cooling capacity (EU-27, ref [2])

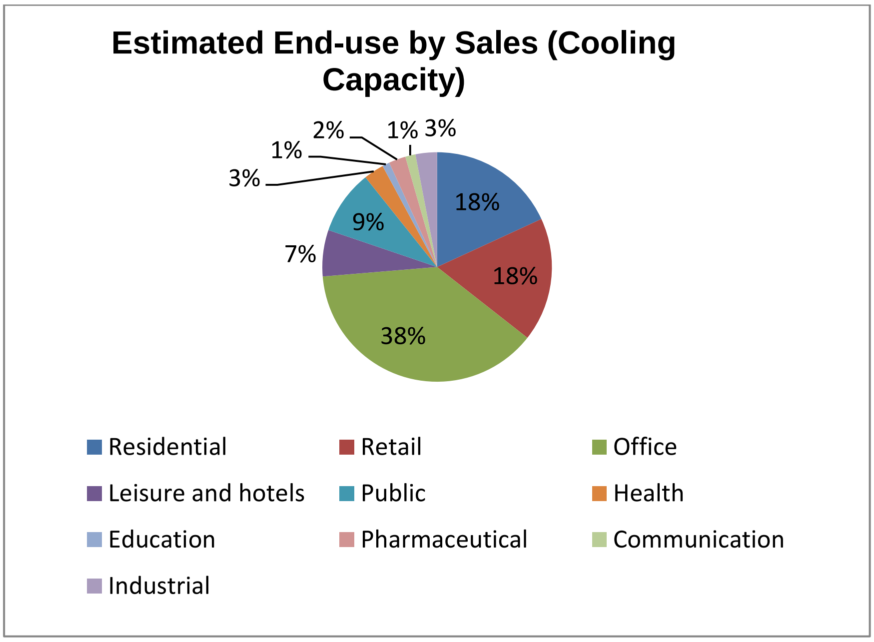

Figure 2. Sales by end-use (cooling capacity) (EU-27, ref [2])

System energy consumption and efficiency

In order to estimate annual energy consumption from the installed aggregate cooling power it is necessary to first estimate the load factor or "equivalent full-load operating hours" (EFLH) of the cooling plant.

The energy efficiency of moveable and fixed room units is defined by a seasonal energy efficiency ratio value (SEER) for a standard climate. In this project the values reflect the specific standardised climate assumptions of the ESEER metric. [4] The estimated energy savings for these products are derived from modelled changes in the mixture of products of different SEER in the installed stock of systems.

Central systems cannot be adequately represented by a single efficiency metric, not least because there are a number of system configurations and within each general configuration there are variations to match the needs of the specific building in which they are installed. The energy modelling is consequently also more complicated. The calculation procedure uses a set of algorithms originally developed for use in software for the implementation of the European Energy Performance of Building Directive (EPBD): SBEM [5] [6]. The software was developed specifically to estimate annual energy consumption taking into account *inter alia* HVAC system characteristics, and consequently has different objectives, structure and capabilities from software developed primarily to support detailed building design. The annual consumption of each combination of system, building, and climate is estimated by combining the total installed cooling power with an aggregate seasonal energy efficiency ratio (SEER) of the cooling plant and with a number of system characteristics that can lead to energy wastage [7]. These characteristics include: fan energy consumption as a function of specific fan power (itself a function of ductwork design), heat energy gains from fans, heat transfer to distribution duct- and pipe-work, control imperfections and duct leakage. For the UK, it produces energy consumption figures that are a close match to empirical benchmarks, including energy use for air movement associated with the air conditioning system. In this study the fan energy used to supply outdoor air (for ventilation) has been separately accounted: air movement for air conditioning is the additional air movement that is used to distribute cooling in some system types. The cooling algorithms have been modified to allow the use of different climates and design conditions. The basic UK load factors (expressed as equivalent full-load hours) for each building and climate combination are consistent with empirical consumption benchmarks. For other countries, they have been modified to reflect differences between building types and climates by scaling them according to the results of previous building simulations carried out by the University of Athens in support of Ecodesign projects. In addition, stand-by and off-mode consumptions have been added.

A general flow diagram for the central system model shown below in Figure 3 illustrates the structure of the central system model.

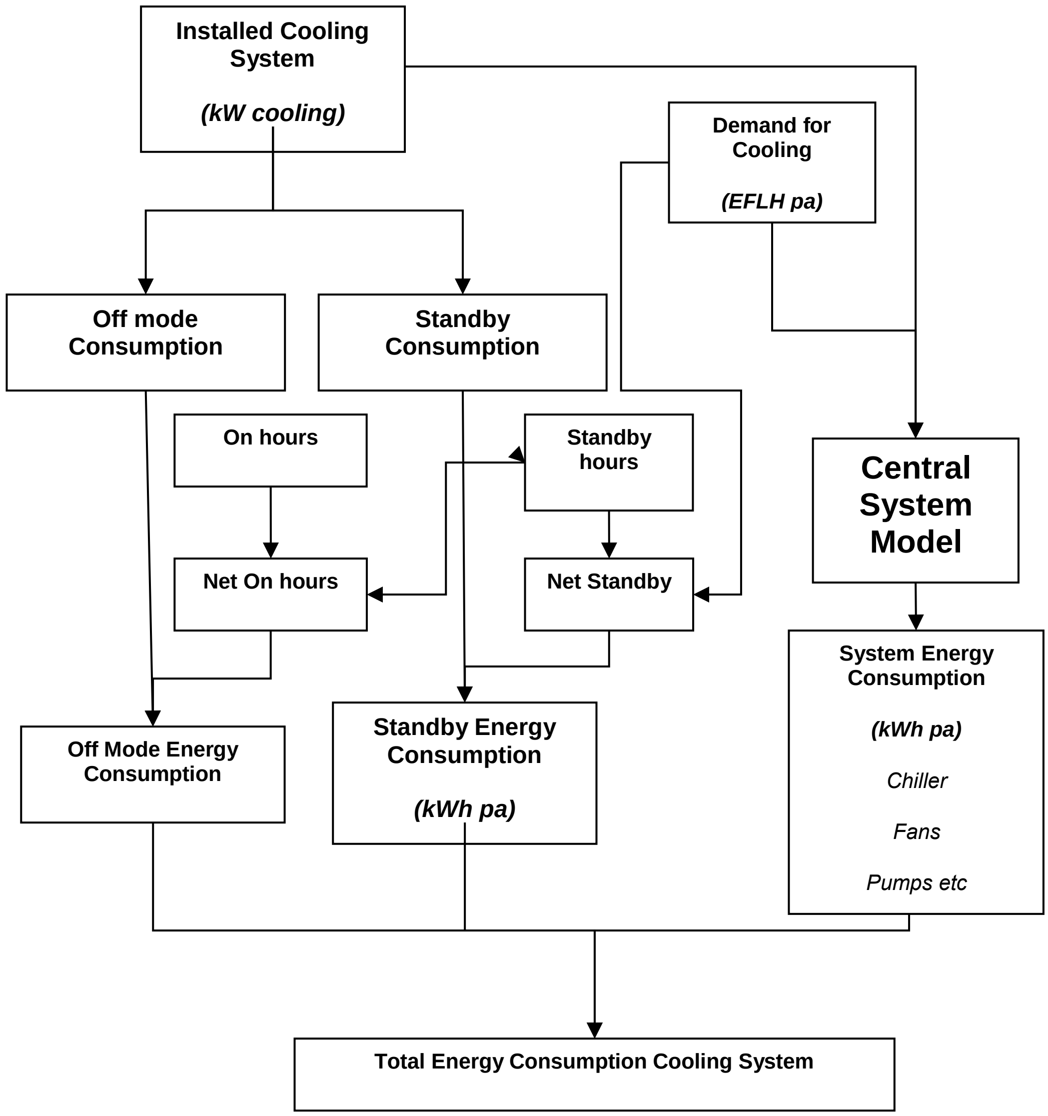

Figure 3. Schematic of Central System Model

Aggregate SEER values for products were derived where possible from the distribution of values weighted by sales figures for each product type. More commonly, sales-weightings were not available and aggregate figures were estimated from the distribution of products listed on the Eurovent database, [8] converted from EER values where necessary. An example of the source data is shown in Figure 4 below.

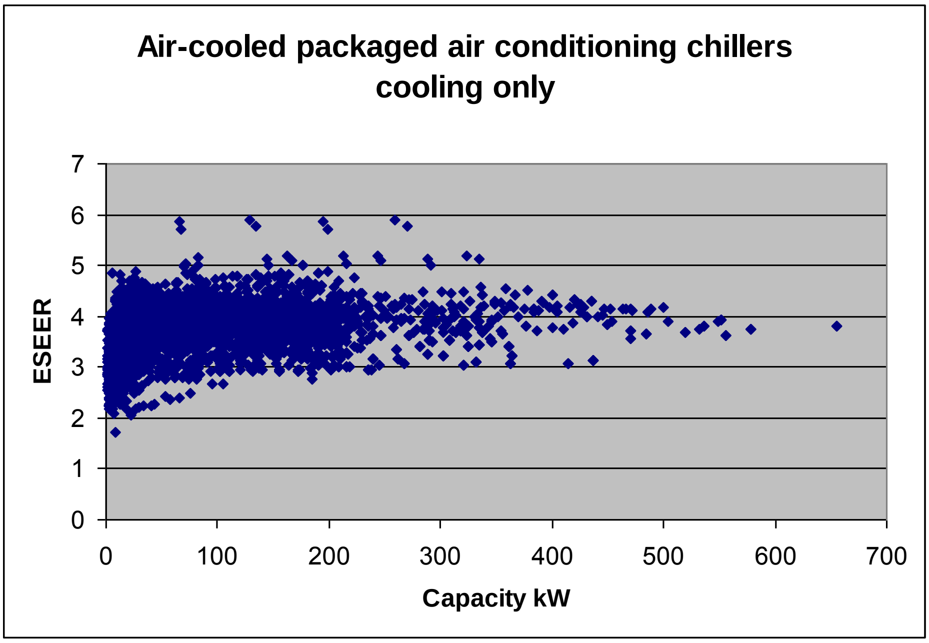

Figure 4. Example of ESEER distributions (air-cooled chillers)

The impact of energy efficiency measures such as minimum performance requirements and energy labelling on the aggregate SEER values were represented by changes to the relative frequencies of products of different performance.

Similar processes were used to estimate other parameter values.

Load Reduction Measures

The principal data sources for estimates of load reduction – both from building envelope measures and from the use of equipment and lighting systems with reduced heat gains – were two previously published studies: KeepCool [9] and Harmonac [10].

The KeepCool project assessed the potential for reducing cooling demand in existing offices across Europe from a number of measures in the following categories:

- Reduced solar gain
- Enhanced ventilation
- Improved equipment and lighting efficiency
- Reflective surfaces and added insulation
- Windows

The study assessed the potential savings by carrying out energy demand simulations for example buildings to which various load reduction measures had been applied in each of five climate zones across Europe. The results were generalized by the KeepCool project assigning each country to one of the zones.

The KeepCool study used energy simulations to assess the potential savings in example buildings in each of five climate zones across Europe. The results were generalized by the KeepCool project by assigning cities in each European country to one of these climate zones.

In the present study, these results were taken to represent the theoretically available savings if there were few practical implementation barriers (including cost). In practice, this theoretical potential is constrained by practical and financial constraints. These constraints were represented in the present study by using additional information from the Harmonac project. The Harmonac project carried out detailed assessments of the practical potential for reducing air-conditioning energy consumption in 42 "Case Study" air–conditioned buildings, including but not restricted to office buildings. The frequency with which measures appeared in these buildings was taken to represent a "technically feasible" level of implementation which might be included in new buildings or in existing ones during major refurbishment.

A second, lower, estimate of realisable savings was developed from the Harmonac project. The project carried out several hundred inspections of air-conditioned buildings in order to determine what energy saving opportunities were identified and the time required to identify them. These were much less detailed studies than for the Case Study buildings, carried out by air-conditioning technical staff (who were briefed to look for demand reduction opportunities) and identified fewer measures, and generally lower-cost variants (for example adding shading film to windows rather than external shading). These measures, and the frequency with which they were identified, were used to represent the effect of generally feasible and identifiable measures.

The impact of the load reduction measures was represented by reducing the EFLH figure to represent the (aggregate) reduction in consumption.

Improved system operation

The EFLH figures used in the energy consumption calculations are consistent with empirical benchmarks and therefore implicitly reflect typical usage. The inspections and Case Study analyses carried out by the Harmonac project confirmed that there is often substantial energy wastage through imperfect operational practices: such as poorly-set temperatures controls and time clocks, missing controls and filters that are in need of cleaning.

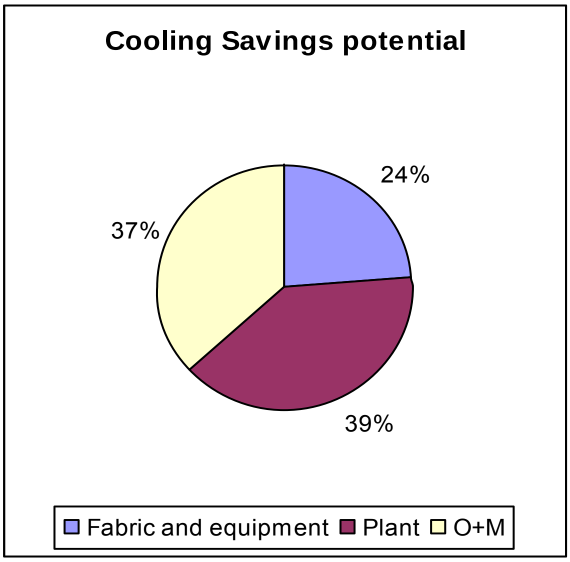

Figure 5. Harmonac Summary of Types of Cooling Energy Saving Potential

The empirical estimates of potential savings from this project were used to estimate the potential savings from better operational practice. "Practically realisable" savings were based on additional results from the project that identified what proportion of this theoretical potential was actually identified by air conditioning inspections.

Cases Examined

The cases examined included the introduction of different levels of minimum performance requirements (including "best available technology"), with and without energy labeling and with and without financial incentives for each of:

- Seasonal energy efficiency ratios for
    - Movable air conditioners
    - Room air conditioners
    - Central system chillers
    - Complete central systems
    - Central system fan coil terminal units

    - Central system pumps
- Specific fan power factors for central system air handling units
- Air leakage requirements for ductwork and air handling units
- Reduced fresh air requirements to reflect smoking bans
- Load reductions from building and equipment improvements
- Measures to improve operational management of systems

The possible take-up rate of measures will clearly be different according to whether they apply to first-time installations of products or systems, replacement products or systems, new buildings or existing buildings. This is reflected in the modeling of the theoretically realizable 10-year savings. In particular, the rate of implementation for measures that would not realistically be likely to be introduced except as part of major refurbishment was controlled by assumed refurbishment rates.

Principal Results:

Base Year: comparison with other estimates

Table 1 compares the estimated aggregate energy consumption for the base year from the present study with figures from other studies and shows generally good agreement, given the different definitions of scope used and the different dates of estimates. The Ecodesign Studies use a similar approach as the present study, while the other figures are derived from estimates of air conditioned floor area and consumption per unit floor area.

The figures in this section relate only to the annual consumption in the base *year* – although this study uses base case covering a ten-year base period, comparable figures are not available from other studies.

Name of Study	Total estimated Annual Energy Consumption TWh pa	Comments
This study	76.91 (moveables+ Room ACs + central systems) plus 63.6 for air movement energy consumption (140.5 cooling and air movement)	“Air movement” excludes that attributable to fresh air supply
EcoDesign Preparatory Studies [12].[13],[14]	Cooling only: 38.6 (Lot 10 but for earlier year) + 74 (Lot 6) = 112.6 Ventilation (not only associated with air conditioning) 100 TWh [1]	Ventilation figure includes use in non-air-conditioning applications
EECCAC study [4]	94.7	EU-12 only, 2003
Harmonac study [10]	198	
Electricity Consumption and Efficiency Trends in European Union - Status Report 2009, European Commission Joint Research Centre Institute for Energy [14]	38.6	Appears to only include room units < 12kW (Lot 10 study)

Table 1. Comparison of estimated annual air conditioning energy consumption for EU from various studies

[1] This figure is not explicitly stated in the report but has been inferred from data in the report)

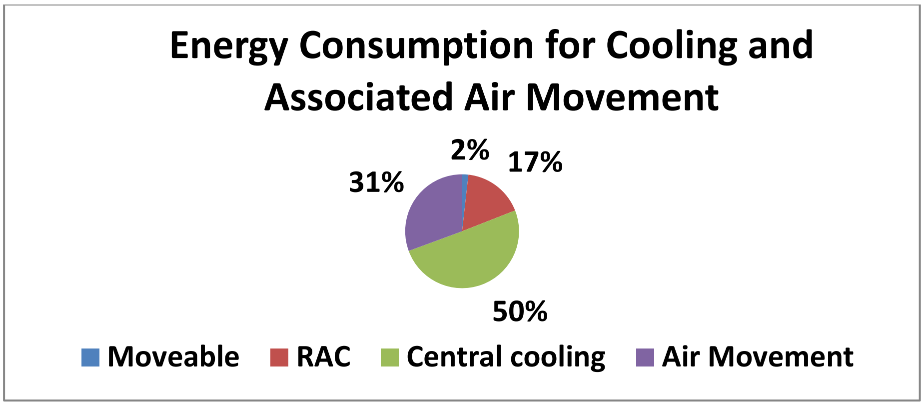

Figure 6. Summary of Energy Consumption for Air Conditioning: Base Case, EU-27

The relative contribution of central air conditioning systems compared to the distribution of installed cooling capacity shown earlier is the result of the higher distribution losses (and energy needed to offset fan energy heat gains) associated with this type of systems. As can be seen, the energy associated with air movement in centralised systems is substantial.

Base Case and Theoretical Potential Savings

In the base case, the market penetration of air conditioning increases but no new energy saving measures are introduced. Existing policies such as energy labelling of room air conditioners and movable units are included in the base case.

From the modelling, we have estimated that universal application of the best available technology and practices in the three categories of energy-saving measures might, in theory, reduce consumption by up to 80%. The maximum realisable ten-year reductions approximately 10% of the base case.

Summary of Principal Results

The seven cases that generated the largest estimated energy savings over 10 years are illustrated below. In most cases there are energy savings related to both the cooling and air movement functions.

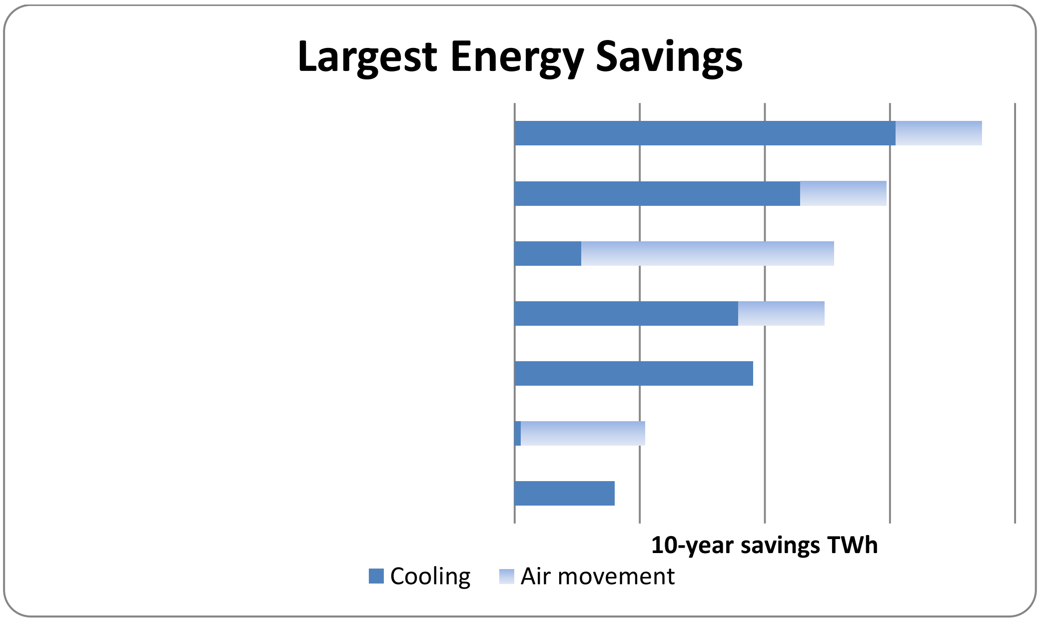

Figure 7. Summary of the Cases showing the largest Realisable Savings

These high-potential cases impact on all three of the types of energy saving mechanism, but it is noticeable that all have some bearing on system efficiency and only one directly addresses operational practice. The number of “X”s indicates our subjective view of their relative impact on the different forms of saving. Thus improved specific fan power can have a major impact on system efficiency through the reduction of fan energy use but a much smaller impact on the cooling load placed on the system (through reduced heat pick-up from fans).

Case	**Impacts on:**		
	Cooling load	System efficiency	Operation
Minimum performance requirements integrating building and system characteristics	XXX	XXX	
Detailed energy audits of air conditioning systems	XX	XX	XXX
Reduced fresh air in spaces where smoking is now prohibited	XXX	XX	
Minimum energy performance requirements for complete systems		XXX	
Demanding minimum performance requirements for chillers		XXX	
Performance requirements for specific fan power and air leakage	X	XXX	
Demanding minimum performance requirements for room air conditioners and other packaged units		XXX	

Table 2. Relationship between Principal Cases and types of Energy Saving

As noted in the previous section, in many of the cases, the 10-year take-up for some savings is constrained by the likely refurbishment rate of existing buildings. In particular major changes to central air conditioning systems (apart from component replacements) and to the building fabric are unlikely except as part of major refurbishment. As a result further savings beyond the 10 years period can be expected for most of the high-impact cases. Few further savings beyond the 10 year period will occur for minimum performance requirements for room air conditioners (of which many existing products will be replaced within the ten-year period), nor for energy audits (we have assumed mandatory application and good take-up of recommendations). The effect is present, but to a lesser extent for minimum performance requirements applied to air conditioning chillers, which typically have operating lives of the order of 20 years, resulting in a significant number of older products still being in use after ten years.

Some measures occur within more than one case – though not necessarily with the same ambition levels – and there are also interactions between measures. The savings from each are therefore not simply additive.

Discussion of Principal Results

Minimum performance requirements integrating building and system characteristics

Scope

This case represents the application of minimum performance requirements to the combination of the building and its air conditioning systems and products, applied during initial design and major refurbishment. It also assumes that minimum performance requirements are applied to replacement air conditioning systems and products, albeit at a less demanding level than assumed in the case for product requirements alone. This combination permits designers to meet the performance requirement by trading off different forms of energy saving according to the specific needs and circumstances of each building. As a proxy for this flexibility, the modelling assumes a combination of moderately demanding performance requirements for systems and load reduction mechanisms.

Specific buildings could, of course, combine more demanding performance in some areas with less demanding performance in others.

Implementation Method

This case follows the principles of the EPBD minimum performance requirements for buildings. As it has to be applied at the level of individual buildings, practical implementation has to be by Member States – most conveniently using the framework of their existing building energy regulations or standards.

Implementation Issues

The savings estimates assume that every Member State has relatively demanding (but not extreme) ambition levels. This is far from certain, notwithstanding the cost-optimality requirements of the EPBD Recast.

As far as is known, only a few Member States building energy regulations apply minimum performance requirements to replacement air conditioning products and systems. The movement towards the introduction of such requirements for products, through the Ecodesign Directive will partially address this gap, though the levels of requirements for products that can be justified for single-market products that may be used in many different climates and applications might be problematical.

A more fundamental barrier is that few Member States' regulations contain detailed calculation methods for the seasonal energy consumption of air conditioning systems. In a survey by the EPBD Concerted Action [15], only 6 of the 15 respondents claimed to have such a calculation method. Where calculation procedures do exist, Member States have largely developed them in isolation from each other and there is a need for a recognised and practicable methodology. A practicable methodology needs to be compatible with the rather low data reliability for existing buildings and systems, balancing the complexity (or otherwise) of calculation against the uncertainty of the data. It should also, as far as possible be consistent and make use of experience with those methods that are already in use.

Recommendations to support implementation

- A consensus should be developed for a generally acceptable energy consumption calculation procedure, which should then be developed and tested.
- Member States should be required to implement an effective calculation procedure.
- In order to support the application of such calculations, energy labelling requirements for air conditioning products should make mandatory the public provision of the part-load data used to define the label.

Detailed energy audits of air conditioning systems

Scope

This case assumes the mandatory implementation "detailed energy audits". These are more detailed – and more costly - site investigations than the "inspection" that is required by the EPBD, In addition to more detailed physical inspection and testing of systems it includes an element of consumption monitoring and associated diagnosis. EPBD inspections have been shown to identify only a small proportion of potential energy savings, albeit these are usually easily-implemented low-cost measures. It is the only case offering substantial savings through improved energy management.

Implementation Method

Since this measure has to implemented at an individual building level, implementation has to be by Member States. A number of Member States already have active programmes of Energy Audits which offer a model for general implementation.

Implementation Issues

Energy audits are not cheap, can intrude on business operations and savings are not guaranteed. Implementation of the less costly, but less effective EPBD inspections has been slow and is widely seen as not being cost-effective. The most effective combination of measurement, analysis and physical inspection is uncertain. The use of remote monitoring as an adjunct to inspection or auditing is currently being investigated [16]. In order to achieve savings, identification of opportunities has to lead to actions, some of which may incur significant costs.

Recommendations to support implementation

- Review existing Member States' energy audit programmes and policies
- Investigate the use of electronic monitoring of air conditioning systems to improve the cost-effectiveness of inspections and audits

Reduced fresh air supply to spaces where smoking is now prohibited

Scope

The supply of outdoor air for many existing air conditioning systems was designed in the anticipation that occupants would be permitted to smoke. In many buildings smoking is now no longer permitted. There is scope for new systems to have lower ventilation energy requirements than older ones, and also for many existing systems to be modified to use lower outdoor air supply rates. This leads to reduced fan energy consumption and, to a lesser extent to reduced cooling demands to deal with hot outdoor air and to offset heat released by the fans.

Implementation Method

Since this measure has to implemented at an individual building level, implementation has to be by Member States. For new systems fresh air rates in design guidance should be reviewed. The energy saving opportunity should be brought to the attention of building operators and air conditioning system inspectors.

Implementation Issues

The savings for this case are rather uncertain since the number of air conditioning systems designed for spaces where smoking is permitted is uncertain and the extent to which Member states have banned smoking is poorly documented

Recommendations to support implementation

- Fresh air design rates and regulatory requirements should be reviewed in the light of smoking legislation and amended where appropriate.
- Air conditioning inspectors should be reminded of the potential for savings.

Minimum energy performance requirements for complete systems

Scope

This case assumes the mandatory application of minimum energy performance requirements for air conditioning systems: in practice central systems, since packaged units and movable air conditioners are series-produced self-contained products that can be subject to Ecodesign requirements. This would apply to new installations in new buildings, new installations in existing buildings and replacement systems.

Implementation Method

Central systems are, in essence, bespoke systems using more or less standard components. They are tailored to match the needs of individual buildings and implementation has to be by Member States. For new buildings and major refurbishments this can be through national building energy regulations and standards, but the scope of these does not necessarily include the installations of new systems in existing buildings.

Implementation Issues

Although this case offers the potential for substantial realisable savings, there are several implementation challenges. The absence of a suitable calculation methodology discussed above applies equally to this case. In addition, installations in existing buildings are commonly outside the remit of national building energy regulations and codes, and additional infrastructure to implement the measure (or an extension of the remit of national building energy regulations) would be needed. For example, either installers or contractors will need training, or they would be required to employ accredited specialists in order to demonstrate compliance. This is not impossible but would add an extra workload onto a structure that is already heavily loaded.

With the exception of new installations in existing buildings, the benefits can more easily be gained through the "*Minimum performance requirements integrating building and system characteristics"* case discussed earlier. Minimum performance requirements for air conditioning components such as chillers would capture a proportion of the savings potential of new systems in existing buildings and it seems debatable whether the advantages of this case justify the need for extra support infrastructure.

The EPBD Recast specifically calls for the introduction of minimum performance standards for technical building systems but does not specify how these are to b implemented.

Recommendations to support implementation

- Air conditioning system-level performance requirements should not be treated as priority issue, but the case for them should be reviewed from time to time.

Demanding minimum performance requirements for chillers

Scope

This case applies demanding minimum energy performance requirements to air conditioning chillers.

Implementation Method

Chillers are series-produced products and can be subject to Ecodesign requirements including minimum energy performance requirements.

Implementation Issues

A Preparatory Study [11] was released in 2012 (after the work summarised in this paper was completed) that makes the case for such requirements. The recommendations are currently being considered. A potentially difficult issue for European product performance requirements for air conditioning products is that the performance levels that can be justified vary, in principle between climates and applications. Demanding requirements – if they incur extra costs – may not be cost-effective for relatively mild climates and national requirements ma offer better value for money than a single Europe-wide requirement. The performance levels proposed by the Preparatory Study are cost-effective for most European climates, at least for the building type considered (although only very marginally so in milder climates).

Recommendations to support implementation

- Introduce mandatory energy labelling and MEPS for chillers
- Before introducing Europe-wide demanding levels of product minimum performance requirements, consideration should be given to implementing them via national building codes, accompanied by an over-riding but less demanding European minimum performance requirement.

Maximum specific fan power requirements and leakage requirements for air handling systems

Scope

A significant proportion of the energy used in air conditioning systems is for air movement. This case assumes the universal application of requirements to limit air leakage from ductwork and to limit fan energy use. The metric for the latter is “specific fan power” and is a characteristic of the air handling system as a whole. It is determined by a combination of ductwork design, air handling unit design, (including cooling coil design and filter specification) and fan and fan motor efficiency.

Implementation Method

A number of Member States have such requirements within their national building energy regulations and standards. This case makes such provision universal.

Implementation Issues

A Preparatory Study into the application of Ecodesign [12] requirements to ventilation products has recommended an alternative energy performance metric for air handling units. This metric relates to the product (the air handling unit) alone and characterises its performance under standardised operating conditions. It therefore ignores the important contribution to energy consumption made by other parts of the air handling system and, from the wider perspective of system performance is incomplete.

Recommendations to support implementation

- Minimum energy performance requirements for specific fan power should be introduced in those Member States that do not already have such requirements.
- Minimum energy performance requirements for ductwork and air handling unit leakage should be introduced in those Member States that do not already have such requirements.
- To assist Member States to introduce these requirements, model clauses and guidelines should be developed, based on the experience of those that already have them

Demanding minimum performance requirements for room air conditioners and other packaged units

Scope

This case considers the implementation of demanding minimum energy performance requirements for room air conditioners and other packaged air conditioning systems.

Implementation Method

From 2013 minimum energy performance requirements for room air conditioners of less than 12kW cooling capacity (the majority) have been implemented under the Ecodesign Directive [14]. The Requirements will be made more demanding in 2014.

Implementation Issues

The analysis supporting the current requirements was carried out some time ago and, notwithstanding some revisions, is less demanding than those assumed in this case. In the meantime, the range of high-performance products on the market has expanded substantially. In some countries, sales of high-efficiency units have also increased significantly. As in the case of chillers, universal requirements for demanding performance levels may not be cost-effective in some milder climates.

Recommendations to support implementation

- Evaluate the case for progressively making the minimum performance requirements more demanding.

Supplementary recommendations relating to the principal results are summarised in table 3 below.

Case	Recommendations and relevant Policy Instruments		
	EPBD	**National Building Energy Codes** *(may be implemented via EPBD)*	**EcoDesign Directives**
Minimum performance requirements integrating building and system characteristics	Develop agreed air conditioning system efficiency calculation procedure		Provision of part-load information
Detailed energy audits of cooling systems	Stronger implementation of current requirements	Explore use of automatic performance monitoring	
Supporting actions for energy audits	Report calculated system efficiency on EPC Report measured air conditioning energy consumption Expand use of measured energy ratings		
Reduced fresh air in spaces where smoking is now prohibited		Review of outdoor air requirements	
Minimum performance standards for air conditioning systems	Introduction of system MEPS		
Demanding minimum performance requirements for chillers			Introduction of MEPS
Performance requirements for specific fan power and air leakage		Wider introduction of requirements	
Demanding minimum performance requirements for room air conditioners and other packaged units			Review MEPS
Generic Recommendations		Consider combination of EU and national MEPS	
Recommendations for further work	Investigate effectiveness of information provision measures in business to business supply chains Investigate relationship between product price trends, energy performance and MEPS		

Table 3. Summary of recommendations (including supplementary recommendations)

A note on cost-effectiveness and ambition levels

The results discussed above relate to the cases which generate the largest 10-year “theoretically realisable” energy savings. In practice they represent relatively demanding levels of ambition embedded policy instruments that either already exist or seem to us to be feasible. Equivalent cases with lower levels of ambition were also examined but are not reported in this summary paper.

Deciding what is an appropriate level of ambition is clearly an important policy decision, but is no simple matter. While the general direction of travel of policy is reasonably clear, the pace of change and justifiable levels are not.

A rational choice of appropriate measures and ambition levels depends, amongst other considerations, on their expected cost-effectiveness. However, the concept and definition of “cost-effectiveness” are also less clear-cut than is often assumed. From a policy perspective, for example, cost effectiveness can be viewed from the perspective of the direct costs faced by building owners and operators, or from the costs and benefits to society as a whole. Regulatory intervention may be justified for measures that are cost effective for society but not from the end-user perspective. Broadly speaking, the “demanding" performance levels referred to above reflect measures that are currently likely to be seen as cost effective by a only few building owners and operators in a limited number of building types and climates, but are – in our opinion - .plausibly likely to become cost-effective for society in general in the foreseeable future.

This section discusses a number of issues that surround (and often complicate) the definition of cost-effectiveness.

These two different perspectives are both important, but for different reasons. Ideally both need to be taken into consideration. Unhelpfully to the development of consistent policy, practice differs between different pan-European and National policy strands relating to energy use for air conditioning.

The two perspectives are:

- The perspective of society as a whole, including shadow prices for externalities (such as damage inflicted by climate change) excluding taxes and subsidies, using a (low) social discount rate.
- The perspective of end-users. This perspective includes taxes and subsidies, excludes non-priced impacts and uses commercial interest rates. Typically this only justifies lower performance levels than the societal perspective

Commonly both types of assessment are based on a hypothetical “typical” user and do not take account of different levels of impact on different parts of society. In the context of air conditioning, this could be users resident in different climates, for example.

From an economic perspective, in principle, all energy policy packages and measures should be designed to be cost-effective to society as a whole. However, policy measures that can be justified from this perspective may seem uneconomic from the perspective of some, or all, end-users. This situation is often used to justify the imposition of state regulation.

In practice, the cost effectiveness of product MEPS in Europe is generally assessed from that of an idealised end-user (who, somewhat inconsistently, is usually assumed to take a perspective that reflects the whole life of the measure and to apply a social discount rate). However, for building energy standards and regulations, the perspective differs between Member States. Roughly equal numbers of countries apply either a societal perspective or an end-user perspective, but a significant number consider both perspectives. Renewable energy policy generally takes a societal perspective.

For consistency of policy making it would be desirable to have an agreed set of conventions. The proposed EPBD methodology for cost-optimal building energy standards could be, in principle, a suitable basis for this but has become unnecessarily complex, yet still incomplete.

A common objective of policy design is that measures should be cost-effective or cost-optimal [2] . A policy is *cost effective* if its costs are less than the value of the resulting benefits. Cost effectiveness is sensitive to the assumed price and performance of the “base case” with which potential measures are compared. A policy is *cost-optimal* when the net benefits are maximised. This is a stronger requirement.

Many of the data needed for cost effectiveness calculations are inherently uncertain. This is most obviously the case for future prices (of, for example, energy) or of “shadow” prices (such a carbon damage price) for which there is no empirical evidence.

---

[2] And improved energy efficiency should not be at the expense of other aspects of performance such as comfort or noise.

For product and system performance policy there is the extra complication of possible interaction between the introduction of minimum performance requirements and product prices. Engineering analysis for products in the USA [17] show ratios of between 0.5% and 1.5%, with the higher figures relating to higher performance equipment. Calculations in Preparatory studies for Ecodesign [11] show a similar range. Japanese product prices [18] suggest that a 1% improvement of efficiency is associated with a 5% increase in price, but that some of this results from non-efficiency factors. Equivalent figures at less demanding performance levels from China suggest a somewhat lower effect.

The impact on market prices may, however, be different since there may be compensating reductions in the cost of stocking and supply resulting from the higher volume of high-performance product sales (and the removal of low-performance products). Non-mandatory high-efficiency products may also command higher prices by being positioned as "premium" products with additional features such as self-cleaning filters.

An IEA report [18] not specifically dealing with air conditioning) concluded that "Although there appears to be no correlation between price and energy efficiency and the average price of appliances has been falling consistency, there is evidence that the most efficient products in some categories are more expensive than products which are less efficient." Some of this increase was thought likely to be due to the inclusion of non-energy-related features in "premium" products. However, "the commercially sensitive nature of pricing policies, together with the complexity of separating out pure efficiency costs from other appliance features, makes it difficult for an outside observer to understand how prices relate to costs of manufacture"

Thus while the idea that policy should be guided by some kind of assessment of the costs and benefits of that policy is generally accepted, *what* costs and to *whom* is the subject of continuing scientific, methodological and political discussion.

Concluding remarks

In this paper we have quantified the growing energy, economic and environmental challenge arising from growing demand for cooling. A significant technical potential for reducing the projected growth in the associated energy demand has been identified at the component, product, system, whole buildings, and operational level. A comprehensive menu of recommendations assembled on how existing and new policies can be mobilised, in an integrated manner, to help curb the projected rise in energy consumption from air conditioning.

Enhance energy efficiency, technical and marketing tools to switch people habits in the long-term

Gilles GUERASSIMOFF, Centre for Applied Mathematics, Mines ParisTech

Johann THOMAS, GridPocket SAS

Abstract

Electricity consumer behaviors are known to be both hard to change and unstable. From this point of view a state of the art of smart-grid experiment and an overview of Home Energy Management Systems show that after a first phase of enthusiasm and energy efficient efforts, the moves cool down. Equipped people tend to take back their habits or to let the system run on its own, giving no more consideration to energy saving actions. Several cases even show a rebound effect, where people consume more energy that before the system was launch.

In order to keep people focused on their own energy efficiency behavior and help them to make the effects more long-lasting, the Grid-Teams project, held in 2012 in the city of Cannes, French Riviera, decided to focus on nudge marketing to assess whether these kind of services could enhance user's loyalty on efficiency habits.

By *nudge marketing*, we mean several tools to help users to understand and act. The experimentation helps them focus and to fully handle their own electrical impact. For this purpose, we metered forty households and built a complete Web user interface with several nudge services including a range of energy consumption, with two bounds; a higher level: the consumption as usual (CAU), and a target to reach: the goal. In the same time a genuine loyalty program called EcoTroks^{TM} was also developed. This paper explains how this electricity consumption range, from CAU to *the goal*, is computed and how the associated loyalty program seems to be an efficient manner to keep people involved in the program.

Introduction

The ongoing research on Smart Grid's deployment and applications [1, 2, 3] promotes the energy management in residential dwelling [4, 5, 6]. The future integration of smart metering needs to set new tools to inform and educate the final user to new consumption modes in the housing. Indeed, for many families, energy management is not a particular priority as the energy price is not high enough to be a significant part of the household expense.

It is still important to find a way of informing the final user so as to put them in a central place to be able to use all the potential of the smart grids. The *demand response* process that will be possible in the residential sector with the appropriate technologies will need the active participation of the final user. So how can we change the end user behavior to become active and reactive in his energy consumption?

It is the aim of the Grid-Teams' project supported by the program “agir ensemble pour l'énergie” of the regional authorities for south east of France (Région PACA) and the French agency for environment and energy management (ADEME) and coordinated by the company Gridpocket. The project involves the following companies: Planete Oui, WIT, the city of Cannes (in the south of France) and research laboratories (the Centre for Applied Mathematics of Mines ParisTech and the Sociological Centre of Telecom ParisTech). This project has developed a specific tool to assess the families' consumption and help them in the energy management of their housing. The originality of the project is to encourage the families in their way of having a better energy management by creating some social and cultural incentives. To verify the veracity of the methodology, the project has conducted experimentation on 40 families during one year in the city of Cannes [7].

We will present in the first part of this paper the methodology that has been employed to assess the housing and the family's energy behavior. In a second part we will present the tools that have been developed and deployed on the experimental panel. Then in the last part we will present some results obtained with some families.

Methodology

The project presented here aims at explaining the families the way of they use energy in their housing. As soon as they will understand where they can act to reduce their consumption, then they will be able to plan actions to reduce their consumption.

To achieve such an objective, we have to propose these families some tools to assess their consumption and other methodologies to make them active in the reduction of their consumption. To be able to show the users their consumption's level and to give them bounds adjusted to their particular case (an upper bound and a lower one), it is necessary to know details about three aspects:

The first one is **the structure of the housing**; the second one is **the appliances employed in this housing** and the third one is **the behavior of the family** living in this housing regarding energy uses. When these three topics will be identified, we will be able to propose them a kind of instrument panel that will show them in real time their consumption and the corresponding level regarding their specific bounds.

For these three levels of information we have to focus on, detailed inputs are very difficult to obtain without a completed study for each housing. The project proposes to elaborate a simplified model that can be representative of each housing without having resort to detailed analysis. To provide such a tool, we have analyzed a panel of 40 housings to validate our methodology.

Structure characterization

First of all we have realized a dynamic thermal simulation of the housing to determine its thermal performance and its sensitivity to its environment [8, 9]. The aim of this simulation is to determine some key parameters to elaborate some criteria that can be reused for similar buildings. For example, in a flat, the numbers of neighbors or the structure of the building is of a high importance to evaluate the bounds of the energy consumption.

Here is a scheme of the model for a flat that has been modeled with Comfie/Pleiade software.

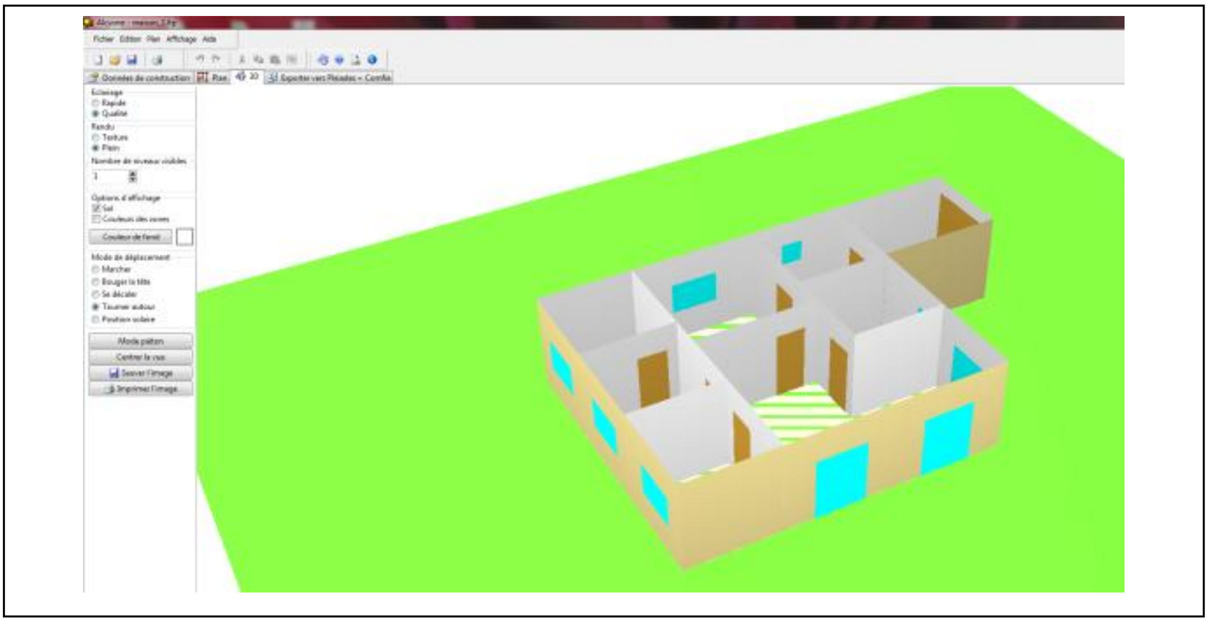

Figure 1 - Example of the housing representation in the dynamic thermal simulation tool.

With this simulation we obtain the need of the energy need of the building to maintain a given comfort temperature during an all year.

After that, the confrontation of these detailed simulations with a simplified thermal model for the building brings us to be able to identify the global thermal looses coefficient that can be identify to a category of building. This combination of the detailed way and a global way of calculus permits to elaborate some cursors to characterize similar buildings in the same range. The finality of this structure's building evaluation is to provide some cursors that can be adjusted with the results of a simplified survey.

Appliances characterization

The second phase is to inventory all the appliances in the housing and to assess the use of them by the families. It is difficult to quantify the reality of a specific use for an appliance. For example, how long do we use a kettle in a day? To achieve this inventory and the level of use of them, we have worked with the results of a European project (Remodece) [10, 11, 12] that has produced a big database of appliances load curves for several countries. Regarding the appliances, first of all different categories have been established to ensure a generalization of the methodology. Indeed, the numbers of appliances are too important and too diversified to have, for each family, and exhaustive count of them. And even it could have been possible, the quantification of their exact use is impossible to implement except with an energy metering for each of them that is not feasible. To compensate this lack of available information, a "brown" category including all appliances dealing with audio and video (TV, DVD player, video games, internet box…) has been created. A "white" category has also been created included all appliances we can find in the kitchen (Washing machine, oven, coffee machine…). The lightning, hot water, heating and cooling of the building are considered individually.

With these categories, two kinds of index have been determined. The first one is the level of equipment of the family. Based on a simplified survey regarding the kind and the number of appliances the family's got, the cursor can be move from a low equipped family to an over equipped family. The cursor will imply a level of power installed for appliance in the housing. The second one is also based on a simplified survey that evaluates the order of magnitude of the use of these appliances. This cursor can vary from a low use to an intensive use of these appliances. This level will determine a level of energy consumption in the housing. The combination of these two cursors gives a characterization of the family regarding their appliances uses in term of energy consumption and then it becomes possible to inform the family on its behavior.

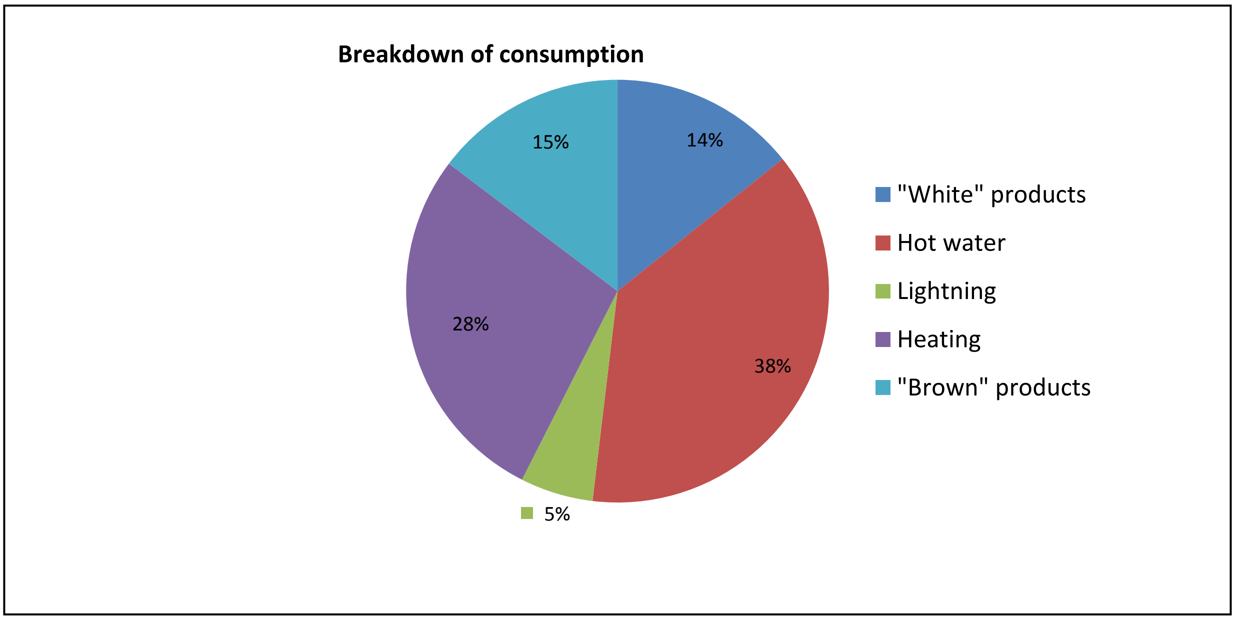

Figure 2 - Example of a breakdown of the consumption a of family provided bay our characterization

Behavior characterization

The last phase is to have an idea of the family behavior inside its housing. It is a very tricky task because this assessment can provide very significant differences in the results. To achieve such a goal, a sociologist team has realized detailed interview of the panel of families involved in the experiment. With these interviews, the sociologists have to identify the most pertinent characterization of a kind of family in term of its energy sensibility to be able to inform them about their uses and to orient them to a path of a more efficient way of their energy management [13, 14].

These interviews have to be match with their relative energy profiles (Building and appliances characterization) to provide an estimation of the differences we can observe between the theoretical energy needs regarding the structure of the housing and the real energy consumption realized. The second important point of this part of the analyses is to characterize the ability of the family to react to its own consumption and its capacity of reaction to these signals. The behavioral changes have to appear and also have to be sustained in a long term. To achieve with goal, the tools deployed in this project have to be well adapted for family that may not have any knowledge of energy topics. Some incentives have been included to strengthen such a goal. Indeed, one of the originality of this project is to add social incentive to the process of encouraging the families to a way of a better energy management of their housing. The goal is double; on the one hand is to encourage the family to make efforts on their energy consumption, on the other hand it is to develop some new social links as a consequence of their efforts. The incentive provides some useful gifts as bus ticket, low consumption light bulb, or social or cultural activities like concert places of tickets for local events.

The results of this behavior's characterizations have to be consolidate at the end of the project to assess its sustainability. The results of such a methodology can strengthen the effect of energy efficiency actions [15, 16].

Tool conception

To assess the characteristics of the buildings and to be able to provide the information in real time to the families, a smart meter has been installed in each housing of our panel. This smart meter is sending to a data center the power consumption of the housing each 50 watt modulation. These data provide to the system the detailed load curve of the family. Moreover, the temperature of the principal room of the housing is also sent to the data center. This temperature measure is very important to assess the comfort level and also give us precious information on the thermal behavior of the family. As the heating and cooling energy consumption can be the most important part in a building that do not correspond to the latest thermal regulation.

Regarding the results of the three characterizations describe previously, a web interface has been created to show the families their load curves and the bounds that correspond to their specific housing. A direct and secure connection for each family has been crated and they can interact by Email with a person that can answer to their interrogation. Moreover, the system can provide individually some advices after a rough analyze of their load curve to put them on the way of their energy management.

Web Interface development

The interface is the meeting point between technic and human. Therefore, it must be a good balance between information and usability, which means that the data should be bring to the user in the more easy to handle manner. This part explains the data path from the dwelling to the final user, from smart meter to Internet browser.

Data harvesting and storage

In France, the smart meter deployment is not completed yet; for the purpose of the Grid-Teams project we enjoy the help of the smart meter made by Wit, a French SME, targeted for industrial activity. This meter is able to measure, collect, store and send data for a huge list of commodity and time slice. On our experiment three commodities were monitored, Table 1, and took as input for both the thermal model and the final display.

Commodity	Unity	Monitor with	Send every...
Power	W	Amper clips after main electrical meter	time a trigger of 50 W is activated
Energy	Wh	Amper clips after main electrical meter	hour during the day two hours at night
Temperature	C°	Thermometer	hour time a trigger of 2° is activated

Table 1 - Commodities monitored in the Grid-Teams project

Three kinds of data sharing information on the three fields characterized earlier see infra p.2. Power and Energy spend were needed to level and understand the electricity consumption but also to assess user equipment rate and to profile usages. In the mean time the inside Temperature was useful to compute the stress on heating devices; to well understand this fight for heating we also collect external temperature to have an amount of degree to beat.

Once collected at the box level, data were sent via the general packet radio service (Gprs) protocol to the Wit datacenter, then forward to GridPocket Datacenter where data were pre-processed for the display on Web Interface. The architecture, Table 2, built on open source technologies helps the data consolidation and display.

Architecture layer	Technology
OS	Ubuntu
SGBDR	Postgresql 8.4.8
Application Server	NodeJs
Web Server	Nginx

Table 2 - Web Display architecture

Web Interface vs. In-home display

In the Grid-Teams project we choose the Web Application display instead of an In-home one because of the lighter development, the cheaper cost and the agility of the process. That means in a large-scale deployment to deal with the Web Access. By agility and large scale of features, we mean examples shown in the next paragraph.

Features

The design process involved final users in a co-conception process, to ease the service's acceptability by all users. There is two ways of displaying data in Grid-Teams, on one hand a simply informational way and on the other hand an augmented way, to nudge the energy efficiency. The second one involves some analyses and engines, when the challenges of the first stay in the best way to display the chart and plot to be understandable[1].

[1] Finding the good shapes and design for plot and graph are not as easy at it seems, these challenges need ergonomics and designer skills. Within this project, with a lack of support in this fields we exchange directly with the users.

Energy data

The way people consume energy could be display through different displays, from a gauge at a specific moment, Figure 3, to a time series with the choice of commodity to display, Figure 5, Figure 4.

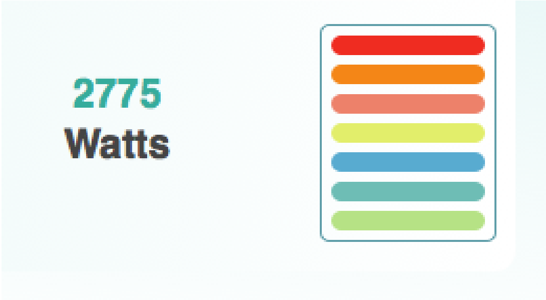

Figure 3 - Wattmeter

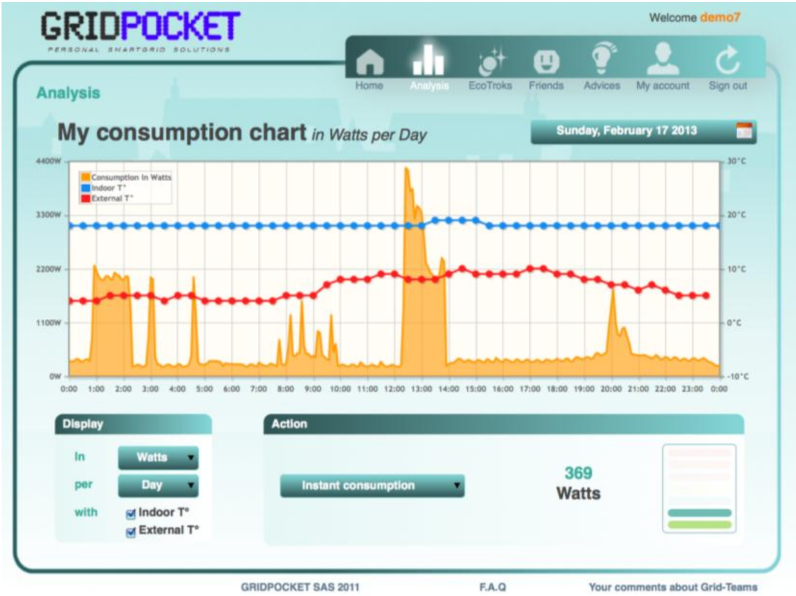

Figure 4 - Load Curve for user Demo 7 the 17th feb.

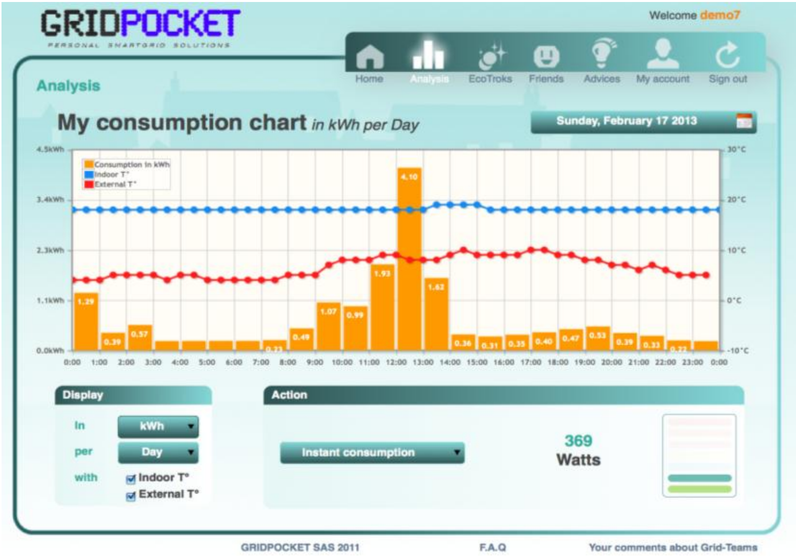

Figure 5 - Energy by hours within a day

Without help these information were already useful, but in some aspects quite difficult to handle and were not that easy to start switching for an energy efficient behavior. Other tools were offered to help the action to start.

Currency data

Speaking in technical terms, like the energy data above, can be sometimes hard to understand, so we decide to translate energy consumption to money.

Figure 6 - From energy to money

Scale and loyalty program

An important thing to do to motivate the participant and to keep him in the dynamic of the project is to show them bounds. The fact to show that you have to stay away from your upper bound and that you have a lower bound that is reachable is crucial. These bounds have been converted into currencies but are calculated with the thermal building knowledge, the appliances and behavior of the concerned candidate. Figure 7 show what the candidate can see on his interface.

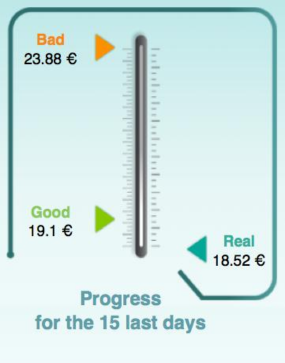

Figure 7 - Energy Scale

Showing bounds permit to assess the efforts that have been made, but for energy savings, due to relative low gains that can produce a real effort, a supplementary action has been integrate to the project. It is the reward mechanism that we have called EcoTroks TM. This reward is calculated regarding the level of effort that can be shown on the previous figure. If the candidate has reduced its consumption during the previous week, it earns some EcoTroks. The calculus of the level of EcoTroks earned by the candidates regarding their specific case is not explained in the present paper. With their EcoTroks, the families can choose rewards on a dedicated WebSite. When it is validated, they can go to the town hall of the city of Cannes to take them. It is the city of Cannes that has provided the rewards for the project. The figure below represents the screen shot of the EcoTroks Shop.

Figure 8 - The program's shop

Experimentation and results

Enrolment of the candidates

The project consist in an experiment conducted on a reduce sample to validate the methodology describe in the previous section. The first step was to proceed to the selection of a representative panel of family that corresponds to the different constraints we have decided previously. To be able to manage such experimentation we decide to choose specific housings principally renters with electrical heaters. We also decide to have various types of families (singles, families with children …).

The selection process was a project's milestone; the enrolment goes through a public advertisement and with the help of a city database of green association[2]. The sociologists have provided some questionnaires to manage the final choice for the experimentation. A panel of 30 families has been chosen at the beginning of the study and at the end of the project, 20 families have conducted the complete experiment. Some of them have given up because of a lack of time or because they have changed their housing. Several causes have been identified but the majority hasn't given up due to their lack of interest in the project.

Smart metering

For each family a smart meter design, built by WIT was installed. This smart meter was programmed to send to the data center of the project every change in the power level as it exceeds 50 watts (See previous part above). The project will assess the capacities of the use of such devices in helping distribution grid operator (DGO) to have a better understanding of final user's behavior. In our experiment, this metering and the frequency of data transmission have a key role in the analysis we can produce and for the representation we want to show to the final user.

Sociological questionnaire survey

For each family that has been enrolled in the experiment, a Sociologist has met the family and several individual and group meetings have been made to explain the purpose of the project and to assess the characteristics of the candidates in term of their level in the energy management feeling at the beginning of the project. Each interview of the candidate has been recorded (audio and video) with the authorization of the participant and the interviews have been transcribed and analyzed. The procedure of explanation in several stages is very important in the acceptance process of the project. This kind of information is essential to be able to establish the progress of the candidates during the project and their ability to continue in the same way.

Results

From a one year experiment a lot of feedbacks were significant for all the partners from the smart grid deployment point of view, technical issues, marketing tools to be improve, thermal model

One of the main results is the involvement within the loyalty program; orders were sent during all the program time.

From energy efficiency perspectives the results need to be improved and tested in a larger scale, but first analyze brings a reduction close to 10 % from an assumed consumption as usual. The loyalty program EcoTroks played a significant role in this dynamics. The two figures below, show two different situation, Figure 9 shows an user earning and spending EcoTroks (TK) in the Grid-Teams shop, we can see a consumption stick to the target while an other user, who didn't care about the loyalty program, who was more erratic (and sometimes even more efficient) and finally less efficient in average.

---

[2] UN's Action 21 for the twenty-first century was implemented by french government in an "Agenda 21" plan where cities and local government were able to labelise associations and other green actions groups.

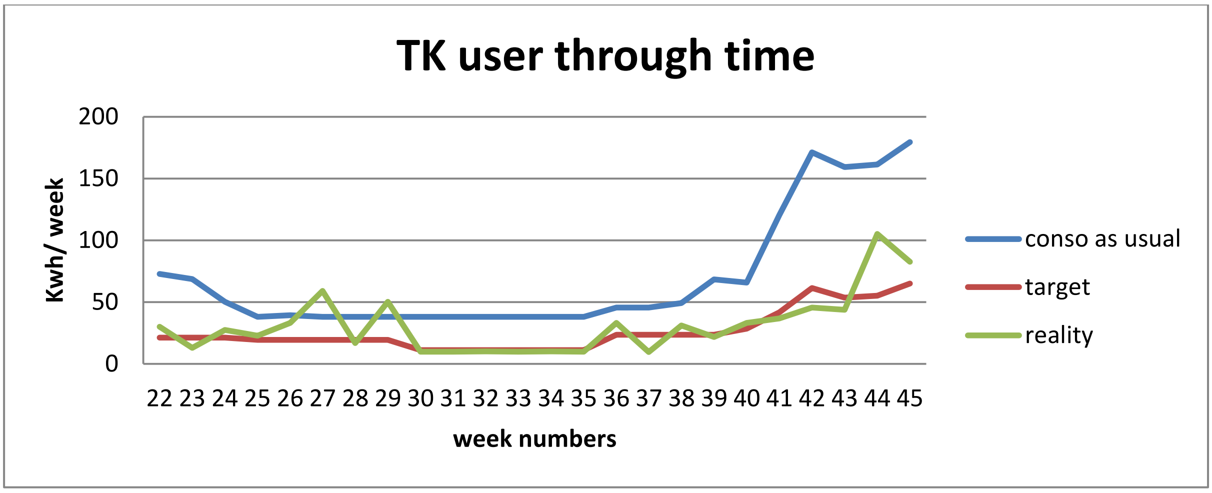

Figure 9 - User with TK gain, with a real consumption close to the targeted one

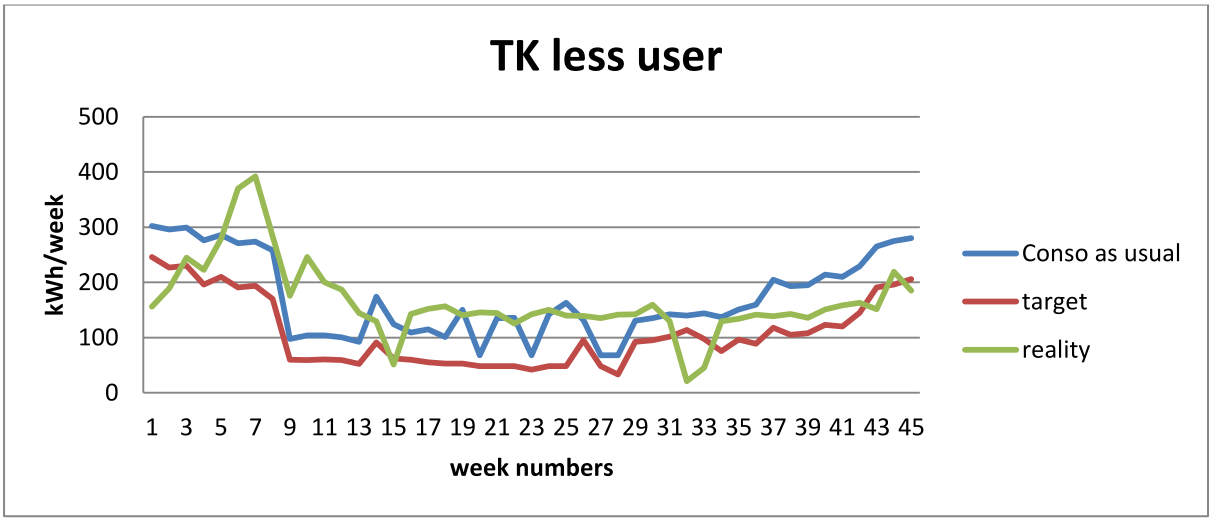

Figure 10 - User without TK, no clear path followed

Conclusion

The Grid-Teams project was an opportunity to test the potential of a smart meter for residential users in a way of energy reduction. The project shows that with a fine data collection, a fine analysis with a sociologist team, families can be involved in an energy management process. The methodology shows that we need some preliminary questionnaires (for the building part and for the inhabitant part) and a quick sample for the electricity consumption to be pertinent in our assessment of the family behavior. The results for the families are really encouraging. They validate the concept of the kind of information we have to provide to the families by our web interface to make them involved in a way of a sustainable reduction of their use of energy.

This is a first step towards robust tools that could be deployed at a large scale as soon as the smart meters will be available. A following project is forecast in this way to test the part that we couldn't test during this project. It is the social implication of the family regarding other similar families. A specific web interface was studied to imply a group of families and to put some competitions between candidates through the social networks to encourage them to reinforce their effort with the comparison they would make between each other.

Monitoring and Evaluation of Green Public Procurement Programs

Aure Adell, Ecoinstitut Barcelona

Bettina Schaefer, Ecoinstitut Barcelona

Kavita Ravi, United States Department of Energy

Jenny Corry, The Collaborative Labeling and Appliance Standards Program

Abstract

Effective procurement policies can help governments save considerable amounts of money while also reducing energy consumption. Additionally, private sector companies which purchase large numbers of energy-consuming devices can benefit from procurement policies that minimize life-cycle energy costs. Both public and private procurement programs offer opportunities to generate market-transforming demand for energy efficient appliances and lighting fixtures.

In recent years, several governments have implemented policies to procure energy efficient products and services. When deploying these policies, efforts have focused on developing resources for implementation (guidelines, energy efficiency specifications for tenders, life cycle costing tools, training, etc.) rather than defining monitoring systems to track progress against the set objectives. Implementation resources are necessary to make effective policies; however, developing Monitoring and Evaluation (M&E) mechanisms are critical to ensure that the policies are effective.

The purpose of this article is to provide policy makers and procurement officials with a preliminary map of existing approaches and key components to monitor Energy Efficient Procurement (EEP) programs in order to contribute to the improvement of their own systems.

Case studies are used throughout the paper to illustrate promising approaches to improve the M&E of EEP programs, from the definition of the system or data collection to complementary instruments to improve both the monitoring response and program results.

1. Introduction

Public procurement is the process whereby government organisations acquire the goods, constructions, and services (referred to hereafter only as “products”) required to operate and perform all necessary functions. By introducing environmental considerations into procurement processes and requirements – that is, by implementing Green Public Procurement (GPP) – the public sector reduces the environmental impacts of its operations, improves efficiency, and can reduce expenditures by reducing purchase needs and minimizing life-cycle costs. GPP requirements encompass a large number of environmental considerations, and usually include energy efficiency as this contributes to reduced energy consumption and costs by organisations.

In OECD countries government procurement represents approximately 18% of GDP [1] and up to 30% of GDP in developing countries [2]. Given the market share that the public sector represents, public procurement can transform the market for green solutions, eco-innovations and new, environmentally conscious business models. Therefore, the public sector is increasingly including procurement as a policy instrument to achieve the objectives set in a wide range of environmental and economic development policies.

To support practitioners implementing green and/or energy efficient procurement, efforts have focused on providing resources for implementation (including guidelines, environmental specifications for tenders with information on verification documents, lifecycle costing tools, best practices recommendations, or training) while little or no attention has been given to establishing mechanisms or systems to monitor and evaluate policy implementation and results.

When monitoring EEP/GPP programs, organisations track the implementation of the actions and measures taken as part of the program. With this information, policymakers can evaluate progress against policy objectives, and identify areas that need improvement, which will help in the development of supportive measures to improve efficiency and effectiveness in policy deployment. Furthermore, making results available both internally and externally demonstrates political commitment, enhances transparency, legitimizes the promotion of sustainable consumption and production by other sectors of society, and promotes policy embedment throughout the organization by keeping each agency accountable. As is often the case, accountability increases policy compliance. The type of M&E system that an organisation will choose to put in place will depend primarily on the objectives and actions set at the policy level, as the system will serve to track and assess progress in relation to them.

2. EEP at Policy Level

2.1. Policies Including EEP Requirements

Public authorities around the world are adopting policies that encourage or require the acquisition of energy efficient products by the public organisations within their jurisdiction [3]. The type of policies range from normative regulations and laws to general guidelines or recommendations, and their focus can vary from a specific energy efficient product, to general green procurement, climate protection, green growth or sustainable development as a whole. Table 1 presents the main type of policies where EEP commitments are included, with some examples from countries with different levels of economic development.

Table 1. Type of Policies Including EPP/GPP Requirements

Policy scope	Examples
Product-specific policies	Examples from the European Union include: - Regulation (EC) No 106/2008 of 15 January 2008 on a Community Energy-efficiency Labelling Programme for Office Equipment. - Directive 2009/33/EC of 23 April 2009 on the promotion of clean and energy efficient road transport vehicles. - Directive 2010/31/EU of 19 May 2010 on the energy performance of buildings.
Energy efficient procurement policies	- China Circular of 17 December 2004 on the Implementation of Government Procurement of Energy-saving Products and Circular of 30 July 2007 on Establishing a Mandatory Government Procurement Scheme of Energy-saving Products. - Japan Green Contract Law (Law No. 56 of 2007) Concerning the Promotion of Contracts Considering Reduction of Emissions of Greenhouse Gases and Others by the State and Other Entities.
Overarching green procurement strategies	- Canada Federal Government Policy on Green Procurement. - Brazil Regulation nº1 of 19 January 2010, on environmental sustainability criteria in the procurement of goods, services and works of the Federal Public Administration and related agencies. - Spain Order PRE/116/2008 of 21 January 2008 publishing the approval of the Plan on Green Public Procurement of the Central Government and Related Agencies.

Energy/ Environmental operations policies	- United States Executive Order 13514 of 5 October 2009 - Federal Leadership in Environmental, Energy and Economic Performance. - United Kingdom Greening Government Commitments: Operations and Procurement (February 2011). - France Circular of 3 December 2008 concerning the exemplarity of the State in respect of sustainable development in the operation of its services and institutions.
Environment protection policies (such as climate protection strategies, sustainable development strategies, etc.)	- Mexico City Climate Action Program 2008-2012. - South Africa Notice 908 of 2009, National Energy Efficiency Strategy of the Republic. - Colombia National Development Plan 2010-2014: Prosperity for all.
Green growth policies	- United States Farm Security and Rural Investment Act of 2002 (FSRIA) and Resource Conservation and Recovery Act (RCRA). - European Union Lead Market Initiative.

2.2. The Effect of Policy Objectives in the Definition of M&E Systems

The objectives and targets of the policies that include EEP requirements are diverse. For example, in its Communication Green Public Procurement for a Better Environment, the EC proposed that by 2010 50% of all tendering procedures should be green [4]. In Japan, the policy concerning the Promotion of Contracts Considering Reduction of Emissions of Greenhouse Gases and Others by the State and Other Entities, also known as Green Contract Law, sets the objective to reduce direct and indirect GHG emissions by 8% from 2010 to 2012 using the 2001 level as a benchmark through contracts related to the supply of electricity, the procurement and leasing of vehicles, the procurement of ships, the construction and/or renovation of buildings, and contracting Energy Service Companies [5]. In Spain, the GPP Plan of the Spanish Central Government sets different objectives depending on the actions. Thus, the plan includes an objective of energy saving of up to 9% by 2010 and 20% by 2016 in buildings; a reduction of 20% in fossil fuel consumption and an increase in the consumption of biofuels to up to 38% in transportation; and for IT equipment, 100% of all new computers, screens and imaging equipment must comply with the energy consumption limits defined in the Energy Star standard [6]. Mexico City's 2008-2012 Climate Action Program set specific annual CO_2-equivalent reduction targets for a variety of energy efficient measures in public buildings, transport, and other areas [7].

The different objectives set at the policy level can be classified into four main goals related to procurement that can be present either individually or in combination:

1. To transform the market for energy efficient products
2. To achieve greenhouse gas (GHG) mitigation and reduce other environmental impacts
3. To embed EEP/GPP in the organisations' operations and procedures
4. To increase actual procurement of environmentally preferable products and services

The first two, *final goals,* justify the inclusion of EEP requirements. The other two, more *practical goals,* determine how to reach those final goals.

As the objectives of each policy might be different, the design of the M&E system will vary, as it has to be in line and able to track and assess progress in the achievement of the set goals and commitments.

3. Monitoring EEP Requirements

As listed above, one of the principal reasons for introducing EEP requirements in policies is to serve as a catalyst for the market penetration of green products and services. As such, an approach to evaluating the success of EEP commitments could be to assess to what extent EEP has contributed to an increase in the market share of more energy efficient products. However, this approach has rarely been followed, this may be due to the fact that market transformation is used as a motive or justification but no targets are set to monitor against. Also, the public sector is not the only player nor is public procurement the only instrument influencing market changes. Instruments such as taxes, subsidies, regulations, and demand from the private sector and consumers can have a more significant impact, making it difficult to measure the effect of EEP in market changes. Furthermore, such studies might have a negative cost-benefit balance, as the resources required to conduct the research does not justify the benefits yielded. These studies analyze the market and may provide limited useful information for better EEP embedment. We should not forget that monitoring is not only used to evaluate policy compliance and results/impact, but also to hold agencies accountable for better implementation and to identify areas for improvement and this information cannot be obtained through market studies.

In comparison to market transformation monitoring, assessing EEP embedment in operations is a much more straightforward process. In all the cases analyzed, the M&E systems to track and assess compliance are based on surveys, which for the most part require little or no data digging and gather qualitative information, making them easy to complete. One weakness of surveys is that the results are not always precise and may represent only the opinion or perception of people who complete them. This is especially critical when results are compiled to reflect the entire organization, because procurement is decentralized and may be implemented differently in each department. To accurately evaluate the extent to which EEP is actually conducted in procurement processes a more objective and quantitative analysis of procurement of energy efficient products is recommended.

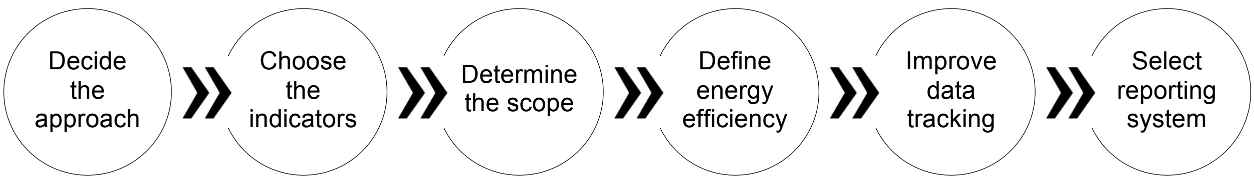
Therefore, this paper focuses on the two M&E approaches to measure EEP implementation and results that have received the most interest from government agencies: 1) the monitoring of the procurement level of energy efficient products and 2) the assessment of the environmental relief achieved through EEP.

3.1. Monitoring the Procurement of Energy Efficient Products

In order to measure actual EEP implementation, many organizations have developed or are developing M&E systems to quantify how many of the products they buy/contract or the tenders they publish include or comply with energy efficient or other environmental criteria. In fact, this is the approach where more examples and experiences from public authorities exist.

In order to set up such a system, different elements have to be considered, which are summarized in Figure 1 and discussed below.

Figure 1. Steps to Design an M&E system for the Procurement of Energy Efficient Products



Source: Ecoinstitut.

3.1.1. Decide the Approach

The first decision to be made is whether to monitor tenders or actual purchases. This decision can be made at the policy level, or may be defined later if objectives are not specified in such detail in the policy. In the second case, it is advisable to first analyse existing data tracking systems (see section 3.1.5) before deciding on the approach.

The main advantage of *monitoring tenders* is that they can be tracked more rapidly than product purchases, as all the information is found in the tender itself and does not require data input from different people or from suppliers.

The disadvantages are that when monitoring tenders, direct purchases are frequently, if not always, excluded from the scope of the monitoring, losing what might be an important portion of overall public procurement. Special attention must also be paid to framework agreements; they might approve several products and/or companies, but the resulting secondary contracts might not qualify as energy efficient. Furthermore, monitoring tenders does not show, in general, the actual result of the process and what is purchased or contracted in the end. Thus, a tender counted as "greened" might not yield the acquisition of an energy efficient product, unless only tenders with compulsory environmental criteria qualify as such. Nevertheless, it is often argued that for public procurement to create a market pulling effect for energy efficient and green products, organizations have to clearly signal to suppliers their green purchasing preferences. Public administrations do this through their tender documents and purchase orders, which capture their organizations' purchasing requirements. Therefore, to evaluate the impact, it would not be necessary to monitor what is actually procured, but the degree to which energy efficiency criteria are included in tender documents.

The advantage of *monitoring acquisition* of energy efficient products is that this shows not just intentions, as could be the case when monitoring tenders, but rather actual purchases. This type of monitoring tends to cover all kinds of purchases—both from contracts and direct purchases—and facilitates the evaluation of environmental relief achieved with EEP (see section 3.2).

However, tracking green product acquisition is less straightforward than tracking tenders. Financial systems and budgets are normally aggregated and coded at a higher level than product procurement, so certain products might not be directly identifiable in existing systems unless they are set up to track information at a product level. Additionally, products used within service contracts cannot be tracked using the organizations' systems, but require input and reporting from the service providers. That can be an obstacle to tracking given the tendency to outsource services, and to change acquisition models from procurement of products to services. Also, purchases occur more frequently than tenders, increasing the number of transactions to be monitored. Such transactions are normally carried out by a larger number of people, which implies the involvement of more staff in tracking green expenditures, increasing the possibility of data errors.

Therefore, tracking tenders is easier than tracking purchases unless products are purchased through procurement platforms (stores or catalogues), which allow direct and automatic tracking.

3.1.2. Choose the Indicators

Secondly, organisations must define the Key Performance Indicators (KPIs) to express and evaluate results. According to the case studies analyzed:

- When monitoring tenders, the indicators most commonly used are the total amount and the percentage of tenders (both in number and in economic terms) that are green in relation to the total amount within a given reporting period.
- When monitoring the acquisition of products, the level of EEP is calculated using the total amount and the percentage of energy efficient products purchased in terms of expenditure and, to a lesser extent, in units in relation to the total purchased during the reporting period. This second indicator is relevant to estimate the environmental benefits of EEP based on products, as normally environmental factors for transforming green purchases into environmental benefits use number of units purchased rather than economic ones (see Section 3.2).

3.1.3. Determine the Scope

Thirdly, the product groups that will be monitored must be identified. Public administrations buy or contract many different types of energy-consuming products (IT equipment, vehicles and transport services, traffic and street lighting systems, building heating and cooling systems, medical appliances, vending machines and kitchen appliances, etc.). Organizations might focus on all of them, but normally a group of priority products is chosen. Examples of criteria considered when selecting product groups to monitor include: 1) prior selection at policy level; 2) the existence of standardized EEP criteria at the regional, national, or municipal level; 3) the availability of energy efficiency standards and/or labels (if no standards exist, it is very difficult to implement EEP); or 4) the significance in terms of expenditure and/or ubiquity within the organizations being monitored.

3.1.4. Define what Qualifies as Energy Efficient

For a tender or purchase to be considered energy efficient, it is necessary to first define the parameters by which it will qualify as such. This is normally based on standardized labels or EEP/GPP criteria implemented at the regional, national, or local levels.

<u>Case 1. Chinese Government Definition of Energy Efficient</u>

In 2004, the Ministry of Finance and the National Development and Reform Commission promulgated an EEP policy, the “Implementation Guidelines for Government Procurement of Energy-saving Products”, which required public agencies to give preference to energy efficient products when procuring (becoming mandatory for certain product groups from 2007). Energy efficient products are defined as those that have been awarded the Energy Conservation Certification of the Chinese Government and are included in the Government Procurement List on Energy Conservation Products [8]. The definition refers to the existing National energy label.

<u>Case 2. Definition of Energy Efficient in the Pilot M&E Methodology of the European Union</u>

In 2008, the European Commission (EC) contracted the development and testing of a methodology to monitor the implementation of GPP in the European Union (EU). Contractors used the existing EC GPP standard criteria developed the previous year to define what qualified as energy efficient. IT equipment had to comply with the energy consumption thresholds defined in the Energy Star standard [9], thus using a standard as reference. For passenger cars and light duty vehicles, there is not yet an energy efficiency label at the EU level (unlike other energy-consuming products such as electrical appliances/white goods or tires), but all vehicles are sold with a compulsory label that informs consumers of the average CO_2 emissions per kilometre of the vehicle. Therefore, the M&E methodology used this label and the GPP criteria to qualify vehicles as “green” if the CO_2 emissions of awarded vehicles were below the maximum threshold defined for the vehicle’s category. [7]. In this case, the EC GPP criteria in combination with the compulsory label were used as reference to define “green”.

3.1.5. Select, adapt or set data tracking systems

One of the difficulties of monitoring EEP in terms of expenditure in green products and services or incorporation of environmental criteria in tender documents is the lack of integration of EEP tracking requirements within existing procurement and/or financial procedures and tools. Because of this, data is not systematically registered and annual tracking of EEP is extremely time-consuming, especially when EEP covers a wide variety of products and services and there is little centralization. Additional difficulties might arise if EEP is monitored as part of GPP policies and the criteria used to define “green products” demands compliance with multiple specifications.

Listed below are methods that may be used to track the purchase of energy efficient products or data on product use in service contracts.

- *Adapt internal financial systems to track expenditure at product level*. This approach might also require adaptation to track the number of units purchased as organizations typically only record expenditures. However, these systems don't allow the tracking of products used within service contracts and require input by many different people, increasing the risk of errors.

- *Insert reporting requirements in tender and/or contract language.* This approach makes providers accountable for tracking green product sales to public authorities and is crucial for tracking products used within services. If this method is used, it is very important to clearly define: 1) what qualifies as green, as vendors might erroneously describe items as green, and 2) what information is needed to integrate data from other providers, compare results between units or agencies, and/or calculate environmental benefits - thus organisations have to develop data reporting standards. Some downsides are that it is difficult to verify data accuracy and information gathering can be time consuming, requiring tight contract management by the administration to ensure that contractors deliver reports.

- *Use or develop electronic catalogues for centrally purchased items*. These systems make information easily available internally, provide accurate data on energy efficient product purchases (for both expenditures and physical units), and allow central analysis without requiring reporting by each organization or department. The downside is that this method is only useful for a limited number of products, as most purchases are not centralized nor are all of them suitable for an e-catalogue, and cannot yield data on products used within service contracts.

The following strategies may be used to track data more efficiently when the monitoring approach is based on tenders:

- *Insert a section in the tender documents that clearly identifies any applicable energy efficiency criteria*. This method makes it easier for departments or organisations to identify green tenders, but it still requires manual analysis and reporting. This may be done for example with: 1) a simple checkbox to indicate whether green criteria have been introduced in the tender; 2) a table for purchasers to indicate where in the tender EEP criteria have been introduced (technical specifications, award criteria, etc.); 3) a list that indicates if criteria for designated products have been introduced; or 4) a table to indicate if national or local standard green criteria have been introduced (fully vs. partially, core vs. comprehensive, mandatory vs. best practice).

- *Request procurers to complete a form when submitting a bid, awarding a contract, and/or completing a project.* The form can summarize the energy efficiency or green criteria introduced in the tender or complied with by the awarded offer, depending on how the indicator has been defined.

- *Adapt information fields if using an electronic tender publishing platform to track relevant information required for the M&E system.* The benefits of such systems are that they allow automatic data analysis, process larger amounts of information quickly, and minimize bias. However, if not properly programmed they might leave out certain energy efficient tenders, and using such automated systems might limit the awareness raised within the organization of the M&E process as no input is required from them.

Therefore, when quantitatively monitoring the level of green procurement, M&E systems should use data sources that are directly available and require the input of the least number of people in order to minimize errors, eliminate bias, and reduce the time required for M&E from the organisation as a whole. Measures that require adapting financial platforms, electronic catalogues, electronic tendering platforms, or any other procurement management software that can facilitate tracking green tenders or expenditures on green products requires an initial investment, but will save resources that would otherwise be required to collect data.

Some cases of administrations that have applied some of the solutions presented are described below.

Case 3. Tracking Green Purchases via the Finance System in Cardinia Shire Council (Australia) [10]

Cardinia Shire Council, a public authority in the State of Victoria (Australia), participates in the State's EcoBuy Program and is committed to buy green products and report progress annually. To do so, the Council has set up mandatory fields in its financial software that procurers fill in to accurately and consistently capture expenditures under various green categories. To ensure appropriate data recording, measuring, and tracking, green procurement has also been integrated into the finance system's procedures and training.

Case 4. Tenders Language for Procurement Tracking by Suppliers in King County (US) [11]

According to the guidelines for procuring environmentally preferable computers by King County, staff are required to include specific language in its call for tenders requiring suppliers to track and report green sales. Two options are provided. The first requires contractors to provide quarterly reports quantifying the EPEAT registered and unregistered products purchased under the contract in a format acceptable to King County. The second option includes a matrix that vendors have to use to report sales (see Figure 2).

Figure 2. Matrix for vendors to report green sales

	Unregistered		EPEAT Bronze		EPEAT Silver		EPEAT Gold		Total	
	No. units	$ spent	No. units	$ spent	No. units	$ spent	No. units	$ spent	No. units	$ spent
Desktops										
Laptops										
Monitors (LCD)										
Monitors (CRT)										
Total

Case 5. Tracking Sustainable Tenders in Chile Through an E-tendering Platform

The public sector in Chile uses two centralized electronic platforms for its purchasing activities. The national tendering platform, *Mercado Público*, centralizes the call for tenders of goods and services from most public agencies in the country (excluding public companies). The online store, *ChileCompra Express*, is used by public authorities to buy products centrally procured through Framework contracts by the Directorate of Public Procurement of the Ministry of Finance (known as *ChileCompra*).

When tendering through *Mercado Público*, public authorities not only upload their tender documents and publicize them, but also fill in several online forms that correspond approximately to the administrative tendering document. In these forms, procurers have to specify, among other details, the selection criteria for companies to be able to participate, administrative information about the tender (duration, guarantees, insurances, etc.), and the award criteria. Procurers can specify different award criteria from a list of categories, including Energy Efficiency and Environmental Impact. This information is registered in the platform database, making it easy to identify tenders that include energy efficiency or other environmental specifications as award criteria. The limitation of the system is that it excludes tenders conducted by public companies and it doesn't allow tracking of tenders that include compulsory energy efficiency criteria, as they are not registered in the platform database (the technical tender is uploaded as a document, preventing automatic search for environmental requirements).

For purchases conducted via *ChileCompra Express*, the environmental characteristics of awarded products are displayed in the online store as an output of the platform database, making it possible not only to quantify the tenders that included sustainability award criteria, but also tenders that resulted in the selection of more sustainable alternatives.

As the monitoring system is designed to use the parameters and variables registered in the e-procurement platform (in the form of SQL databases), the sustainable procurement indicator is very easy to obtain and therefore to monitor. Through standardized queries to the e-platform database, *ChileCompra* monitors the evolution of the percentage of sustainable procurement each month at the internal level, without requiring input from the organisations tendering through the platforms.

Case 6. Tracking green tenders in Malta [12 and 13]

Since 2012, procurers in the Government of Malta have been required to include GPP criteria set by the government in the tender documents for certain prioritized product groups. To monitor compliance, all calls for tenders must be supported by a form (Tender Originators Form), which was revised to include data on the application of GPP along with information on the tender (promoter, estimated value, lots, etc.). Procurers must submit a scanned signed copy of this form to the Office of the Prime Minister by e-mail to track and verify compliance.

3.1.6. Establish the Data Reporting System

After tracking the relevant data, information has to be reported to the organisation or department in charge of the overall monitoring for evaluation. As presented in the previous section (3.1.5), each department or organization may track and/or gather information from different data sources. For example, some data can be accessed directly by the "monitoring" agency or a central body reporting for all the organisations subject to the monitoring, while other data collection requires compilation by each department or organization.

Reporting data from procurement or tenders via a survey can be time consuming if too much information is required and no automatic system (not even at department level) exists, reducing the response rate. Moreover, results are rarely verified unless a small amount of data is required, and departments or organizations with low performance might not respond. However, the request can raise awareness and promote EEP implementation in the future. If all information is processed automatically and no benchmarking, training, or communication efforts are in place, departments or agencies may not be aware that EEP requirements exist and have no incentive or knowledge to implement EEP.

If data is centrally available, EEP evaluation can be conducted directly by the "monitoring" agency, reducing the monitoring time as little or no waiting time is required as compared to surveys. A central data source also makes it possible to analyze results from organizations with varying levels of performance. Thus data and results are more reliable and comprehensive than those obtained through a questionnaire/survey.

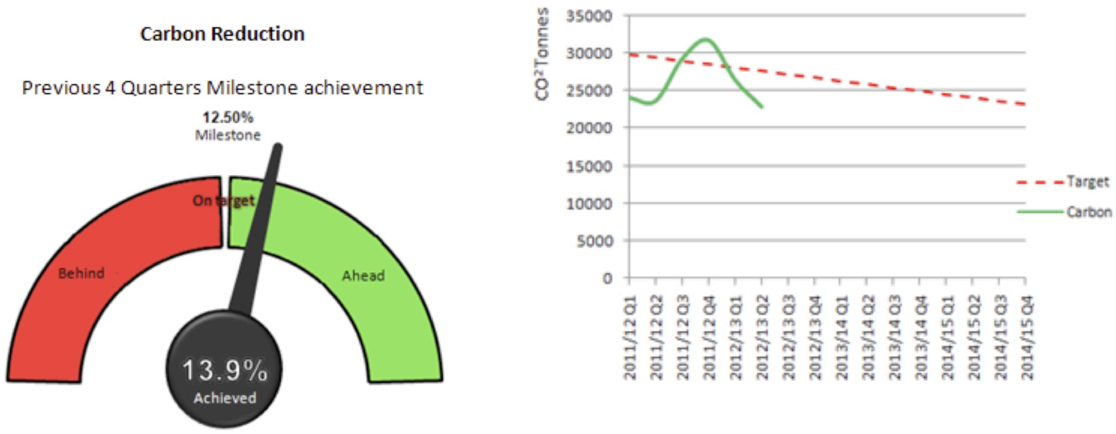
Whenever possible data reporting systems should: 1) be integrated with other reporting tools to simplify procedures; 2) be standardized to allow comparison among organisations; 3) be designed to require information in the same format as organisations gather it to avoid confusion; 4) be in an electronic format to facilitate data aggregation by the "monitoring" agency; and 5) be able to provide instant feedback on performance and progress to the organisations.

Case 7. Reporting Mechanism for GPP Monitoring in the United Kingdom (UK)

In 2006, the UK Government approved the Framework for Sustainable Operations on the Government Estate (SOGE) and the Sustainable Procurement Action Plan for the public sector as a whole. As the SOGE is the Central Government's umbrella for sustainable operations, it was agreed to integrate all elements of government sustainable operations, including those from the Sustainable Procurement Action Plan, into the SOGE monitoring and reporting system. The reporting mechanism was through an on-line questionnaire that gathered performance data reported by departments. Each department had its own system to collect and process the required data, but all of them input data in a standardized manner to allow comparison and benchmarking among departments. Until 2008 the questionnaire was a stand-alone tool, but from the fiscal year 2008–09 until the end of the SOGE reporting process in 2010–11 the questionnaire was integrated with the e-PIMS platform, an existing central government property database used to collect building-level data for other SOGE targets.

In 2011, the SOGE framework was replaced by the Greening Government Operations and Procurement Commitments (GGC) and the reporting system changed. The new system uses a spreadsheet as a template. One advantage of this method is that the spreadsheet automatically calculates and graphically presents each organization's performance against baseline data to show progress towards achieving the targets and forecast the evolution to the GGC deadline in 2014/15.

Figure 3. Defra's GGC Carbon Dashboard and Carbon Chart



Source: Department for Environment, Food and Rural Affairs. Greening Government Commitments: Defra's Performance. 2012/13 & Baseline. December 2012.

3.2. Monitoring Environmental Relief

Despite the fact that EEP is promoted as a means to reduce the environmental impacts of an organisations' activities and processes, very few of the EEP or larger GPP programs analyzed actually monitor the environmental relief obtained through the procurement of energy efficient or further green products. However, its calculation is more frequent when monitoring "green-the-government" or climate protection policies that include EEP requirements, as most of them set specific environmental relief objectives.

One of the main differences between general GPP and EEP is that purchasing energy efficient products can directly impact an organisation's environmental performance. The impacts of many green products (e.g. products with a high percentage of recycled content, bio-based, or free from certain hazardous substances) occur during the production phase and if they do occur during use by the administration, they don't have a direct impact on organisations' environmental parameters that can be monitored to evaluate environmental results. Energy efficient products influence the organisation's energy consumption, which is a measurable parameter. Therefore, environmental relief achieved through EEP can be measured or calculated by 1) the environmental characteristics of the products purchased or used in services and constructions and 2) on the energy performance of the products, constructions and services during its use phase, that is, while they are used by the organisation.

To evaluate results, the KPIs for EEP programs are quite straightforward and in line with other energy-related policies, namely energy consumption and GHG emissions (expressed frequently as CO_2-equivalent).

Given that this kind of monitoring tracks or estimates energy consumption, and information on product costs are also available, cost savings achieved with EEP can also be used as KPIs to support EEP in regions or organisations where costs of green products are often highlighted as an obstacle to GPP implementation.

3.2.1. Estimates Based on Products Purchased

When the environmental benefits are calculated based on the purchase of energy efficient products, the resulting figures are only estimates that can either over- or underestimate final performance. Furthermore, impact analysis generally focuses on the impacts during the use phase linked to energy consumption and is therefore expressed as a reduction in energy consumption or GHG emissions.

For such calculations, the first data points to gather are the number of products purchased or used. Data will have to be reported or adjusted to be in units that are consistent with the consumption units (see below). M&E system designers should take into account that sometimes only expenditures are recorded, thus requiring additional information can present a challenge for those that collect data.

Secondly, the environmental characteristics of the products, namely energy consumption per unit and energy source (electricity, gas, diesel, biomass, etc.), have to be registered. These characteristics can be either of the product – direct evaluation – or of an agreed proxy – proxy evaluation. In the first case, the exact energy consumption in each operating mode of the items purchased in a contract has to be registered. In the proxy evaluation, a reference energy consumption value is selected as proxy and applied to all products. For example, if televisions rated class-A according to the national energy label are purchased, reduction in energy consumption can be calculated using the exact energy consumption of each TV (direct evaluation) or using the minimum consumption for class-A as a proxy. While direct evaluation of the estimated environmental benefit is slightly more accurate, that level of data tracking makes the process burdensome and unnecessarily exact given that other approximations have to be used to calculate the environmental benefits afterwards. Proxy evaluation is less precise and might underestimate environmental benefits, but it is simpler and data is easier to track. That is why most organizations use proxy evaluations to estimate the environmental benefits of EEP/GPP.

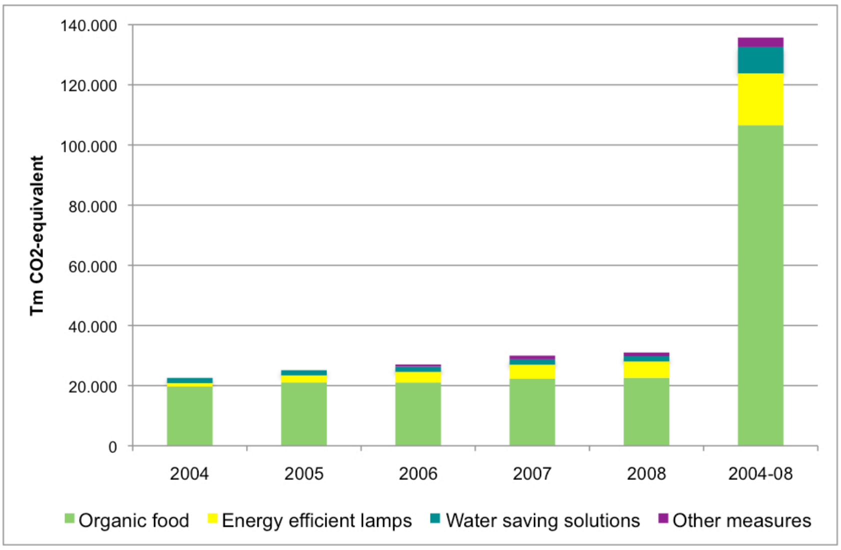
Thirdly, the environmental impact factors have to be established. This includes estimated functioning modes (for computers, it might be hours a day in “on”, “stand-by” and “off” mode and annual workdays; for vehicles annual mileage is normally used) and conversion factors. These conversion factors translate estimated consumption units into GHG emissions by energy source (for example grams of CO_2 by kWh of electricity, litre of fuel or m^3 of natural gas).

Finally, and in order to communicate how EEP has reduced energy consumption and GHG emissions, the environmental characteristics of products used previously or non-efficient alternatives have to be recorded. When doing so, it is recommended to track not only the improvement ratios between green and not-green products, but also the absolute figure to calculate the environmental relief achieved from buying less. GPP is meant to improve the environmental performance of public authorities throughout the whole purchasing cycle. Thus, the effects of these programs can go beyond buying green product and include other activities in the field of responsible consumption, such as reducing needs or using resources more efficiently. If only the environmental benefits of buying green are evaluated, an organization buying a larger quantity of products might show better results in environmental relief than another one that reduced its overall consumption. Therefore, monitoring the environmental performance on the basis of purchased products should also consider overall purchases to avoid penalizing organizations that become more efficient and reduce their purchasing needs.

Case 8. Benefits of Vienna’s ÖkoKauf Program

The green procurement program of the Vienna City Council, known as *ÖkoKauf Wien*, was set up in 1999 as one of the key elements of the city’s climate protection program, *KliP Wien*. Even though *ÖkoKauf* does not maintain detailed records of the environmental relief achieved, some calculations have been done to communicate the environmental benefits and cost reductions of the program, as there is a general misperception that ecological goods and services always come with a price premium. For the environmental component, the program calculated impacts during either the use or production phase of the product or service. For example, with organic food an estimated factor of the environmental relief during production of organic versus conventional food was used. For energy efficient lamps and water-saving devices, the impact was estimated based on the reduction of water, hot water, and electricity consumption during use [14].

Figure 4. CO_2-equivalent reduction achieved with GPP in the City of Vienna, Austria (2004-2008)



Source: Patak, G. *ÖkoKauf Wien* [slides presentation]. European Public Sector Award 2011 (Maastricht, the Netherlands 15-17 November 2011).

3.2.2. Calculations Based on Energy Consumption

Due to the influence of energy efficient products on the organisation's energy consumption, the benefits of EEP can also be calculated indirectly by monitoring the energy consumed by the organisation. For example, the reduction in vehicle fuel consumption expected from buying energy efficient vehicles can be estimated, or annual fuel consumption can be tracked to measure the actual reduction due to green procurement.

The procurement of energy efficient products and services is key to reducing energy consumption; however, product use and behaviour may have a greater impact on actual energy consumption. In fact, energy savings estimates based on purchases (see previous section 3.2.1) does not guarantee a decrease in energy consumption, and how the product is used and consumer usage habits must be taken into consideration. Therefore, whenever possible, it is best to calculate real energy savings and CO_2 reduction by monitoring actual energy consumption. This approach reduces the number of parameters to track and makes it possible to monitor the effects of green solutions without making estimates. However, as an indirect evaluation, EEP effects might be masked due to the interaction with other variables.

Case 9. Indirect Evaluation of Green Vehicle Procurement in the USA [15]

In the United States, energy efficiency improvements and GHG emissions reduction achieved in government owned vehicle fleets through green procurement actions are not monitored based on annual purchases, but indirectly through the overall performance of the improved fleet using real usage data. Through the web-based Federal Automobile Statistical Tool, agencies input data required by several regulations (both energy and economic/budget related). These inputs include: vehicle inventory, purchases and disposals (actual, planned, projected, forecast), type of fuel, type of ownership (purchased, GSA-leased, commercially-leased), mileage, cost data (acquisition, indirect, maintenance and depreciation costs), and fuel cost and consumption. Using this information, GHG emissions reduction associated with vehicle procurement and use can be calculated and integrated into the overall target for GHG emissions reduction by the federal government.

4. Supportive Instruments

4.1. Incentives

Even when monitoring is part of EEP policies, organizations' commitment to implement a policy and track progress on achievements may vary, especially when the targets or objectives are voluntary, no enforcement mechanisms are in place, and/or when policy commitments are set at a higher administration level with little or no jurisdiction over other administrations' activities.

In order to promote implementation, monitoring, and reporting some administrations have supplemented EEP policies with incentives. Two types of incentives, economic and reputational, are described below.

4.1.1. Economic Incentives

Monetary incentives reward public administrations that advance EEP implementation and may also punish organisations or departments that fail to comply with minimum green procurement levels. The economic incentive can be designed in many different ways. The following cases reflect some of those options.

Case 10. GPP Reporting Incentives in South Korea [16]

To promote the purchase of green products and reporting results, the "Korean Act on Encouragement of Purchase of Green Products" from 2011 states that the Ministry of Environment may grant environment-related subsidies preferentially to local governments with excellent purchase records of green products. This assessment is based on the annual green products records that each public institution submits to the Ministry of the Environment within the three months after the end of each fiscal year.

Case 11. Financial Mechanism to Promote Environmental Monitoring and Performance in France's Central Government [17, 18 and 19]

In 2008, the French Central Government, recognizing the unique role of the government in achieving sustainable development, passed a regulation requiring all ministerial departments to develop an Exemplary Administration Plan to achieve sustainable development in their services and operations. To guarantee a certain consistency and efficacy in the government's actions, a set of common measures and targets for all Ministries was defined, focusing on procurement, eco-responsibility (mainly consumption reduction), and social responsibility. To track compliance, mandatory annual reports are also required.

To encourage the achievement of common objectives and the integration of sustainable development in the Ministries' operations, a financial mechanism was established to accompany implementation and reporting of the plans (from 2009 onwards). The mechanism consists of a virtual fund of approximately 100 million Euros created by setting aside ("freezing") 1% of the budget that each Ministry is allocated for procurement at the beginning of each year. Each ministerial department has to report on its achievements against the commonly set targets to recover the "frozen" budget. The frozen funds are redistributed among the departments according to their performance in achieving the targets. Thus, the more targets achieved, the higher the return will be, with a minimum number of targets reached to participate in the redistribution (in 2012, at least 11 out of 18 indicators had to be met- including requirements on energy consumption, procurement of low CO_2 emitting vehicles and work related travels). Two cases may arise:

If a department does not reach the minimum threshold of indicators, it immediately loses 50% of its contribution, which will be redistributed among the departments that meet or exceed the threshold (explained below). The department can recover the other 50% if it complies with the objectives for the previous reporting year during the following year. If it still fails, the money cannot be recovered and is added to the fund for next year's distribution among those that do comply.

If a department meets or exceeds the minimum threshold, it immediately gets 50% of its contribution and benefits from the redistribution of the other portions (from them, the other departments that met the threshold, and percentages lost by other departments). The amount allocated to each ministry is proportional to its financial contribution to the fund and its performance.

4.1.2. Reputational Incentives

Comparison between peers and recognition of achievements and improved efforts can have a positive effect on policy implementation if it impacts the reputation of organizations. Agencies with low performance in certain areas become motivated to improve their results and thus their reputation. Those with higher achievements get recognition for their efforts and improve their image with stakeholders. In order to have an impact, results have to be published internally, or ideally publically, and they can be presented in two ways: 1) as a ranking or benchmark of agencies based on their results, presenting both good and bad performances, or 2) as a list of top-performing agencies based on overall results or on leadership in specific areas of EEP implementation, such as policy quality, supplier engagement, monitoring systems, etc.

These mechanisms require, in general terms:

- Defining simple indicators that easily convey the different performance levels if more than one parameter is monitored (e.g. traffic light indicator, stars rating, medals indicator, etc.).
- Evaluating organizations' performance against the defined indicators to benchmark agencies according to their results.
- Making results public through a regular publication, organization's website, awards ceremony, etc.
- Keeping the mechanism in place for a defined period of time to be able to have an impact on agencies' reputations.

To leverage the impacts from these programs the publication of results should share lessons learned and best practices from departments and organizations excelling in a particular area. These examples can help other organisations improve their performance.

<u>Case 12. Green Procurement Performance Appraisal and Award in Taiwan [20]</u>

To promote GPP implementation and recognize efforts of leading agencies, the Government of Taiwan annually evaluates agencies' performance on green procurement based on "Green Procurement Amount Reports" and rewards those with excellent performance at a public event. Performance evaluation is based on three elements:

1. Percentage of total products procured from a list of designated green products—this list covers 20 product groups including: office stationery and paper products, office ICT equipment, electronic appliances, and a set of other items such as cleaning products or paints (70 points)
2. Number of other green products purchased (10 points)
3. Activities to support GPP implementation, including training courses, communication and dissemination actions, involvement of chief officers and subordinated agencies, creative procurement, etc. (20 points)

Depending on the total points obtained, agencies can be classed as Superior, Grade A, Grade B, or Grade C. Results by class from 2002 to 2006 are summarized below:

Figure 5. GPP Performance Appraisal of Taiwan Government Agencies 2002-2006

Appraisal class	Points (out of 100)	2002	2003	2004	2005	2006
Superior	More than 90	1	26	17	16	23
Grade A	More than 80	6	33	26	38	41
Grade B	More than 70	32	0	16	7	0
Grade C	Less than 70	21	1	1	0	0

Source: http://greenliving.epa.gov.tw/GreenLife/eng/E-The_Green_Procurement_Promotion_Result.aspx

Case 13. Mayor of London's Green Procurement Code [21]

The Mayor of London's Green Procurement Code is a support service for organisations committed to reducing their environmental impact through responsible purchasing. Awareness that management and behavioural changes are as important as technical specifications to source green products, the initiative provides assistance to embed green purchasing into all aspects of the organizations.

Organisations that sign the Green Procurement Code commit to achieving progressive environmental targets and can be awarded bronze, silver, or gold status as a mark of their success, depending on the results of their progress review and the completion of a third-party audit. The progress review consists of two parts: 1) performance against a set list of management questions based on the UK Government Flexible Framework; and 2) green purchases of products and services recorded during the previous financial year. Based on the combined results of both parts, organisations can be awarded one of the three levels:

Figure 6. Level awarding in the Mayor of London's Green Procurement Code

Part two \ Part one	Bronze	Silver	Gold
Bronze	Bronze	Bronze	Bronze
Silver	Bronze	Silver	Gold
Gold	Silver	Silver	Gold

Source: http://www.greenprocurementcode.co.uk/?q=node/304

Once organizations have been audited, success is celebrated at an annual awards ceremony, and award winners are listed online and in the initiative's annual progress report.

4.2. Integration in Environmental Management Systems

Environmental Management Systems (EMS) are management approaches that serve to systematically:

- Evaluate the environmental performance, risks, and impacts of an organization's operations and activities (caused directly or indirectly);
- Establish objectives, measures, and procedures to address issues causing or threatening significant environmental impacts in order to improve the organization's environmental performance; and
- Monitor and analyze performance in implementation in order to define new actions and ensure continual improvement.

When first implemented, EMS programs tend to focus on direct impacts occurring in the organisation's facilities (e.g. water and energy consumption, waste generation and recycling, use and manipulation of hazardous products, generation of noise, odours, and gases emissions, etc.). Particularly in administrative and office buildings, the scope is soon enlarged to include indirect impacts stemming from the supply chain, including first-tier contractors and following-tier suppliers. Including procurement activities as part of EMS will serve not only to apply EEP as a measure to reduce direct impacts, but also to evaluate the overall effects of unsustainable acquisition practices and help implement EEP in a consistent manner.

As EMS requires regular monitoring of results, such systems help define and implement mechanisms for careful tracking of EEP measures. When doing so, special attention must be given to defining mechanisms and monitoring systems that yield results in line with the EEP monitoring requirements and objectives set at a policy level. In any case, EMS will monitor the impact of EEP actions, though indirectly, when tracking energy consumption.

Additionally, the integration of EEP into the EMS should foresee that adverse findings are fed into the EMS corrective action process to ensure that action is taken and EEP implementation is progressively improved.

<u>Case 14. Implementing GPP Requirements in the EMS of U.S. Department of Energy Facilities [22]</u>

Executive Order 13423 directed U.S. federal agencies to implement EMS at all appropriate organizational levels to ensure the use of EMS as the primary management approach for addressing environmental aspects of internal agency operations and activities. In order to coordinate this requirement with others on GPP, the U.S. Department of Energy (DoE) approved an internal order for all facilities managed by federal staff or contractors, requiring: 1) the implementation of EMS in all DoE sites integrated with the site's Integrated Safety Management System, and 2) the inclusion in the EMS of the objectives and targets for annual review that contribute to achieving DoE sustainable environmental stewardship goals, including those on the acquisition and use of environmentally preferable products (including energy efficient products) in the conduct of operations.

5. Conclusions and Recommendations

Even though the results and impacts of many policies that include EEP requirements are not routinely monitored, the proper tracking, evaluation, and reporting of results can yield remarkable benefits to organisations. Through monitoring, policymakers can improve efficiency and effectiveness in policy deployment by identifying areas or elements that need improvement, which will help to target supportive measures. Furthermore, making results available both internally and externally demonstrates political commitment, enhances transparency, and legitimizes the promotion of sustainable consumption and production by other sectors of society. The publication of results also promotes policy embedment by keeping each agency accountable.

Existing M&E approaches applied by different public administrations show a broad range of priorities and systems for the monitoring and evaluation of EEP. Reasons behind this diversity include the variety in policy objectives, targets and goals, the relation to other sectoral policies, the difference between policy development and implementation, the structure and level of centralization of purchasing systems or the commitment level of involved actors, among others. A clear definition of policy goals and indicators, embedment in existing tracking systems, additional facilitating measures, and visibility of results are necessary for successful and cost-effective implementation of M&E systems.

5.1. Ensure Leadership and Clearly Define Objectives, Indicators and Progress Tiers

As can be observed in Table 1, EEP requirements are generally embedded in environmental policies, creating a gap between who is responsible for defining the policy and who is responsible for implementing it. The former (usually the Environment or Energy Departments) predetermines policy objectives and targets that affect the monitoring system, but it is within the Procurement units that policies are implemented. Therefore, it is key to have procurement managers participate in developing an efficient M&E system that is accurate and representative, but not too complex or burdensome, and that is integrated in existing purchaser workflows (especially when monitoring actual procurement of energy efficient products). The same applies if EEP is monitored based on consumption levels where other staff are involved (for example fleet or building managers).

In general terms, policies tend to define overall EEP targets, however it is recommended to set progress levels and evaluate against them to encourage implementation, as green procurement requires changing habits and practices, and performance tiers convey that sense of progress and the time needed to achieve those targets. Furthermore, tiers help communicate achievements to all relevant stakeholders.

To measure success, key performance indicators have to be identified. Typical indicators used to monitor the procurement of products are the total and percentage of green products and/or tenders (in units and economic terms) in relation to the total acquired or tendered for a list of prioritized product groups. When evaluating the environmental relief obtained with EEP, as highlighted in a recent report by the Energy Sector Management Assistance Program [3], indicators such as energy consumption, GHG emissions, and even cost savings are commonly used.

5.2. Set efficient systems to monitor products procurement

M&E systems might cover different objectives; therefore, an appropriate approach should be selected for each objective and this may results in a mixed system. Regardless of the system(s) selected, it is key to accompany a M&E system with clear definitions, explanations, instructions, and verification documents (if required) to avoid misinterpretations, improve the efficiency of the organisations responsible for monitoring,, and ease the centralization of data at a pan-government level. Organisations should be able to invest less time to answer queries or verify data and more on data analysis and evaluation of results. The systems should also be tested in advance, as sometimes definitions are not as straightforward as intended, and defined with the relevant parties. Linked to this, changes in the M&E systems should be minimized to facilitate understanding, ensure data comparability, and identify trends.

In general terms, monitoring green product purchases is more burdensome than monitoring green tenders. Furthermore, with the trend to change contracting models from purchase to service contracts, it can be foreseen that tracking product consumption will be increasingly onerous, as more data will be required from suppliers. Therefore, strong relationships and good reporting habits will need to be established with contractors. When monitoring tenders, the risk is to count as “green” tenders that in the end don’t yield a green result. To avoid it, only compulsory criteria should be used to qualify tenders as “green”.

For quantitative data, an early analysis of existing tracking mechanisms (of tenders, expenditure, consumption, etc.) is advisable in order to start monitoring where data is available or to introduce the required changes for efficient and reliable data tracking. This is especially relevant when monitoring green tenders and/or acquisition of green products. To be efficient, EEP tracking has to be integrated from the beginning into the procurement process and tracking systems.

Tracking mechanisms vary depending on what is monitored; however, for quantitative indicators, it is always preferable to use public data (i.e., from e-tendering platforms) or data centrally collected (such as centralized purchases), as data tracked through questionnaires is less reliable and more time consuming. In the era of electronic information technologies, online applications and internal software are the most efficient solution for compiling information and processing it automatically. Such software can be programmed to retrieve data from other platforms (reducing data input duplication) and to produce direct calculations and graphical outputs of results and their deviation from the set targets. That requires certain standardization in procurement management software and other applications, which might not exist within an organization, let alone between different public authorities. However, when tracking systems are semi-automatic and multiple users are responsible for inputting data, providing training to understand definitions, information requirements, and tool operation (either a spreadsheet or an online platform) is key to ensure appropriate data tracking and minimize errors.

5.3. Calculate Representative Environmental Benefits

As EEP has an impact on organisations' energy consumption, in most cases it is best to evaluate the evolution in real energy consumption when calculating the environmental relief achieved with EEP, to identify if EEP yields results or if other factors are overriding them. If the environmental relief is calculated only on the basis of purchased products, benefits are only theoretical, misrepresenting the EEP impacts. In spite of that, if environmental benefits are calculated directly or by proxies based on purchased products, this has to be taken into consideration from the beginning when identifying the data to be reported, as some parameters might be necessary for a meaningful assessment (for example, to report both in expenditure and physical units). And special attention should be paid to establishing an M&E system that calculates environmental benefits not only in relation to energy efficient versus conventional products, but also in relation to overall purchases and to communicate the benefits of reducing procurement needs and rationalise acquisitions.

In those regions or agencies where green procurement is considered more expensive, it is advisable to evaluate, either as a one-time evaluation or as part of the regular monitoring, the lifecycle cost reductions achieved, to make the business case for EEP and GPP, as savings achieved with EEP can be used to compensate premium costs in other GPP actions.

5.4. Implement Facilitating Measures

In order to ensure or promote better monitoring and overall implementation, organizations might design reputational and/or economic incentives to accompany M&E systems. Reputational incentives are linked to the public presentation of results and can be designed as "rewards", when only the best are acknowledged, or as "rewards and punishment", when all departments or organizations are benchmarked, from the most to the least performing. Economic incentives can also take the form of rewards and/or penalties. In the second case, it is best when all parties agree on how the penalties are to be applied in order to minimize opposition.

Another strategy to facilitate monitoring and implementation is to integrate EEP requirements within existing EMS, as EMS requires regular monitoring of results and therefore they "force" organisations to define and implement mechanisms for careful tracking of EEP measures. When doing so, attention has to be paid to define procedures that yield results in line with the EEP monitoring requirements set at policy level.

5.5. Communicate and show results

Finally, EEP individual results (by department or administration, depending on the level of monitoring) should be published and made publicly available in order to increase government transparency and demonstrate public leadership. Visual elements such as graphics and simple evaluation and rating indicators serve to present progress in an easy-to-understand manner that can be used to openly report on government performance and to benchmark progress by each agency, fostering improvement through reputational incentives. However, reports should not focus only on results but also include information on why and how department or public agency's excelling in a particular area have achieved such results, in order to tie actions to results and share examples that can help others improve.

Energy Efficiency and the Australian Water Heating Market

Mr Michael Whitelaw

Australian Department of Resources, Energy and Tourism

Abstract

Recent increases in energy prices have led to a focus on cost-of-living issues in Australia. Water heating in Australia accounts for approximately 25% of household energy use, second only to space heating and cooling, and plays an important role in relation to energy costs. Hot water energy use plays an important role in the magnitude and management of 'peak' electricity demand and associated grid infrastructure requirements. Over the past decade the increase in the Australian water heating market has been extraordinary. Factors attributed to driving this change include regulations, subsidy programs, technology advancements, shifts in consumer demand, fuel price inflation, carbon pricing, and changing attitudes towards water consumption. The ability for policy makers and stakeholders to develop and set appliance-specific energy efficiency requirements in a timely and efficient manner have been impacted by rapid changes in the hot water market. Decision makers established limited incentive programs to institute long-term changes in the market. The setting of hot water appliance energy efficiency requirements remains a highly effective tool and recent national legislation has streamlined processes and improved responsiveness. However, reliance on government 'push' policies may not provide optimal outcomes. New regulatory policies may be needed to improve efficiency for all hot water technologies (electric resistance, heat pump, solar, gas etc.). Information-based 'pull' policies can effectively promote new energy-efficient products, provide manufactures with greater certainty, and reduce costs for governments. New 'push' policies can help consumers make informed decisions to purchase energy efficient water heaters.

Introduction

Importance and pressures in the Australian hot water market

Water heating is responsible for approximately 25% of energy consumed in Australia's residential sector. Conventional hot water heaters are installed in nearly half of these eight million homes that in turn produce nearly three times the amount of greenhouse gas equivalents (CO_2-e) as more efficient technologies, while potentially costing significantly more to operate. The lifespan of water heaters can exceed 10 years. Therefore, the choice of a water heater can cause large and long lasting implications on consumer energy bills.

Australian water heater market shares are as follows: 52% conventional electric storage water heaters, 40% gas water heaters, 9% solar water heaters (both gas and electric), and 2% heat pump water heaters [1, 2]. The breakdown of technology by Australian jurisdiction varies substantially and is driven by factors such as different climatic conditions, availability of gas networks, and separate tariffs.

There are two broad, related sources of pressure on the Australian hot water market.

1. 'Cost of living' pressures have become a priority issue. The substantial reliance on expensive-to-operate conventional hot water heaters and increasing energy prices is creating pressure to reduce this reliance and reduce energy bills for consumers.

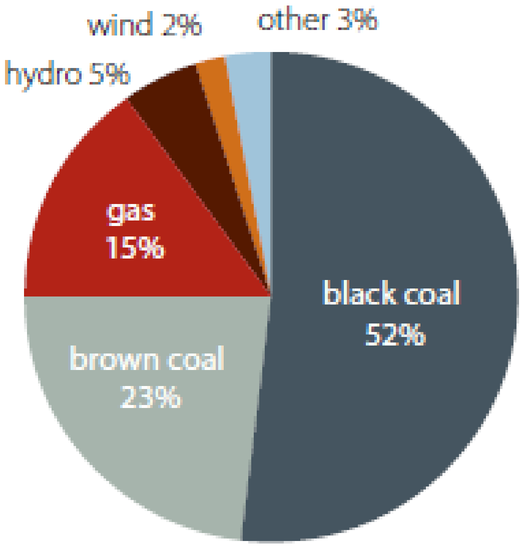
2. The hot water market remains subject to two distinct of 'market failures'. These failures can be described as information failures (inability to access independent and reliable information on the lifetime costs of various water heating technologies) and 'split-incentives' where the purchaser of hot water systems will not be responsible for the operating costs of the appliance (e.g. a landlord purchasing an inexpensive conventional water heater while the renter will ultimately become responsible for the associated running costs).

Pressures in the Hot Water Market

Pressure One – Cost-of-Living and Energy Costs

Energy Consumption and Cost Pressures

Australia is the world's eighteenth largest energy consumer and ranks fourteenth on a per-person basis. Australia's energy consumption is primarily composed of non-renewable energy sources [3]. **Figure 1** shows electricity generation by energy source in 2009-10. Coal accounts for approximately 75% of total generation, gas accounts for 15%, and renewable energy accounts for 8% (mainly hydroelectricity, wind and bio-energy). The high reliance on abundant non-renewable sources has led to recent price pressures as governments have sought to address carbon emissions though interventions such as a nation-wide carbon price (currently $AUD23 per ton of CO_2-e) and renewable energy targets.



a Other includes oil, bioenergy and solar PV.

Figure 1. Australia's Electricity Generation by Energy Source in 2009-10

Source: Energy in Australia, 2012.

Growth in peak daily electricity demand over recent years has been a significant contributor to rising electricity costs. Between 10% and 25% of maximum demand occurs for only 1% of the time, creating demand for high-cost, fast-start generation capacity and additional network infrastructure to be maintained. The two main drivers causing the growth in inefficient peak demand are the increased use of relatively low−cost, energy-intensive domestic appliances and inefficient pricing structures [4]. More recently, there have been declines in average annual consumption and reduced rates of peak demand growth, but these trends have yet to impact retail prices.

Australia's gas market is undergoing major transformation, including increased demand competition and rising costs of production from new gas fields. While Australia has adequate overall gas reserves to meet projected domestic demand and exportation needs until at least 2035, there may be some transitional tightness in the east coast gas market as new coal-seam gas and LNG projects ramp up to full production. These factors are already manifesting in higher gas prices and tighter supply dynamics.

Impact on Cost-of-Living

Rising electricity and gas prices are affecting the costs-of-living of many Australian households. Recent increases in power prices reflect mainly increases in network costs caused by a complex combination of increasing peak demand, replacing and augmenting ageing infrastructure, as well as a marginal impact from various energy efficiency and renewable energy policy interventions at both the state and national levels [4]. Australia's electricity prices were slightly below the Organization for Economic Co-operation and Development (OECD) average in 2010. Since that time there has been rapid price increases in most areas of Australia. Retail electricity costs have increased on average by around 40% in the past three years, and by well over 50% in certain regions.

Pressure Two - Market Failures

Information Failures

A rational, informed consumer wishing to minimise the 'lifetime-cost' of purchasing a water heater would ideally research and take into account both the initial purchase cost and the projected running costs associated with the appliance. Water heaters are purchased in drastically different ways than other household appliances which complicates the ability to make informed decisions. Market research shows 'people usually understand the appliance, a range of makes and models is readily available and able to be directly compared in showrooms, and energy usage parameters are simple as the appliance is on all the time…the decision regarding a water heater is often unexpected (water heaters rarely give warning of problems), hasty and ill-considered. The current study clearly identifies that the appliance installer (plumber and/or electrician) has a primary role to play in the water heater decision' [5].

BIS Shrapnel quantified the magnitude of information failures in a survey on purchasers of water heaters. They found that 22% of water heater buyers conducted no research at all in purchasing a water heater and 66% of conventional electric storage water heater buyers considered no alternatives. Low consideration of alternative water heating technologies with significantly lower operating costs suggests that consumers may not be aware of options available [6].

The market failures relating to energy efficiency were also investigated. The nature and implication of the informational market failure was described as, "residential consumers are poorly informed when it comes to retail electricity arrangements, the price of electricity and how their electricity consumption impacts on their bill. As a consequence, consumers have been unable to choose retail electricity offers better suited to their needs or modify their electricity consumption in ways that would help minimise their electricity costs" [7].

The Select Committee described energy efficiency as 'the "low hanging fruit" of electricity consumption and emissions reduction efforts and as 'the easiest, simplest and most cost efficient' tool to meet these goals. The report also noted arguments that energy efficiency efforts should focus on heaters, air conditioners and hot-water systems as these appliances can offer faster payback periods and will result in 'material' rather than 'symbolic' benefits to households.

Split Incentives

A split incentive situation can arise when an agent (landlord, plumber or builder) is acting on behalf of a principal (buyer, tenant) and therefore may have different motivations. The split incentive is caused an insufficient focus on the likely running costs of the water heater which will be payable by the end-user, rather than the agent. It is estimated that approximately 20% of sales may be affected by a builder/owner split incentive while at least 30% of sales may be affected by a landlord/tenant split incentive. The purchase and installation cost of an average conventional electric water heater in 2012 was approximately $800 cheaper than a heat pump water heater, however the latter can offer savings of $330 per annum. 270,000 conventional water heaters are estimated to have been sold in Australia in 2011 and 50% may have been affected by split incentives; clearly the implications of sub-optimal purchases are substantial.

Impact of Failures

Due to the sheer number of expensive-to-operate conventional water heaters, there is significant opportunity for Australians to shift to more efficient water heating technologies. However, information failures reduce the ability for a consumer to easily identify and understand the lifetime benefits of more efficient heaters. Since up to half of all water heater purchases may be driven by the upfront cost of the heater rather than the lifetime operational costs, there is vast room for informational improvement.

Current Hot Water Market – Trends and Current Interventions

Technological and Consumer Trends

Australia has recently experienced a high level of technological advancement in the water-heating sector. In recent years the heat pump water heater sales have rapidly risen as shown in **Figure 2**. Established technologies, such as solar water heaters, have also continued to be refined with in-line boosting rather than tank boosting becoming increasingly common.

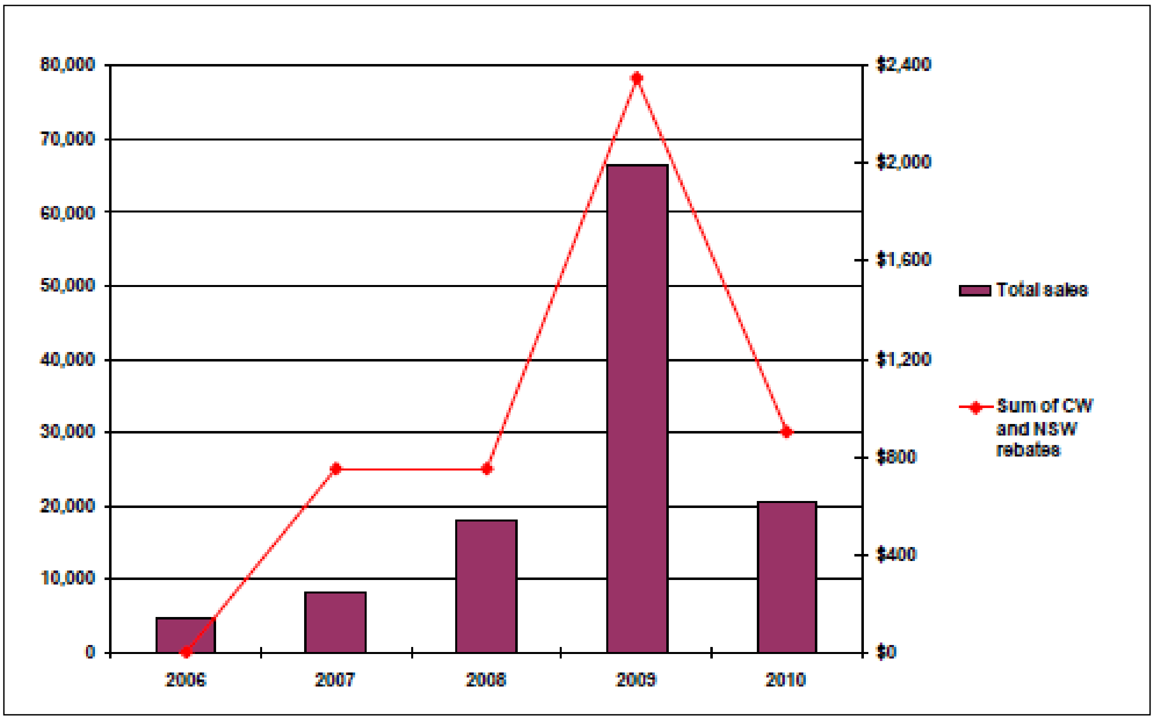


Figure 2. Heat pump water heater installations by year

Source: Product Profile: Heat Pump Water Heaters, Equipment Energy Efficiency Program June 2012.

The issues facing consumers are more complex than just water heating priorities. With increasing energy bills there can be trade-offs in consumer purchasing habits such as diverting their funds to more efficient water heating products or to reducing their net-power demand through actions such as installing solar PV. While the number of solar hot water installations has historically overshadowed solar PV, both experienced significant growth since 2009 as shown in **Figure 3**. In 2011, solar PV installations overtook solar hot water, especially as installations of the latter declined.

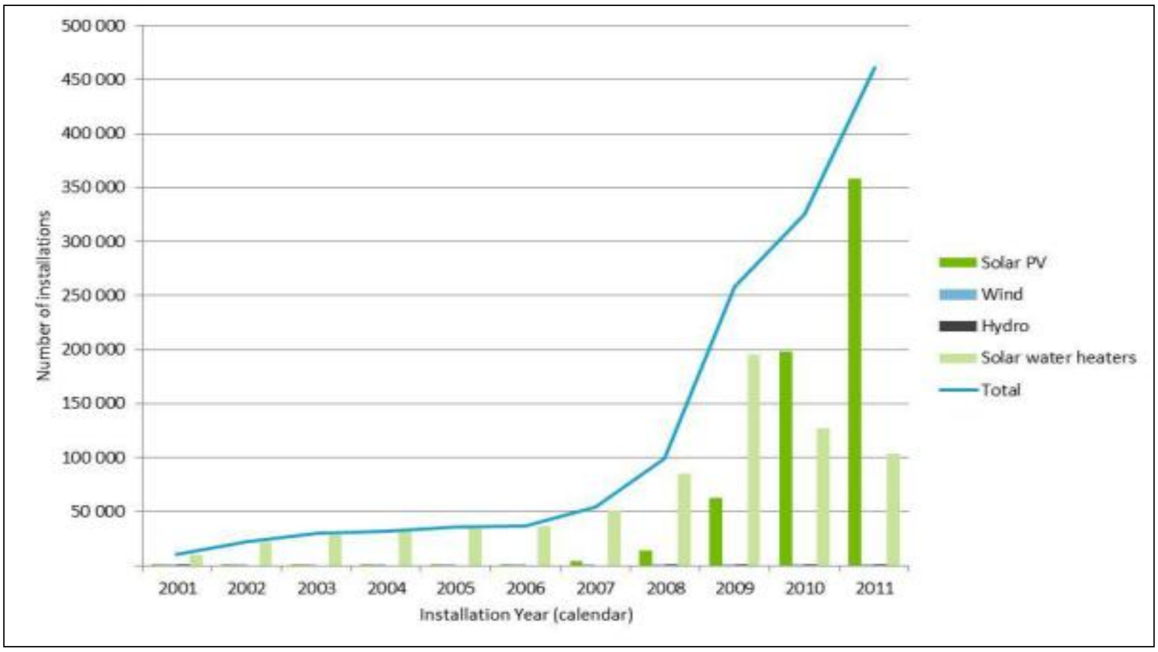

Figure 3. Number of installations of small-scale systems

Source: Renewable Energy Target Review – Final Report, Climate Change Authority, December 2012

From 2003 to 2012 many parts of Australia experienced a severe drought with various degrees of water usage restrictions imposed. While the drought did not explicitly alter the market for hot water appliances, a stronger focus on water efficiency emerged. Through general consumer action, construction requirements, and other government initiatives lower levels of demand may now impact the average hot water appliance. There has also been new areas of consumer concern in purchasing water heaters – such as an interest in the amount of water an 'instantaneous' water heater may supply before providing peak hot water temperature.

There are many factors that led to the above changes in consumer behaviors such as changing electricity tariffs, solar 'feed-in' prices, government subsidies, and decreases in solar PV costs. This is a good example of how different elements can rapidly change the market in a short period of time. This makes the need for efficient government intervention critical to achieving desired policy outcomes.

Limitations to Current Government Interventions

The Australian hot water market is currently subject to a number of energy usage or energy efficiency related interventions. The most significant include:

1. Subsidies for solar and heat pump water heaters based on potential energy displacement

2. Electric storage water heaters - maximum tank heat loss limits

3. Gas water heaters - an industry managed label as well as government managed maximum annual gas consumption levels

4. Government mandated installation codes specifying minimum 'star ratings' for gas water heaters and minimum energy displacement levels for solar and heat pump water heaters

5. An economy wide carbon price scheme which assists in internalizing economic externalities associated with the CO_2-e emissions For water heaters the impact of the carbon price is largely through increased electricity or gas prices, although the carbon intensity of such inputs vary across the nation.

While assessing the level of success of the above interventions is outside the scope of this paper, some broad observation about the limitations of the above policies can be noted.

Subsidies

In relation to subsidy-based programs Australia is facing challenging fiscal circumstances. While rebates can be effective in influencing consumer purchasing decisions, maintaining rebates of sufficient magnitude, scope, and duration to permanently shift the market is expensive. Additionally, there is the potential for disruptions to industry when such programs commence or cease. While carefully targeted programs can deliver strong net-benefits, it is unlikely that the more broad and persistent market failures can be solved by subsidy programs alone.

Minimum Energy Performance Regulation

Regulatory intervention in the form of minimum energy performance metrics can be justified where it provides an economic net-benefit. Australia, like many OECD nations, has a robust regulation impact assessment (RIA) framework that ensures all interventions are well designed and model the national net-cost. As part of the RIA framework, appliance energy efficiency interventions typically require three significant technical reports produced over a series of years to ensure that an appliance under investigation is suitable for regulatory intervention, to ensure that stakeholders have multiple opportunities to provide feedback and the eventual decision makers can be provided a range of reform options. Even if this process results in an agreed upon regulatory option, implementing the decision through changes to national Standards as well as providing sufficient notification time can take years.

Performance metrics can be a powerful tool in improving appliances and aid in mitigation of problems. However, the regulatory process is both time and resource intensive and as such is poorly suited to take advantage of rapid changes in technology or consumer preference. Such regulation can help address split-incentive issues but ultimately has little effect on market information failures.

Installation Requirements

Installation requirements are an effective tool for minimising split-incentives by effectively banning the worst performing products. However, installation requirements often require an established and suitable metric upon which to base the aforementioned requirements. Where ideal benchmarks do not exist, installation codes can be based on ‘proxy’ requirements. For example, in the energy efficiency sections of the National Construction Code for residential buildings, requirements for solar water heaters and heat pump water heaters are based on energy displacement metrics, not energy efficiency metrics. While the energy displacement metrics may improve the overall outcome, issues such as oversizing can result.

Increasing the Responsiveness of Government Intervention

Each key water heating technology will still be subject to an investigation of minimum level of acceptable energy efficiency along with possible additional requirements to ensure that the products are fit-for-purpose. However, as such interventions need to proceed cautiously through a comprehensive RIA process while issues facing consumers constantly evolve, reliance on such defined government ‘push’ policies may not provide optimal outcomes.

Labelling initiatives that provide customers with simple and easy-to-understand information are key to overcoming current market failures. Educating customers will not only address current information failures, but an information-based ‘pull’ approach will also immediately capture new products. If a particular technology offers the best outcome, the market will be able to quickly shift to that specific appliance type. This will place a higher onus on all manufacturers and importers to ensure that their products are competitive in regards to both cost and energy efficiency. An information-based approach may also provide manufactures with a higher level of certainty as well as reducing overhead government costs. An example of such a consumer information initiative is the climatic hot water labelling framework currently being pursued in the EU[1].

---

[1] http://www.eceee.org/Eco_design/products/water_heaters/

Conclusion

Given the increasing focus on the price of energy and cost-of-living, government interventions into the Australian hot water market can offer significant net-benefits. Government policies need to address current market failures in the form of split incentives and informational failures in order to optimise efficiency. While government 'push' policies such as rebates and minimum energy performance standards play a very important role in achieving policy goals, such tools may not be able to keep pace with the rapid level of change occurring in the water heating market. Information-based 'pull' policies can promote new energy-efficient products, provide manufactures with greater certainty, and reduce costs for governments.

Avoiding 100 New Power Plants by Increasing Efficiency of Room Air Conditioners in India: Opportunities and Challenges

Dr. Amol Phadke, Dr. Nikit Abhyankar, and Dr. Nihar Shah

Lawrence Berkeley National Laboratory, Berkeley, USA

Abstract
Electricity demand for room ACs is growing very rapidly in emerging economies such as India. We estimate the electricity demand from room ACs in 2030 in India considering factors such as weather and income growth using market data on penetration of ACs in different income classes and climatic regions. We discuss the status of the current standards, labels, and incentive programs to improve the efficiency of room ACs in these markets and assess the potential for further large improvements in efficiency and find that efficiency can be improved by over 40% cost effectively. The total potential energy savings from Room AC efficiency improvement in India using the best available technology will reach over 118 TWh in 2030; potential peak demand saving is found to be 60 GW by 2030. This is equivalent to avoiding 120 new coal fired power plants of 500 MW each. We discuss policy options to complement, expand and improve the ongoing programs to capture this large potential.

1 Introduction
Room air conditioner (AC) demand is growing rapidly at rate of 20% on average per year over the last ten years and is likely to be a major contributor to the need for new power plants in India. In 2010, the room AC saturation amongst urban households was only 3% compared to 100% in China ([1], [2], [3]). With rising incomes and urbanization, falling AC prices, and a hot climate, it is expected that the AC ownership is going to rapidly increase in India. Based on the projections in [4], the authors have estimated the electricity demand from ACs to increase to 239 TWh/yr by 2030, which translates to a peak demand contribution of about 143 GW. Meeting this demand requires construction of nearly 300 new coal fired power plants of 500 MW each. We show in this paper that the efforts to accelerate the adoption of efficient ACs can lead to reduction of the AC demand by more than 40% cost effectively; this translates to avoiding building more than 100 new power plants. Since most of the AC stock in India is yet to be purchased, the demand could be reduced at lower costs if the actions are taken now compared to actions taken after most of the stock is installed.

Limited technical and economic analysis exists on options to improve the efficiency of room ACs in India, the cost effectiveness of these options, and the total saving potential. In this paper, we undertake a detailed engineering-economic assessment of the efficiency potential of room ACs in India and verify some of our findings using efficiency and prices observed in the market.

In section 2, we summarize the current status of the room AC efficiency and related policies in India, and compare them to other countries and regions. We show the engineering options to improve the efficiency of room ACs and the costs of these options in India, and estimate the cost of saving electricity by implementing these options in section 3. In section 4, we present the correlation of air conditioner ownership with income and weather, and estimate the electricity demand from room ACs in 2020 and 2030. In section 5, we estimate the total electricity and peak demand saving potential by improving the efficiency of room ACs. In section 6, we conclude the analysis by providing insights for policies and programs to accelerate the penetration of efficient ACs and realize the electricity savings.

2 Current status of room AC efficiency and related policies

2.1 Status of the room AC market

AC market in India is dominated by room ACs, which make up nearly 99% of the annual sales [5]. The room AC market in India has seen a rapid growth in the last several years as shown in the following chart. Since 2004, except the small drop in 2011, room AC sales have grown at an average annual growth rate of 17%.

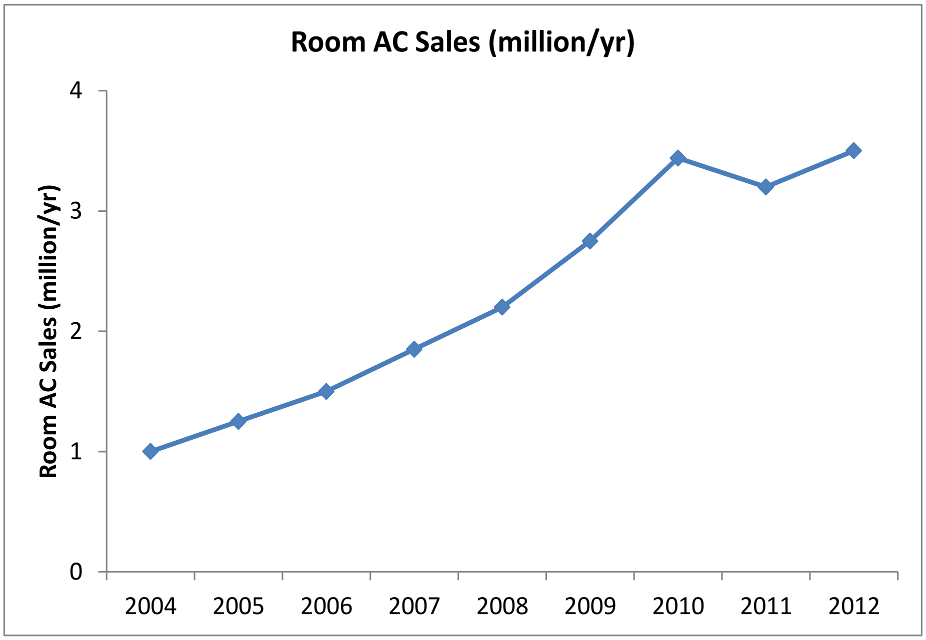

Figure 1: Sales of Room ACs (split and window units) in India

(Data Source: [6])

The Room AC market is increasingly dominated by split ACs (split-packaged non-ducted units). In the financial year 2011-12, split units accounted for 75% of the total room AC sales, while the window units (single packaged non-ducted) accounted for the remaining 25% [6].[1] Rooms ACs are primarily used in the residential, and small and medium commercial sector. According to [5], about 80% of the window units and 50% of the split units are sold in the residential market; moreover, the current market trends indicate that share of the residential sector is increasing faster than that of the commercial sector [7].

2.2 Status of efficiency and related policies

Since 2006, the Bureau of Energy Efficiency (BEE), a nodal agency for implementing energy efficiency policies in India, has initiated a standards and labeling (S&L) program for different electrical appliances. The energy efficiency labels in India are given in the form a star rating - from one-star to five-star; five-star being the most efficient. The labeling program has been made mandatory for all room ACs sold in India since 2012. This implies that any room AC must earn at least the one-star label before it could be marketed in the Indian market. Therefore, the efficiency level for one-star label serves as the de facto Minimum Energy Performance Standard (MEPS). The following chart shows the current and future ranges of the energy efficiency ratios (EER) for different star ratings in India.

[1] The Indian financial year starts in April and ends in March. For example, financial year 2011-12 started in April 2011 and ended in March 2012.

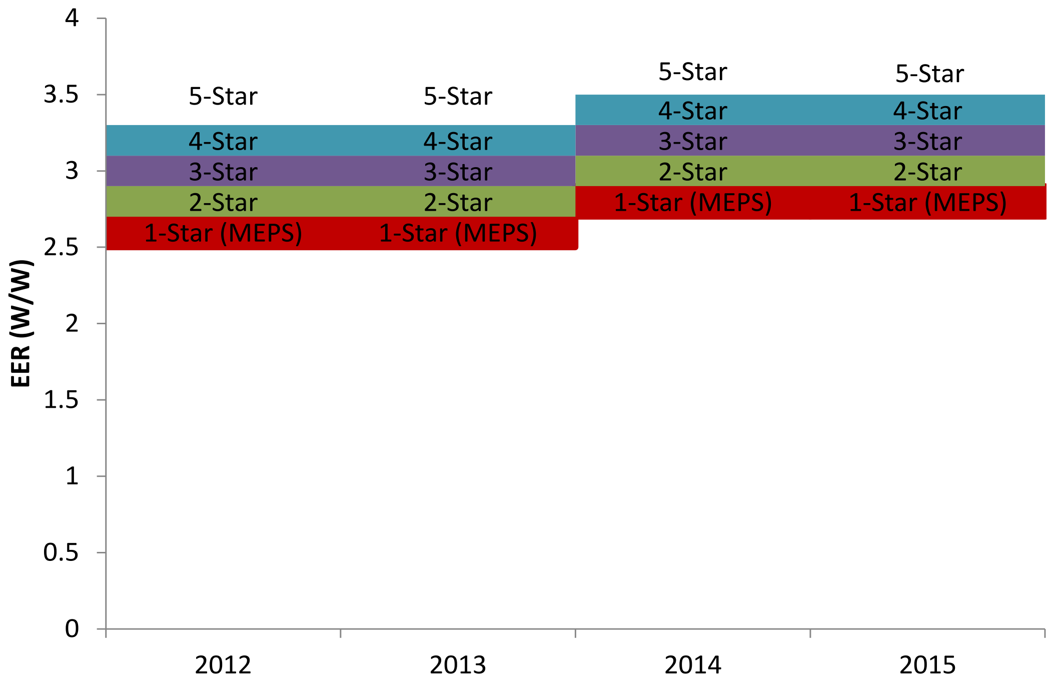

Figure 2: Current and Future Schedule of energy efficiency labels for Room ACs (split units) in India

(Data Source: [8])

It can be seen from the chart that the current MEPS for split ACs in India is an EER of 2.5, which is scheduled to increase to 2.7 by January 2014. Similarly, all ACs with EER of 3.3 and above are currently labeled as 5-star, which is scheduled to increase 3.5 by January 2014.

MEPS and maximum efficiency labels of the Indian room ACs, however, are significantly lower than that compared with other countries as shown in the following table.

For countries which implement product specific MEPS (all countries shown in the table except Japan and South Africa), the minimum EER is influenced by MEPS whereas the average and the maximum EER depend on several factors such as market conditions, energy efficiency policies etc. Compared to several countries, MEPS in India is less stringent. For example, in China, the MEPS is 16 % more stringent than India; the average EER of the Indian room AC market is comparable with the products with lowest energy efficiency rating in China.

Table 1: Minimum, Maximum and Average EER (W/W) in the room AC market (split units) in different countries (illustrative)[2]

	EER (W/W)		
Country	**Min**	**Max**	**Average**
Australia	2.67	4.88	3.16
Brazil	2.92	4.04	3.19
Canada	2.14	4.33	3.6
China	2.9	6.14	3.23
EU	2.21	5.55	3.22
India	2.5	3.8	2.9
Japan	2.37	6.67	4.1
Korea	3.05	5.73	3.78
Mexico	2.42	4.1	2.92
Russia	2.5	3.6	2.79
South Africa	2.28	5	2.91
UAE	2.14	3.22	2.69
USA	-	4.6	3.04

(Data Source: [9], [10])

We understand that the EER values are not directly comparable across different countries because of the minor differences in the test procedures followed in each country. Moreover, comparison of the MEPS and market average EERs between different countries offer few insights for improving energy efficiency policies and programs. This is primarily because of the differences in the weather conditions, usage patterns, electricity rates, and discount rates across countries. These factors influence the efficiency of the air conditioners in the market as well as the level of MEPS. Therefore, in this paper, we assess the cost-benefit of improving efficiency of room ACs only in the Indian context.

3 Techno-economic analysis of efficiency improvement options for Room ACs in India

In this section, we first summarize the efficiency improvement options considered, the amount of efficiency gains, and estimate the corresponding incremental costs. We then estimate the cost of conserved electricity (CCE) for each of these options, and then compare it to the cost of supply from several perspectives to provide insights into the cost effective efficiency improvement levels.

3.1 Various options to improve the efficiency of the room ACs

Following on from [9], we present a list of design options that can improve the efficiency of room air conditioners and estimate the incremental cost of such options. In this paper, we have considered only such design options that can be directly applied within the standard room air conditioner technologies currently on the market; these options will show energy savings under the existing product energy performance test procedures and they can be integrated into current products (i.e. do not imply changing the basic product configurations). The following room air conditioner features were considered for design improvements, namely: compressor efficiency, compressor control, heat exchanger performance, expansion valves, crankcase heaters and controls, and standby power use [9]. For each design option, there are up to five levels of efficiency improvement. The following table summarizes these options, levels of efficiency improvement, possible efficiency improvement over the base case and incremental manufacturing cost.

[2] This data should be treated as illustrative as no overlapping datasets were available to cross-check these data points. [9], [10].

Table 2: Summary of the efficiency improvement options and incremental manufacturing cost

	Base Case (Market Average)	**Level 1**	**Level 2**	**Level 3**	**Level 4**	**Level 5**
Option 1: Compressor Efficiency (Increase compressor efficiency)	Base case compressor	**6.5%** improvement at Rs 1,310	**12.3%** improvement at Rs 4,138	**18.7%** improvement at Rs 12,270		
Option 2: Compressor Control (Variable speed drives)	Single-speed compressor control	**20%** improvement at Rs 4138	**20.7%** improvement at Rs 8067	**24.8%** improvement at Rs 11996		
Option 3: Heat Exchanger (Increase exchanger efficiency)	Base case heat exchanger	**9.1%** improvement at Rs 3391	**16%** improvement at Rs 7271	**21.3%** improvement at Rs 11122	**24.8%** improvement at Rs 14948	**28.6%** improvement at Rs 18753
Option 4: Expansion Valve (Use thermostatic or electrostatic valves)	No expansion valve control	**5%** improvement at Rs 728	**8.8%** improvement at Rs 2038			
Option 5: Crankcase heater efficiency and crankcase heater control (increase efficiency & reduce heating period)	Base case crankcase heating and control	**9.8%** improvement at Rs 1048	**10.7%** Improvement at no incremental manufacturing cost.			
Option 6: Standby (Reduce standby load)	Base case standby loads	**2.2%** improvement at Rs 786				

(Source:[9]

Note: 1. EER for the base case air conditioning unit is taken as the market average EER.
2. All the efficiency improvement numbers are relative to the base case.
3. Design options 2, 4 and 5 require a seasonal metric to show savings and will not show savings under EER metric even though annual energy consumption may be lower, due to savings during operation at partial load.)

The efficiency gains associated with these options depend on the seasonal load characteristics assumed and hence depend on the climate and usage factors. In India, a room air conditioner is assumed to run for about 8 hours every day for 6 months in a year i.e. 1440 hours/year. This assumption is in agreement with multiple other sources such as [10], [11], [12], [13].

3.2 Incremental Costs of Efficiency Improvement

Table 2 shows the incremental manufacturing cost for each design option. However, the final price that the customers pay (which we term as the installed cost) includes the manufacturer's selling price, installer margin and tax. To arrive at the installed cost for each design option, we have used a set of multipliers developed in [9], which represent the mark up from the original manufacturer's cost.

The following chart shows the total manufacturing cost and total installed cost against the EER for each design option. The chart also shows the actual retail price in the Indian market for a few room AC units selected randomly against their EERs. The retail price data was taken from www.compareindia.com.

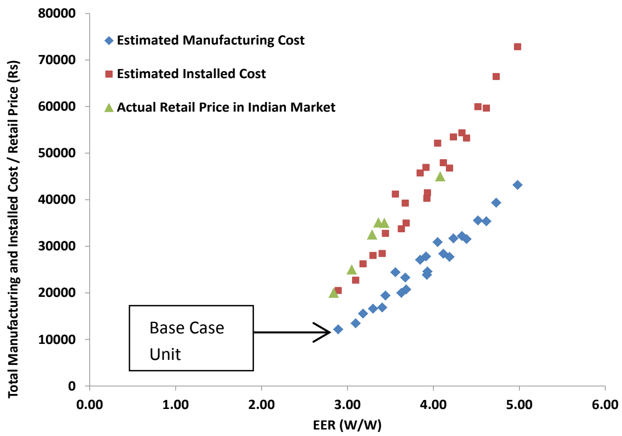

Figure 3: Total Manufacturing Cost, Installed Cost and Actual Retail price for a range of EERs

(Data Source: [9], [14])

3.3 Cost-Effectiveness of Efficiency Improvement

3.3.1 Cost of Conserved Electricity

In this analysis, the cost effectiveness of efficiency improvement options and the corresponding savings potential is assessed by comparing the cost of conserved electricity (CCE) for these options with the cost of electricity. CCE is estimated by dividing the incremental cost of the design change by the incremental energy saving due to the efficiency gain.

$$CCE = \frac{Annualized\ incremental\ cost\ of\ efficient\ AC}{Annual\ electricity\ saved\ by\ efficient\ AC}$$

CCE, therefore, could be readily compared against the consumer tariff or the marginal cost of supplying electricity. If the CCE is lower than the consumer tariff, it will be cost-effective for consumers to invest in the efficient AC. Similarly, if the CCE is lower than the long run marginal cost of electricity, investing in a market transformation program would be cost-effective relative to building new power plants.

In this analysis, we have estimated two types of CCE: cost to the manufacturer of conserved electricity, CCE_m and cost to the consumer of conserved electricity, CCE_c. CCE_m uses the incremental manufacturing cost, while CCE_c uses the incremental installed cost of the higher efficiency models. Naturally, CCE_m is lower than CCE_c because it does not include the distributor markups and installation costs. Therefore, CCE_m can be used to measure the cost-effectiveness of a market transformation program such as an upstream incentive program, while CCE_c would be used to measure the cost effectiveness of a standards program or a downstream incentive program targeting the consumer [9].

We understand that the seasonal energy efficiency ratio (SEER) provides a fuller picture of the energy efficiency of a room AC, since it captures AC operation at partial loads. However, in India, MEPS and labels are prescribed using EER; therefore, in this paper, we have chosen to use EER as the efficiency. If SEER metric is used, potential energy savings could be higher by nearly 20%, if part load conditions are prevalent often [9]. For more discussion on EER and SEER, refer to [9].

3.3.2 Electricity costs and consumer tariffs in India

Consumer tariffs in India include government subsidies and cross subsidies among consumer classes. However, under the current power sector reforms, there is a strong push for tariff rationalization and reduction of the amount of such cross-subsidy. The domestic fuel sector in India (mainly coal and gas) is severely constrained. Therefore, most of the marginal generation capacity addition is coming in the form of imported coal or imported LNG. Imported coal prices have been increasing in the world market and are significantly above the domestic coal prices in India. The following table shows the average consumer tariffs and the long run marginal costs of electricity supply (including the transmission and distribution costs).

Table 3: Consumer Tariffs and Long Run Marginal Cost of Power Supply

Consumer Tariffs	
Average residential tariff (Rs/kWh)	4.5
Average commercial tariff (Rs/kWh)	6.0
Long Run Marginal Cost of Electricity Supply	
Cost of generation – imported coal (Rs/kWh)	3.5
Transmission and distribution loss %	15%
Transmission and distribution cost (Rs/kWh)	1
Long Run Delivered cost of electricity supply (Rs/kWh)	5.12

Note: The cost numbers shown here are the 2013 values and do not account for discount rates.

(Data Source: Authors' calculations)

3.3.3 Cost-Effective Electricity Saving Potential

The following chart shows the cost of conserved electricity from consumers' perspective (CCE_c) against the EERs of all the design options discussed in the earlier sections. It also shows the average consumer electricity tariff for residential consumers and the long run marginal cost of electricity supply. As shown in the chart, CCE is lower than the consumer tariff up to an EER of nearly 4.21; this implies that from consumers' perspective, achieving an efficiency gain up to an EER of 4.21 is cost-effective i.e. consumers would be better off if they bought an AC with EER of up to 4.21. This makes a strong case for setting the MEPS at the cost-effective EER from consumers' perspective. From the utility's perspective, the long run marginal cost of power supply is higher than the CCE up to an EER of about 4.7; this implies that the utility would find it cost effective to offer a downstream incentive (like a consumer rebate) than investing in a new power plant.

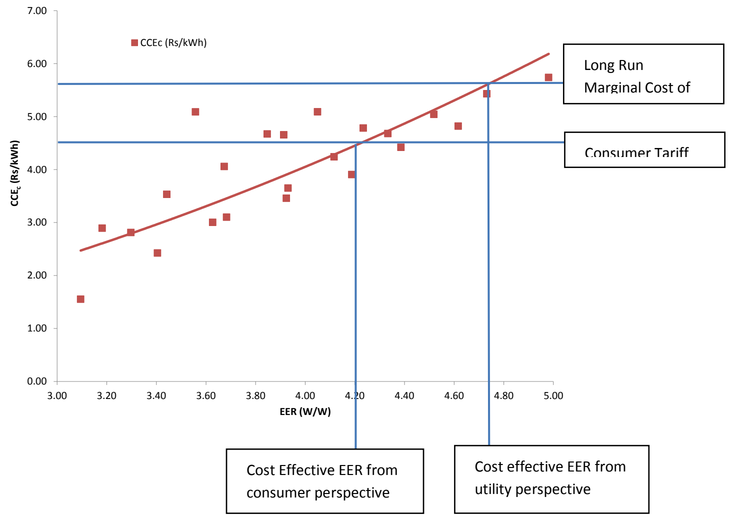

Figure 4: Cost of Conserved Electricity and Cost-effective energy saving Potential

4 Current and future electricity demand from Room ACs and energy and peak power saving potential

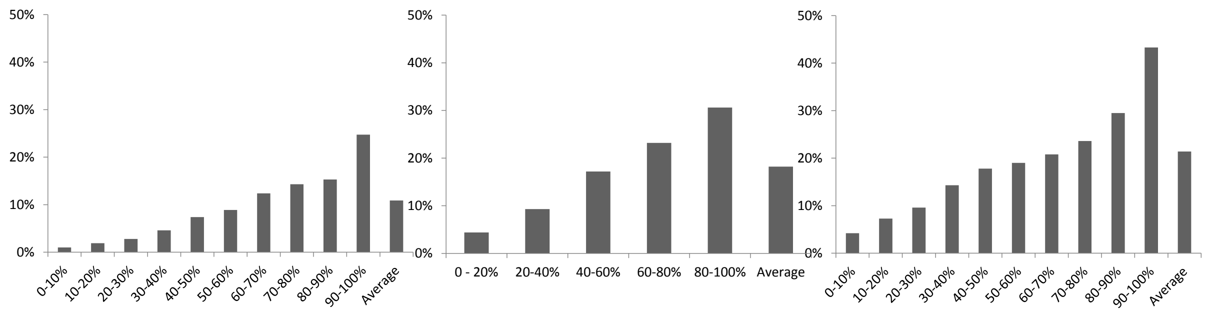
In this section, we estimate the current AC stock in India and project the future demand for air conditioners in India and their contribution to total electricity consumption and peak demand.

4.1 Future Demand for Air Conditioners

Ceiling fan is the most common household and commercial appliance used for space cooling in India. However, the saturation level of ceiling fans in urban households is more than 90% [1]. The demand for other space cooling appliances like air coolers and air conditioners has been increasing rapidly, as shown in the subsequent sections of this paper.

4.1.1 Current Stock of Air Conditioners in India

Unfortunately, national level electric load survey is not conducted in India. The national sample survey, conducted by the ministry of program implementation and statistics of the federal government of India, does collect information on household appliances; but it reports air coolers and air conditioners together. The following chart shows the total saturation of air conditioners and air coolers in the urban Indian households over the last ten years by expenditure class.



(a) 1999-2000 **(b) 2004-2005** **(c) 2009-2010**

Figure 5: Saturation of air conditioners and air coolers in urban Indian households by expenditure decile

(Data Source: [1], [2], [15])

There are two important observations that can be made from these charts, namely: (a) ownership of air coolers and air conditioners has increased significantly across all income classes. On average, the penetration of air coolers and air conditioners has doubled between 2000 and 2010. The increase in ownership in the top 2 income deciles is even more striking. (b) There is a non-linear relationship between incomes and the ownership of air coolers and air conditioners. The appliance ownership in the highest expenditure decile is significantly higher than that in the lower deciles.

In major cities like Delhi, where the temperatures and incomes are higher than the national average, the air cooler and air conditioning appliance penetration is significantly higher. Note that, on average, air conditioners account for about 15% of the total air cooler and air conditioner saturation. However, in the higher expenditure brackets and in urban areas with higher average incomes like Delhi, the share of air conditioners is as high as 30-60% [2], [16]. This implies that, on average, the saturation of room ACs in the urban Indian households in 2010 was about 3.1% (15% of the air cooler and air conditioner ownership). While average household incomes have risen significantly over the last decade, prices of electrical appliances have dropped in real terms. Most of the major Indian cities are populous and have very high number of cooling degree days compared to other cities in the world.

In short, Indian cities have significantly high cooling requirement; the AC and air cooler ownership in India shows a strong correlation with urbanization and income, and there is a non-linear relationship between income and AC ownership. Moreover, a few media reports have indicated that the share of air coolers in the Indian market is slowly being taken over by air conditioners. With rising incomes and falling prices, room AC penetration is expected to increase rapidly in India.

4.2 Projecting the Future Room AC Stock

The example of China is illuminating for understanding the rapid growth in household appliance ownership as a result of rising incomes and urbanization. The saturation of air conditioners in urban China went from nearly zero in 1992 to about 100% by 2007 i.e. within a span of 15 years [3]. Because of the factors mentioned in the previous section, we believe that the AC ownership in India is may witness a similar growth. In this paper, we have estimated the future AC stock based on [4]. The future stock is estimated by dividing the electricity saving projected in [4] by unit energy consumption of the efficient AC. The stock projections are shown in the following table.

Table 4: Room AC Consumption and Stock in 2020 and 2030

	2010	2020	2030
Total Electricity Consumption by room ACs for Business as Usual (BAU) (TWh/yr)	8	77	239
Total stock of room ACs (millions)	4	37	116
Room AC penetration in urban areas (total stock as % of urban households)	3%	22%	47%

(Data source: [1], [4], authors' calculations)

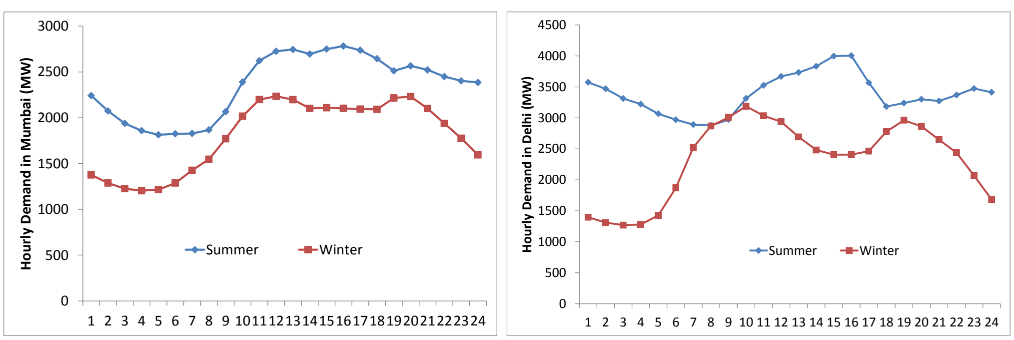
As shown in the table, we estimate that about 22% of the urban households will own a room air conditioner by 2020 and about 47% would own a room air conditioner by 2030. Given the projected incomes and urbanization in India, we believe that these are fairly conservative estimates of the future AC stock.

4.3 Contribution of ACs to the Peak Electricity Demand

In this section, we describe the usage pattern of the space cooling load in India and assess the impact of high penetration of room ACs on peak demand.

Several load surveys in India have found that the space cooling demand in India is highly coincident within a sector and also with the peak demand [11], [13], [16], [17]. Based on these surveys, the following observations could be made: (a) If a household or a commercial establishment owns an AC, its contribution to the peak demand is significant, (b) Residential and commercial space cooling demand has a significant seasonal correlation, (c) diurnally, residential AC demand peaks at night and commercial AC demand peaks in the afternoon. But during the afternoon, there are a few hours where residential and commercial demands coincide, and (d) space cooling is the only end-use that shows significant seasonal variation.

The following charts show the hourly system demand curves on average summer and winter days in two major Indian cities: Mumbai and Delhi. More than 75% of the load in these cities is residential and commercial; moreover, these cities have a modest level of AC penetration in the residential and commercial sector. Therefore, the system level data essentially represents the pattern in which these two consumer types use the electricity.



(a) Mumbai **(b) Delhi**

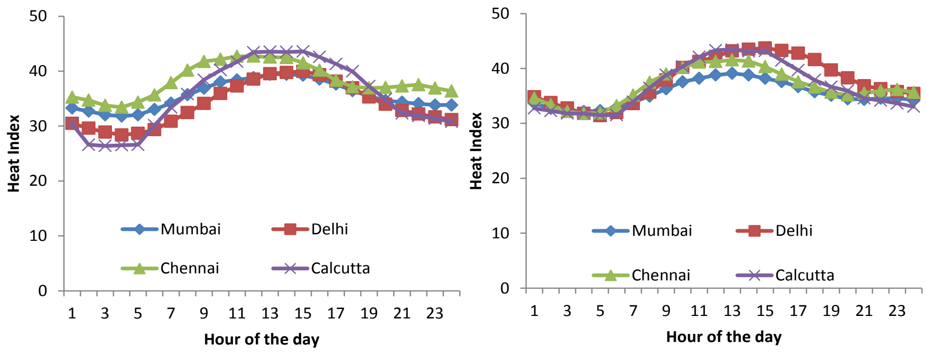
Figure 6: Average Hourly Demands in Summer and Winter in Mumbai and Delhi

(Data Source: [18], [19])

Both Mumbai and Delhi systems are afternoon peaking in the summer; coincidence of the residential and commercial space cooling demand in the afternoon causes the system demands to peak in summer afternoons. Since space cooling is responsible for the seasonal variation in electricity demand in both sectors, the peak demand in winter drops by nearly 40% and 25% respectively in Mumbai and Delhi.

4.4 Coincidence of the space cooling demand across regions in India

So far, we have shown that the space cooling demand from residential and commercial sector makes a significant contribution to the peak demand. The following chart shows the hourly heat indices in four large Indian cities located in different geographic regions in the country.



(a) May (b) June

Figure 7: Average Hourly Heat Indices of Major Indian Cities in May and June

(Data Source: [20])

It can be seen that the average heat index pattern during the summer months in India is very similar across geographic regions in India. There would be some daily variation due to local conditions, but in general, the space cooling demand may have a high peak coincidence across geographic regions.

4.5 Estimation of the Peak Demand from room ACs

Because of the reasons mentioned in the previous section, we have assumed a peak coincidence factor of 0.7 for the room ACs in India. The demand for space cooling would peak during summer afternoons. The following table shows our estimates of the peak demand contribution from room ACs.

Table 5: Projected Peak Demand from room ACs

	2010	2020	2030
Total stock of room ACs (millions)	4	37	116
BAU Electrical load per AC (W)	1500	1500	1500
Peak Coincidence factor	0.7	0.7	0.7
T & D Loss	15%	15%	15%
Peak demand contribution from room ACs (GW)	5	46	143

Note that because of the daily variations in heat indices, the actual peak coincidence and therefore the peak demand contribution from ACs may be more or less than what we have estimated. More work is needed to account for such variations possibly by introducing random variables while estimating the daily peak demands.

5 Saving Potential

5.1 Energy Saving Potential

Based on the efficiency improvement design options discussed in the previous sections, the total technical potential for saving electricity by improving efficiency of the room ACs in India is found to be 118 TWh at bus-bar in 2030. The efficiency supply curve is shown in the following chart:

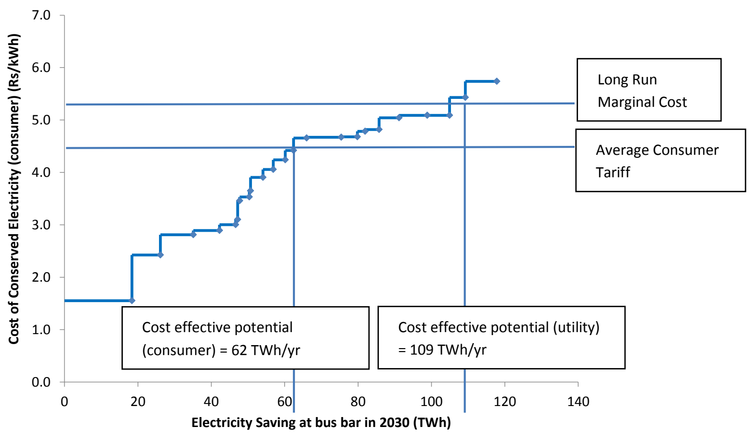


Figure 8: Efficiency Supply Curve in 2030 for Room ACs in India

The cost-effective saving potential from consumers' perspective is 62 TWh at bus-bar while the cost-effective saving potential from the utility perspective is found to be 109 TWh at bus-bar in 2030.

5.2 Peak Saving Potential

The following chart shows the peak demand from room ACs in 2020 and 2030. The chart also shows the peak saving potential in the form of wedges; each wedge refers to an efficiency improvement design option presented in section 3.1.

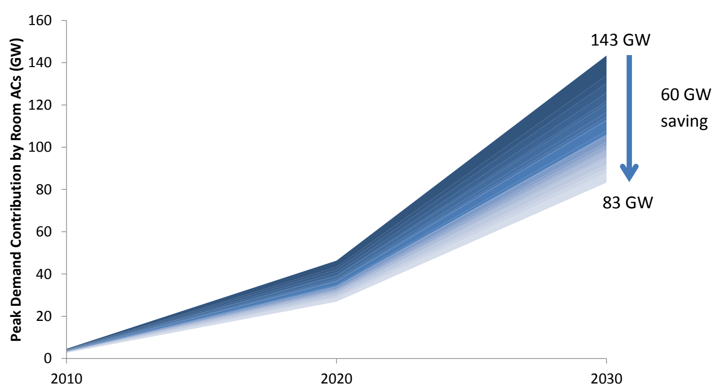

Figure 9: Peak Demand Contribution by room ACs and Peak Saving Potential

By 2030, enhancing the AC efficiency can save nearly 60 GW of peak demand at bus-bar. This is equivalent to saving nearly 120 power plants of 500 MW each. Note that power system has to be planned for meeting the total energy as well as peak demand. High seasonal or diurnal variation in demand makes inefficient use of the generation and transmission assets and therefore increases the total cost of system operation. Reduction in the peak demand lowers the power system investment and also improves the capacity factor of the existing power plants.

6 Conclusions

In this paper, we have showed the design options and estimated the incremental cost for enhancing efficiency of room air conditioners in India. Electricity consumption by room ACs is expected to increase from 8 TWh in 2010 to 239 TWh by 2030. Such growth would have significant impact on the Indian power sector and would require unprecedented construction of new power plants. We find that 40% of the energy consumed by room ACs could be saved cost-effectively by enhancing their efficiency. This translates to a potential energy saving of 118 TWh at bus-bar or a peak demand saving of 60 GW by

2030. This potential saving is equivalent to avoiding the construction of 120 new coal-fired power plants of 500 MW each. In order to realize this large cost-effective potential, a coordinated approach of market push (standards) and market pull (awards, labels, and incentives) is needed. Indian MEPS is one of the lowest in the world; therefore, the standards and labeling program in India need to be revised significantly. Given that the AC demand reduction is cost-effective from consumer as well as utility perspective, ratepayer funds can be used to undertake incentive programs. Such funds for ACs can be collected from high electricity consumption customers to ensure equity. Because the space cooling demand in India is temporally coincident across regions, the contribution of room ACs to the peak demand would be significant. Therefore, standards for making the room ACs demand response ready are recommended. It is also important to pursue efforts such as improved building design and cool rooms to reduce or postpone the AC demand. More research and analysis is required for assessing the use of climate specific space cooling technologies like modified evaporative ACs designed specifically for humid climates. For estimating the peak demand contribution and saving from ACs more accurately, daily and hourly variations in the space cooling demand (i.e. heat indices) should be considered. Therefore, an important future work emerging out of this analysis is developing a methodology for estimating the impact of space cooling demand on the power system more accurately. This analysis could be performed by introducing a random variable for local weather changes, and elementary load-flow analysis.

TRANFORMING A RESIDENTIAL APPLIANCE MARKET

K H. Tiedemann and I. Sulyma

BC Hydro

Abstract

This report provides an evaluation of the impacts of the Energy Star Appliance Rebate Program in British Columbia, Canada. BC Hydro's Energy Star Appliance Rebate program is a multi-year energy acquisition and market transformation initiative that encourages its customers to purchase energy-efficient Energy Star appliances. The program objectives are to: (1) significantly impact market penetration of Energy Star appliances to increase market share and energy savings, and (2) drive future enhancements to energy efficiency legislation for household appliances. The purpose of this study is to conduct a process, impact and market evaluation of BC Hydro's Energy Star Appliance Rebate program.

Introduction

This report provides an evaluation of the impacts and effects of the Energy Star Appliance Rebate Program. BC Hydro's Energy Star Appliance Rebate program is a multi-year energy acquisition and market transformation initiative that encourages its customers to purchase energy-efficient Energy Star appliances. The program objectives are to: (1) significantly impact market penetration of Energy Star appliances to increase market share and energy savings, and (2) drive future enhancements to energy efficiency legislation for household appliances. The purpose of this study is to conduct a process, impact and market evaluation of BC Hydro's Energy Star Appliance Rebate program.

The Environmental Protection Agency introduced the Energy Star program as a voluntary initiative in 1992 (Brown, et al. 2000). The purpose of the program was to identify and promote energy-efficient products with the goal of reducing carbon dioxide emissions. The program began with computers, computer monitors and printers in 1992. Subsequent additions included: fax machines, copiers, residential heating and cooling equipment, thermostats, new homes, commercial buildings and exit signs in 1995; refrigerators, room air conditioners, clothes washers and dishwashers in 1996; windows in 1998; and screw-in CFLs in 1999. From January 2008 to May 2010, the BC Hydro Appliances Rebate Program provided rebates on Energy Star labelled clothes washers, refrigerators and freezers.

Literature Review

Market transformation programs create new challenges and opportunities for program evaluation. On the one hand, traditional evaluation techniques such as use of pre/post comparisons with treatment and control/comparison groups may not be possible if the treatment group is potentially the whole population. On the other hand, econometric techniques, such as the interrupted time-series model, can potentially deal with confounding market effects including free riders and spillover in a comprehensive and credible manner. The program evaluation literature on appliance markets includes both econometric and non-econometric studies. In this brief review, some of the peer-reviewed literature on market transformation in the residential sector is summarized.

The econometric studies use information on sales and drivers of sales to estimate the impact of program interventions on sales of energy-efficient products. Duke and Kammen (1999) found that accounting for the interaction between the demand response and production response for electronic ballasts increases the consumer benefit-cost ratio. Habart et al. (2004) found a significant impact of Energy Star promotion on sales of qualifying refrigerators and clothes washers. Horowitz (2001) found that coordinated national electronic ballast programs were more cost effective than local efforts. Horowitz and Haeri (1990) found that the cost of energy efficiency investments was fully capitalized in housing prices and that purchasing an energy-efficient house was cost effective. Jaffe and Stavins

(1995) found that insulation levels in new residential housing appropriately reflect energy prices. Tiedemann (2004) found that the China Green Lights program, which was closely modeled on the U.S. program, had statistically significant positive impacts on sales of more efficient lighting products and negative impacts on sales of less efficient lighting products. Tiedemann (2007) found that increases in energy prices and energy efficiency activities launched in the wake of the 2001 California energy crisis led to increased sales of Energy Star appliances. One reviewer commented that the following factors were important during the California energy crisis: they saw a four-fold increase in EE PGC-funds; were in the news all the time; there was a “panic” and rebates that were too juicy to pass by. Retailers sought to differentiate themselves by stocking more (and one even exclusively) E Star products. It was not just about prices and energy efficiency activities—there were many other reinforcing elements—social pressure, media, and the like that were adding significant impetus.

The non-econometric studies employ a variety of approaches. Nadel et al. (2003) provided a comprehensive overview of market transformation activities in the United States, and they found the beginnings of significant transformation in appliance markets. Titus and Feldman (2003) defined the analytical and data requirements for tracking the effectiveness of energy-efficient appliance programs, and they applied their model to the Wisconsin Focus on Energy’s CFL Program and to the Efficiency Vermont’s appliance program. Rosenberg (2003) used cross-section state data to estimate the determinants of Energy Star market share for the four major household appliances. Webber, Brown and Koomey (2000) provided a comprehensive set of both historical energy savings and forecast savings due to Energy Star. They explored the magnitude and allocation of Energy Star savings in detail, but they did not examine the determinants of sales. Meyers et al. (2003) estimated historical and forecast impacts of Energy Star sales on energy use and carbon emissions, and they estimated that Energy Star products saved 740 PJ of energy and 13 million tonnes of carbon emissions through 1999. Mauldin et al (2005) examined determinants of prices for Energy Star and non-Energy Star room air conditioners. Vine et al. (2010) developed a comprehensive framework for the evaluation of market effects in California. Their framework included six components: (1) prepare a scoping study: (2) analyze market conditions; (3) analyze market effects; (4) assess attribution; (5) estimate energy savings; and (6) assess sustainability. Using this framework, their study examined market transformation for three California programs, CFLs, residential new construction and high bay lighting.

Method

For this study, there were five main activities: (1) conduct a program review; (2) undertake a supply-side assessment; (3) undertake a demand-side assessment; (4) review price trends for Energy Star-qualifying and non-Energy Star-qualifying appliances; and (5) estimate energy and peak savings.

- **Program Review.** To conduct the program review and develop the program logic model, we reviewed program documents, interviewed BC Hydro program staff, and conducted a literature review focussing on recent studies and reports of residential appliances.
- **Supply-Side Assessment.** To undertake the supply-side assessment, we tabulated and examined relevant results of the annual in-store surveys of appliance stock behaviour in representative samples of retail sales establishments. The surveys have about 40 participants per year.
- **Demand-Side Assessment.** To undertake the demand-side assessment, we tabulated and examined relevant results of the quarterly Energy Star Tracker surveys. The surveys have about 700 participants per quarter.
- **Price Trends.** To review price trends for Energy Star and non-Energy Star appliances, we tabulated and examined relevant results from the annual in-store surveys.
- **Energy and Demand Savings.** To estimate demand and energy savings, we used the following algorithms:

  (1) ΔkW = Incremental units*unit energy savings,

(2) ΔkWh = Incremental units*unit peak savings.

The number of incremental units is based on an econometric model, and the unit energy savings are based on information on models available for sale from the in-store surveys.

Results

Program Review. At the time of program launch in 2008, a market analysis indicated that there were several barriers to market transformation including low awareness of Energy Star appliances among consumers, low availability of Energy Star product in stores, and high prices for Energy Star products. BC Hydro has employed a phased strategy to transform the household appliance market and acquire energy and peak savings. The program has successfully addressed these barriers through four main activities: information and promotions, sales tax exemption, financial incentives and legislative support for more stringent Minimum Energy Performance Standards.

Table 1 provides a program logic model focussing on input, output, purpose and goal statements for each of the four main activities. The program rationale was examined using this program logic model, which was developed from interviews with staff, a documents review and a literature review. This review and analysis confirmed that the basic program logic was valid. There were strong linkages among inputs, outputs, purposes and goal statements. Indicators for key components of the logic model were clear, well defined and measurable.

Table 1. BC Hydro Energy Star Appliance Rebate Program Logic Model

	Information and promotions	**Sales tax exemption**	**Financial incentives**	**Legislative support**
Inputs	Develop information and promotional materials	Provincial Sales Tax (7% PST) exemption for Energy Star clothes washers, refrigerators and freezers thru March 31, 2010	$50 (CAD) incentive for Energy Star fridges and clothes washers and $25 (CAD) incentive for Energy Star freezers thru March 31, 2010	Technical support for efficient appliance standards development
Outputs	Customer product awareness increased	First cost of Energy Star appliances reduced	First cost of Energy Star appliances reduced	Legislation and regulations in place
Purpose	Increased customer intent to purchase Energy Star appliances	Increased consumer purchases of Energy Star appliances	Increased consumer purchases of Energy Star appliances	Prevent backsliding in the residential appliance market
Goal	Significantly impact market penetration of Energy Star appliances to increase market share and energy savings of 4.9 GWh Drive energy efficiency legislation for household appliances			

Supply-side Assessment. In this section, we examine the supply side of the market for refrigerators, freezers and clothes washers. The surveyed retail stores averaged 35 refrigerator units on display. The product shares are as follows: bottom mount - 56%, top-mount - 26%, side by side - 19%. Table 2 shows the Energy Star share for refrigerators by type of store. The Energy Star share increased from 57% in 2009 to 78% in 2010.

Table 2. Energy Star Share of Refrigerators by Store Type

	Department store	Appliances/ furniture	Other	Total
2009	61%	46%	71%	57%
2010	84%	71%	78%	78%

The surveyed retail stores averaged 8 freezer units on display. The product shares are as follows: chest freezers - 61%; upright freezers - 39%. Table 3 shows the Energy Star share for freezers by type of store. The Energy Star share decreased from 48% in 2009 to 39% in 2010. The reason for this is not clear, but with a small sample size there may be a high level of variability.

Table 3. Energy Star Share of Freezers by Store Type

	Department store	Appliances/ furniture	Other	Total
2009	53%	25%	73%	48%
2010	43%	15%	60%	39%

The surveyed retail stores averaged 24 clothes washer units on display. The product shares are as follows: front load - 73%; top load - 27%. Table 4 shows the Energy Star share for clothes washers by type of store. The Energy Star share increased from 70% in 2009 to 79% in 2010.

Table 4. Energy Star Share of Clothes Washers Freezers by Store Type

	Department store	Appliances/ furniture	Other	Total
2009	72%	66%	75%	70%
2010	74%	81%	80%	79%

Demand-side Assessment. To determine unaided awareness of Energy Star, respondents were asked “Have you seen or heard of the Energy Star label?” Those who indicated “yes” were viewed as having unaided awareness of the Energy Star label. Those who responded “no” to this first question were asked “Please look at the Energy Star label: have you seen or heard of this label?” Those who responded “yes” were added to the unaided aware to determine aided awareness. Table 5 shows the results for Energy Star awareness for the period 2007:Q4 to 2010:Q2. Unaided awareness has increased substantially over the period surveyed, from 46% in 2007:Q4 to 68% in 2010:Q2. Total awareness has also increased, rising from 72% in 2007:Q4 to 85% in 2010:Q2.

Table 5. Energy Star Awareness

	Unaided (%)	Additional (%)	Total %
2007:Q4	46	26	72
2008:Q1	49	25	74
2008:Q2	50	26	76
2008:Q3	53	20	73
2008:Q4	61	23	74
2009:Q1	62	21	83
2009:Q2	62	19	81
2009:Q3	75	13	88
2009:Q4	70	16	86
2010:Q1	65	24	89
2010:Q2	68	17	85

Respondents who purchased various products over the 12 months before the survey were asked a series of questions about the label and about the product they purchased, but it should be noted that the sample sizes were relatively small, since in any given year, only a small share of customers purchase a new major appliance.

Table 6 shows the results for Energy Star recall for the period 2007:Q4 to 2010:Q2. For all three appliances, the share of Energy Star label recall increased over the period covered by the surveys. Energy Star label recall increased from 51% to 62% for refrigerators, from 45% to 54% for freezers, and from 58% to 65% for clothes washers.

Table 6. Energy Star Label Recall

	Refrigerators (%)	Freezers (%)	Clothes Washers (%)
2007:Q4	51	45	58
2008:Q1	40	41	41
2008:Q2	57	56	53
2008:Q3	56	48	45
2008:Q4	63	68	56
2009:Q1	68	58	61
2009:Q2	55	59	61
2009:Q3	57	59	66
2009:Q4	65	61	68
2010:Q1	66	54	66
2010:Q2	62	54	65

Respondents who saw the Energy Star label on the products they purchased were asked questions about the importance of the influence of the Energy Star label on their purchase decision. Table 7 shows the results of this enquiry. For all three appliances, the influence of the Energy Star label is quite high, but there is no particular trend in the share of respondents saying that the Energy Star label is very or somewhat important in the purchase decision. In other words, using 2007:Q4 as the baseline period, there is little apparent movement in the share of respondents indicating that the Energy Star label was very or somewhat influential in their choice of product.

Table 7. Energy Star Influence on Purchase (very/somewhat influential)

	Refrigerators (%)	Freezers (%)	Clothes Washers (%)
2007:Q4	86	90	86
2008:Q1	74	78	75
2008:Q2	81	95	78
2008:Q3	89	100	79
2008:Q4	93	91	83
2009:Q1	90	93	90
2009:Q2	88	86	88
2009:Q3	90	90	90
2009:Q4	86	90	90
2010:Q1	77	67	86
2010:Q2	85	95	80

Prices. Appliance price comparisons are complicated because prices are driven by a number of factors including volume, features, materials used as well as whether or not they are Energy Star compliant. Table 8 shows the prices for major appliances by Energy Star status for the 2009 in-store survey. This study suggests that the wedge between Energy Star and non-Energy Star appliances may be substantial, with Energy Star appliances being more expensive than non-Energy Star appliances.

Table 8. Energy Star and Non-Energy Star Prices, 2009

	Energy Star	Non-Energy Star	All appliances
Clothes washers	$1250	$767	$1105
Refrigerators	$1586	$1346	$1501
Upright freezers	$831	$488	$638
Chest freezers	$431	$356	$395

Table 9 shows the prices for major appliances by Energy Star status for the 2010 in-store survey. This study suggests that the wedge between Energy Star and non-Energy Star appliances may have widened for clothes washers and refrigerators but narrowed substantially for upright freezers and for chest freezers.

Table 9. Energy Star and Non-Energy Star Prices, 2010

	Energy Star	Non-Energy Star	All appliances
Clothes washers	$1266	$734	$1149
Refrigerators	$1646	$1219	$1589
Upright freezers	$635	$581	$611
Chest freezers	$344	$311	$331

Energy and Peak Savings. The energy and peak savings were estimated in several steps. First, unit energy savings were calculated for each appliance, using the information on the Energy Star labels. Second, the program impact on shipments of Energy Star appliances was estimated using an econometric model. Third, the results of the regression model were used to estimate the program impacts on appliance shipments. Fourth, engineering algorithms were used to estimate energy and peak impacts.

Information on kWh per cubic foot for Energy Star and non-Energy Star appliances and average volumes in cubic feet were obtained from the in-store survey.

Step 1. The following algorithm was used to estimate energy savings per unit for appliance j:

(3) Unit savings$_j$ = (ES kWh per cu ft$_j$ – Non-ES kWh per cu ft$_j$)* (Volume in cu ft$_j$)*(1 –cross effects$_j$).

The results are shown in Table 10. Unit savings for clothes washers were estimated to be 188.0 kWh per year. Unit savings for refrigerators were estimated to be 55.9 kWh per year. Unit savings for freezers were estimated to be 29.3 kWh per year.

Table 10. Appliance Unit Energy Savings

	ES (kWh per cubic ft)	Non-ES (kWh per cubic ft)	Volume (cubic ft)	Cross effects (%)	Savings (kWh per unit)
Clothes washers	48	95	3.9	-	188.0
Refrigerators	23	26	20.3	8.2	55.9
Freezer	39	42	10.0	2.4	29.3

Step 2. The following monthly econometric model for the period January 2003 to March 2010 was used to estimate the impact of the program on monthly appliance shipments:

(4) $Ship_m = \alpha + \beta Perm_m + \gamma Wage_m + \delta PSARP_m + \theta\, Q2_m + \lambda Q3_m + \eta Q4_m + \varepsilon_m$

where variables (and their sources) are as follows: Ship is shipments of ES qualifying refrigerators and clothes washers (from the Canadian Appliance Manufacturers Association). Perm is residential building permits (from BCStats[1]); wage is wage rate (from BCStats); PSARP is dummy variable for presence of program; Q2, Q3 and Q4 are quarterly dummy variables; ε is an error term; m indexes months.

Results are shown in Table 11. The regression results are good with an adjusted R-squared of 0.66, and all of the coefficients are significant at the 10% level. The key point is that realization on the program variable is 2,355 units per month compared to program incentives of 4,874 for clothes washers and refrigerators for a realization rate of 48.3%. We use this realization rate for freezers too, where we have no monthly shipments data.

Table 11. Regression Results for Refrigerators and Clothes Washers

Variable	Coefficient	Standard error
Constant	-18686*	9584
PSARP	2355***	824
Wage	28.2**	12.9
Building permits	0.0049***	0.0012
Q2	1045**	501
Q3	1582***	494
Q4	1374***	501
Adjusted R-squared	0.66	

One, two and three asterisks mean that the coefficient is statistically significant at the 10%, 5% or 1% level respectively.

Step 3. The following algorithm was used to estimate net units shipped for appliance j:

(5) Net $unit_j$ = Rebates per $month_j$*Net to gross ratio.

Results are shown in Table 12. As explained above, a common net-to-gross ratio of 0.483 is applied to the average number of rebates per month. The number of units attributable to program activities per month is 1,249 clothes washers, 1,106 refrigerators, and 155 freezers. It should be noted that regression models were also run separately for clothes washers and refrigerators. However, the project team decided to use the results of the pooled regression and apply the results to freezers because of the absence of freezer shipment data.

Table 12. Net Units per Month

	Rebates per month	Net to gross ratio	Net units per month
Clothes washers	2584	0.483	1249
Refrigerators	2290	0.483	1106
Freezers	320	0.483	155

Step 4. The following algorithm was used to estimate energy savings for appliance j:

(6) Energy $savings_j$ = Unit $savings_j$*Change in net number of $units_j$.

Results are shown in Table 13. For clothes washers, annual energy savings are 6.1 GWh and annual peak savings are 1.9 MW. For refrigerators, annual energy savings are 1.6 GWh and annual peak savings are 0.5 MW. For freezers, annual energy savings are 0.1 GWh and annual peak savings are 0.04 MW. It should be noted that the current residential appliance metering project will provide more accurate and recent information on peak savings in relation to energy savings.

[1] http://www.bcstats.gov.bc.ca/Home.aspx

Table 3. Energy and Peak Savings

	Savings (kWh per unit)	Change in net number of units	Energy (GWh per year)	Peak (MW per year?)
Clothes washers	188.0	32474	6.11	1.91
Refrigerators	55.9	28756	1.61	0.51
Freezers	29.3	4030	0.12	0.04
Total			7.84	2.49

Conclusions

Program Design and Implementation. The BC Hydro Residential Energy Star Appliance Program achieved considerable success in building product awareness, and purchase behaviour for Energy Star qualifying appliances. Total awareness increased, rising from 72% in 2007:Q4 to 85% in 2010:Q2 and for all three appliances, the share of Energy Star label recall increased over the period covered by the surveys. The program is cost effective (Total Resource Cost greater than 1.0 and Ratepayer Impact Measure greater than 0.8) and has evolved over time in response to changes in market conditions, with the current program focusing on the highest tier of energy efficient appliances.

Program Energy, Peak and Price Impacts. Engineering algorithms informed by customer survey data and by the showroom stock study were used to estimate program impacts. Evaluated energy savings were 7.8 GWh compared to business plan forecast energy savings of 11.6 GWh, while evaluated peak savings were 2.5 MW. The price wedge between Energy Star qualifying and non-Energy Star qualifying appliances may be substantial, but it is not clear how much of the price wedge is due to energy-efficient features and how much is due to other factors.

Evaluation Methods. Evaluations of residential appliance programs usually rely heavily on self-report information to deal with attribution including the issue of free riders. However, in market transformation programs, the evaluation issues are relatively subtle and may require more sophisticated methods. In this study, econometric modelling of appliance demand has been used to estimate program impacts. This may be a fruitful approach for the future evaluation of residential appliance programs.

Costs and Benefits of Energy Efficiency Improvement in Ceiling Fans

Nihar Shah, Nakul Sathaye, Amol Phadke and Virginie Letschert

Energy Analysis Department, Environmental Energy Technologies Division, Lawrence Berkeley National Laboratory, Berkeley CA USA

Abstract

Ceiling fans contribute significantly to residential electricity consumption, especially in developing countries with warm climates. The paper provides analysis of costs and benefits of several options to improve the efficiency of ceiling fans to assess the global potential for electricity savings and green house gas (GHG) emission reductions. Ceiling fan efficiency can be cost-effectively improved by at least 50% using commercially available technology. If these efficiency improvements are implemented in all ceiling fans sold by 2020, 70 terawatt hours per year could be saved and 25 million metric tons of carbon dioxide equivalent (CO_2-e) emissions per year could be avoided, globally. We assess how policies and programs such as standards, labels, and financial incentives can be used to accelerate the adoption of efficient ceiling fans in order to realize potential savings.

Introduction

This report presents the results of an analysis of ceiling fan efficiency, prepared in support of the Super-efficient Equipment and Appliance Deployment (SEAD) initiative.[1] SEAD aims to transform the global market through increasing availability of efficient equipment and appliances. The objective of this analysis is to provide the background technical information necessary to improve the efficiency of ceiling fans and to provide a foundation for the voluntary market transformation activities of SEAD participating countries.

Ceiling fans contribute significantly to residential electricity consumption in warm climates and especially in developing countries. For example, in India, ceiling fans alone accounted for approximately 6% of residential energy use in 2000. This figure is expected to grow to 9% in 2020 [1], an increase that is equivalent to the energy output of 15 mid-sized power plants.[2] In addition, ceiling fan ownership rates have been shown to significantly increase in low-income Indian households as income levels increase [1]. Although ceiling fan standards and labeling programs are specified for every major economy in the world, these programs only discourage the use of highly inefficient fans [8]. In developed countries and countries with milder climates, a smaller fraction of electricity consumption is attributable to ceiling fans. Nevertheless, ceiling fans account for as much as 5% of residential electricity use in the U.S., although this varies greatly by region [12]. Even in those areas where they do not constitute a significant fraction of electricity demand, ceiling fans can reduce energy consumption by reducing the use of other cooling devices. Fans are well known to be a cost-effective option for reducing the electricity demand of air conditioners [13], [14]. Air conditioners are responsible for approximately 16% of residential electricity consumption in the U.S. In addition, ceiling fans are essential features in passive cooling systems aimed at achieving energy-efficient thermal comfort [15], [16].

This study assesses the potential for global ceiling fan energy-efficiency improvement. We analyze the cost-effectiveness of ceiling fan efficiency improvements while estimating the global potential for both energy consumption and CO_2-e emission reductions. We utilize the Bottom-Up Energy Analysis System

[1] An initiative of the Clean Energy Ministerial (CEM) and a task within the International Partnership for Energy Efficiency Cooperation (IPEEC), SEAD seeks to engage governments and the private sector to transform the global market for energy-efficient equipment and appliances. As of October 2012, the governments participating in SEAD are: Australia, Brazil, Canada, the European Commission, France, Germany, India, Japan, Korea, Mexico, Russia, South Africa, Sweden, the United Arab Emirates, the United Kingdom, and the United States. More information on SEAD is available from its website at http://www.superefficient.org/ .

[2] For this estimate we assume an increase in BAU power consumption of ~20TWh, as outlined in the section titled " Energy Savings Potential". We also conservatively estimate that one-tenth of ceiling fans are used during the peak hour and that a mid-sized power plant has a 500-megawatt capacity and runs at 70% efficiency (as described in [11]). However, currently installed power plants in India have a much lower average efficiency [1].

(BUENAS) to make these estimates [11]. First we present a technological economic analysis of fan efficiency improvement options followed by global energy savings estimates. Finally we discuss implications for design of market transformation programs, and conclude the paper.

Techno-Economic Assessment of Efficiency Improvement Options in Ceiling Fans

Ceiling fan energy performance is typically measured in units of meters cubed per minute per Watt (m^3/min/W). This represents the ratio of air delivery to power input. The term "efficiency" is commonly used to represent the ratio of mechanical-output to electrical-input power. In this paper, we follow the example of earlier studies [17]. The term "efficacy" refers to fan performance, while the term "efficiency" is used as a general performance descriptor and when discussing the performance of motors.

Note: In Europe and India the term "Service Value" is used to refer to efficacy.

Table 1. Summary of characteristics used in various standards and labeling programs

Country	Agency	Standard/ Label Type		Speed	Size category	Rating type
India	BIS	Standard	Voluntary		Yes	Specifies minimum efficacy for various fan sizes
India	BEE	Label	Voluntary		Only 1200 mm	Assigns star ratings to fans meeting minimum efficacy requirements
China	NDRC, AQSIQ	Standard	Mandatory		Yes	Assigns ratings based on efficacy, to fans classified by size
U.S.	EPA	Label	Voluntary	Yes		Specifies minimum efficacy for fans classified by operating speed
Europe	Ecodesign Forum	Standard	Mandatory		Yes	Specifies a minimum efficacy for various fan sizes

Standards and labeling programs for ceiling fans are typically designed to ensure a specified level of efficacy. Specifications include sub-categories that are classified by characteristics such as fan size, operating speed, or airflow. Fans have higher efficacy at lower speeds meaning standards and labeling programs categorize fans by operating speed [17]. Fan efficacy can be increased through increasing blade length because power consumption decreases with as blade length increases assuming constant airflow. Accordingly, some programs categorize fan standards and labels by fan size or sweep. Table 2 summarizes fan standards and labeling frameworks in various countries. In the U.S., the ENERGY STAR program specifies minimum ceiling fan efficacy rankings for three different airflow levels [3]. Similarly, the Indian standard IS-374 defines minimum efficacy levels for five different ceiling fan size categories [10]. In addition to this, the Indian Bureau of Energy Efficiency (BEE) maintains a star rating system based on fan efficacy [4]. However, the Indian star rating system is applicable to only one size of fan (1200 mm) and does not vary by fan speed.

Efficiency Improvement Options for Ceiling Fan Systems

The ceiling fan system consists of multiple components that together determine the fan's overall energy consumption. We focus on engineering improvements that are easily quantifiable such as changes to fan motors and blades that improve ceiling fan efficiency.

Fan Motors

Historically ceiling fans have utilized AC induction motors because these motors are durable, easy-to-construct, and relatively inexpensive to manufacture. Permanent split-capacitor motors are prevalent in ceiling fans manufactured in India, and shaded-pole motors are prevalent in ceiling fans manufactured in the U.S. and Europe [20]. However, these AC induction fan motors are relatively inefficient because of the slip[3] associated with single-phase induction motors. Brushless DC (BLDC) motors have become increasingly common in appliances in recent decades due to developments in electronic commutation and the availability of inexpensive and high-performing magnetic materials [21]. Such motors are more efficient than brushed DC motors because they do not have the friction loss associated with mechanical commutation. Induction motors are inefficient because their rotors do not rotate synchronously with the magnetic field that induces rotor motion which results in slip. BLDC motors alleviate these issues because the rotor moves synchronously with the rotating AC magnetic field produced by electronic commutation. For instance, a 75 W BLDC motor has been estimated to have an efficiency of up to about 90% whereas the average new 75-W AC induction motor has an efficiency of around 75% [21]. Table 2 shows these efficiencies along with those of other 75-W motors.

Multiple engineering studies have estimated the potential for reducing energy consumption through the use of BLDC motors. One experimental Taiwanese study shows that the energy consumption of a ceiling fan with a BLDC motor is about 50% that of a fan with a split-phase induction motor [22]. An experimental study from Australia shows that BLDC motors decreases ceiling fan energy consumption by a factor of three at low speeds and a factor of two at high speeds [23]. Industry experts indicate that using a BLDC motor can reduce energy consumption by an estimated 60% in the U.S. and 50% in India [24],[20]. In addition to the potential energy efficiency improvements achieved with BLDC motors, some fans in India incorporate a combination of elements that affect AC induction motor efficiency. These fans consume significantly less energy than normal [20],[25]. At high speeds, these fans can reduce power consumption from 70-75 W to about 45-50 W. The elements that [20] cites as influencing AC induction motor efficiency in these fans are increased amount of “active” material (such as lamination steel and copper), reduced air gap between stator and rotor and incorporation of standard-grade aluminum for die-cast rotors.

Table 2. Efficiency data for various 75-W motor types in the U.S.

Motor type	**Efficiency**
NovaTorque[4]	90%
Practical Limits BLDC[6]	87%
Practical Limits AC Induction	84%
Average New Production	75%
Average Installed Base	60%

Fan Blades

Improving fan blade design has been shown to have significant influence on fan efficiency. Efficiency improvements have been achieved by multiple approaches. Incorporation of aerodynamic attachments for conventional blades [26]; a decrease in the angle of attack through the use of twisted, tapered (TT) blades [27]; and use of TT blades with an air foil [28]. We focus on the last of these options due to wide use of this type of blade and the potentially large energy savings that are associated with this design.

[3] The slip is the difference between the speed of the rotor and the magnetic field in an AC induction motor.

[4] The company Novatorque has incorporated technical improvements to push efficiency further beyond the so-called “practical limits” of a BLDC motor.

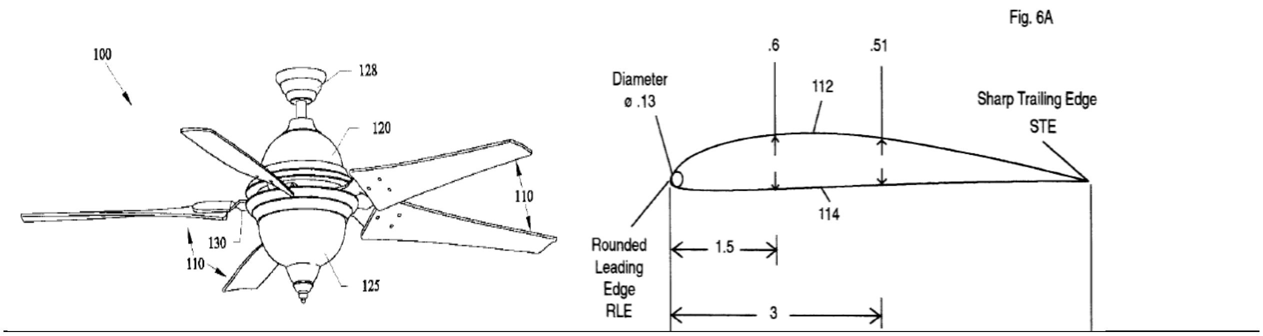

Figure 1. Design drawings from a patent for a ceiling fan with twisted, tapered blades with an airfoil. [5] Source: Parker et al. [40]

TT blades with an airfoil increase efficiency by reducing energy lost to turbulence and flow-separation as shown in Figure 1 [29]. Optimal blade design requires a balance between multiple objectives including maximization of air speed, uniform air speed along the fan radius, and maximization of airflow coverage. A test of one such patented blade design indicates that the subject invention has an efficacy 86%-111% higher than that of a conventional flat blade, indicating remarkable potential for energy-efficiency improvements from changes in fan blade design [30]. These blades can also be used to reduce motor size and cost, and the resulting device will still outperform a conventional fan [30]. Some efficient blade designs have been adapted for aesthetic purposes to appear like traditional blades from the bottom-side while being aerodynamic on the top-side, thus improving efficiency 10%- 26% when compared to conventional designs [31]. The blade has been designed to meet a market preference by some consumers for energy-efficient fans with a traditional appearance.

Fan Efficiency Improvement Opportunities: Empirical Evidence from the US Market

Figure 2 shows ENERGY STAR market data for qualifying fans being sold in the U.S. and Canada [3]. The information regarding motor and blade type was obtained from product catalogs and phone calls with representatives from ceiling fan manufacturers producing fans with the highest efficacies. These companies include Monte Carlo, Fanimation, Regency, and Emerson [32]. The data in the figures are comparable to the performance of the most efficient fans being introduced in U.S. and Canadian markets. For instance, the Emerson Midway Eco fan is advertised as having a 75% reduction in energy consumption due to the Emerson EcoMotor TM [9].

[5] We note that most fans sold in India have 3 blades as opposed to the 5 pictured here. However, to be consistent with the patent filed by Parker (2003), we have pictured the 5 bladed design from the patent. The blade improvements will be similar for a fan with 3 blades.

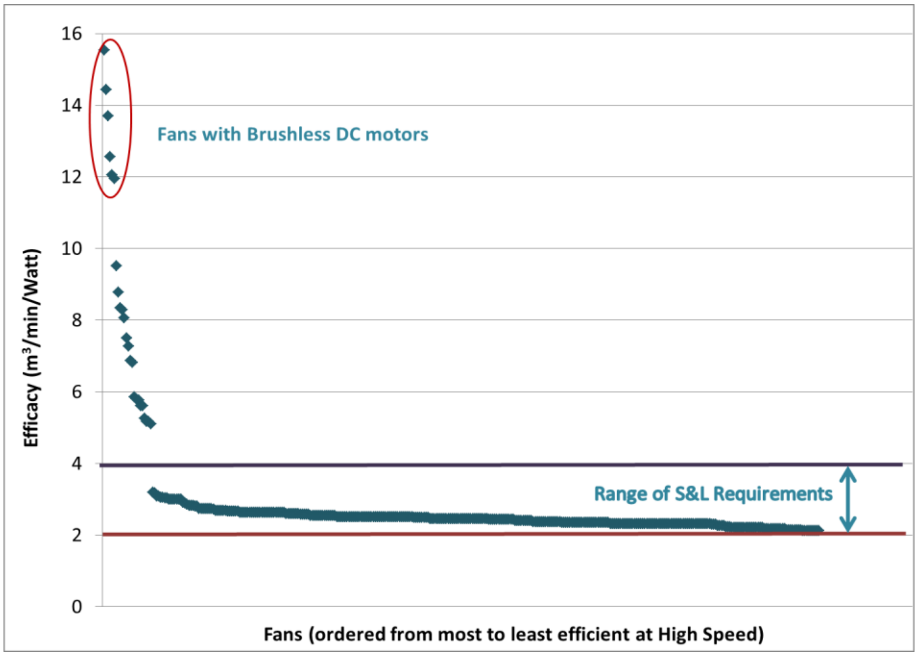

Figure 2. Efficacies for ENERGY STAR ceiling fans (fan only, without lights) at high speed[6]

Source: ENERGY STAR [33]

The figure shows that fans with BLDC motors have far higher efficacies than the current ENERGY STAR high-speed standard requires (2 m^3/min/W). This data indicates that engineering improvements, such as those previously discussed, can be used for purposes other than increasing efficacy. Other purposes include reducing motor size or material quality to reduce manufacturing costs in the absence of policy intervention to improve efficiency. To the authors' knowledge, there are no fans with BLDC motors in these figures other than those highlighted, although this is unconfirmed as we were not able to contact every fan manufacturer.

Technical and Economic Analysis of Efficiency Improvement Options

Here we estimate the costs of efficiency improvement of ceiling fans using the options previously described. We estimate the cost of conserved electricity (CCE) to assess the cost-effectiveness of these efficiency improvements. Due to data constraints, we only cite costs from a few countries while estimating the CCE.

Fan Motors

Based on data collected from industry experts we estimate the incremental cost of efficiency improvements of motors typically used in ceiling fans. We consider two types of efficiency improvement options. First, given that BLDC motors are significantly more efficient than induction motors, we estimate the incremental cost of BLDC motors of the same size and performance specifications over the typical induction motor. Second, we consider the cost of improving the efficiency of the induction motor itself, where the efficiency improvements are smaller and less costly compared to those achieved by a BLDC motor. BLDC motors are typically more expensive when compared to induction motors primarily because of the extra cost of the controller. Note that induction motors and BLDC motors have similar materials costs (excluding the BLDC motor controller). This is primarily because the extra cost of permanent magnets in a BLDC motor is compensated by reduction in costs due to less copper and steel (See [36] and [21] for a detailed discussion). Desroches & Garbesi find that that the global cost of materials for a 750-W (note that fan motors are typically much smaller, < 75W) induction motor is about US$43.80, and, for a BLDC motor, the materials cost ranges from US$24.20 to US$36.74, as of 2011 [21]. This indicates

[6] In 2010 and 2011, the market penetration of ENERGY STAR qualified ceiling fans was 18% and 13%, respectively [34] [35].

that the *materials* cost of a smaller BLDC motor, such as would be used in ceiling fans, should also range from a little less than to about equal to that of a comparable AC induction motor. Therefore, the incremental cost of the BLDC motor over an induction motor is essentially the cost of the controller. A BLDC motor controller is estimated to have a manufacturing cost between INR300-700 in India [20], [25]. The same controller would cost between US$3.2 to US$22.5 in the US [36]. We assume the incremental cost of a BLDC motor that replaces a typical ceiling fan induction motor of 75 W to be approximately US$10.50 for the purposes of this report.

Fan Blades

The cost of manufacturing efficient ceiling fan blades in the U.S. is estimated to be about US$2.25, versus US$0.25 per conventional flat blade [31], [30]. The incremental cost of manufacturing an efficient blade versus a conventional blade in India is about INR60 for 3 blades i.e. US$0.36/blade [20]. Although these appear to be significant cost increases for these components, they are not very large (~5%) compared to the total retail price of a ceiling fan. An important point to mention in the case of efficiency improvement through blade design is that blade design and manufacturing are driven by aesthetic considerations rather than just efficiency. This is also reflected in *divergent* estimates of the costs of manufacturing depending on the design, material, manufacturing, and treatment/finishing processes. The significance of aesthetic considerations in blade manufacture implies that *mandating* more efficient blades through minimum energy performance standards (MEPS) is not likely to be a practical or desirable option. However, given that some fans may be designed to meet energy efficiency policy specifications by using more efficient blades, it is still useful to estimate the costs of efficiency improvement through more efficient blades, particularly for labeling and incentive programs. Table 3 reports these costs in dollar terms along with average numbers, which are used as the input for the cost effectiveness calculation.

Table 3. Summary of reported manufacturing costs in dollars of efficiency improvement options[7]

Efficiency Improvement Option	**India**		**US**		Average($)
	[20]	[25]	[36]	[31]	
Improved AC Induction Motor	$1.09	$1.82			$1.5
BLDC Motor	$5.45	$10.91	$3.2-$22.5		$10.5
Efficient Blades	$1.09			$6.00	$3.5

Cost of Conserved Electricity

This section presents the CCE in India for motor and blade improvements described above, using the efficiency assumptions discussed earlier along with corresponding cost assumptions. Two kinds of CCEs are calculated as follows: the manufacturing cost of conserved electricity (CCE_m) which considers the incremental cost of the higher efficiency fan to the manufacturer and the cost to the consumer of conserved electricity (CCE_c) which considers the incremental cost of the higher efficiency model to the consumer. The former metric (CCE_m) is lower than the latter (CCE_c) as it does not include markups or taxes. Therefore, CCE_m can be used to measure the cost-effectiveness of a market transformation program, such as an upstream incentive program, while CCE_c can be used to measure the cost effectiveness of a standards program, or a downstream incentive program.

[7] In converting from a per-blade to a total incremental cost we assume the fan has 3 blades.

Table 4. Cost of conserved electricity for various efficiency improvement options in India[8]

Efficiency Improvement Option[9]	Average Power Savings (W)	% Reduction from baseline power	Average incremental manufacturing cost($)	CCE_m ($/kWh)	CCE_c ($/kWh)
Improved AC Induction Motor (A)	25	36%	$1.5	$0.003	$0.005
BLDC Motor (B)	35	50%	$10.5	$0.014	$0.027
Efficient Blades (C)	10	15%	$3.5	$0.015	$0.031
A+C	32	45%	$5.0	$0.007	$0.014
B+C	40	57%	$14.0	$0.016	$0.032

Assumptions: Lifetime=10 years; hours of use per day = 8.7; discount rate = 7.6%; multiplier for markup and taxes = 2.0

Shown above, improved AC induction motors are the most cost effective single option, followed by BLDC motors. We also note that our cost and efficiency assumptions (and resulting CCE estimates) regarding efficiency improvement using more efficient blades are *conservative* and may very well be lower than those shown. This can be attributed to using cost and efficiency estimates for more efficient blades with a traditional appearance as discussed earlier rather than the most efficient blades [31]. Also, data on blades indicated *divergent* estimates of the costs of manufacturing depending on design, material, manufacturing, and treatment/finishing processes, which varied due to aesthetic considerations. Given the globally traded nature, maturity, and high contribution of material costs to the total costs of the efficiency technologies considered, we argue that cost estimates based on the data in India and US are likely to be a reasonable approximation of the costs in other regions.

Energy Savings Potential

We used the Bottom-Up Energy Analysis System[10] (BUENAS) to estimate the potential global energy and CO_2 emission savings from accelerated implementation of the engineering developments for ceiling fans described earlier. A detailed description of the methodology is available in [11] and [38]. This version of BUENAS covers thirteen major economies, representing 80% of the world's total energy consumption. Our objective is to provide an approximate estimate for the potential savings from accelerated adoption of efficient fans. Precise estimates of the saving potential in each of the economies covered will require significant further work in order to provide a more robust empirical basis for the assumptions used. Note that we have more robust data on India, China, and the US compared to other countries and hence the estimates of saving potential for these countries are likely to be more accurate than for the others.

Data and Methodology

BUENAS is an end-use energy forecasting model designed to provide a detailed assessment of the potential for energy savings and GHG emissions reductions from energy-efficiency standards and labeling programs worldwide (see [38] for a detailed description of the model). The model is "bottom-up" in that it calculates energy demand based on input data for individual appliance products. BUENAS is composed of three modules. The first calculates the number of appliances per household (diffusion) in a country at a given point in time, primarily based on an empirical relationship observed between appliance ownership and macroeconomic household variables such as household income. The second module

[8] We have assumed a 100% markup in estimating costs to the consumer in line with [25]. Lifetime and hours of use assumptions are in line with [37].

[9] Efficiency improvement options from single components (A, B, C) are presented first followed by efficiency improvement options from combining two options (A+C and B+C). The options are subsequently ordered by increasing cost of conserved energy. Also option C, efficient blades can be used with both BLDC and AC motors. While BLDC motors and AC motors are widely available, efficient blades may be proprietary designs, and also carry associated aesthetic tradeoffs.

[10] http://www.superefficient.org/en/Products/BUENAS.aspx

estimates energy consumption and efficiency improvements at the appliance level. The third module is a stock turnover module that calculates the sales of appliances every year based on retirement of old units and increased penetration of appliances in households. This module combines the sales in every year with unit energy consumption (UEC) to estimate the total stock energy consumption. The difference in stock energy consumption between a Business As Usual (BAU) and an efficiency case equals the savings. Energy savings are then converted into CO_2 equivalent emission mitigation according to the power generation mix from each country.

Results

This section presents the BUENAS results in terms of stock energy consumption and global potential energy savings. BUENAS also provides CO_2 emission mitigation potential calculated using country-specific carbon factors [11].

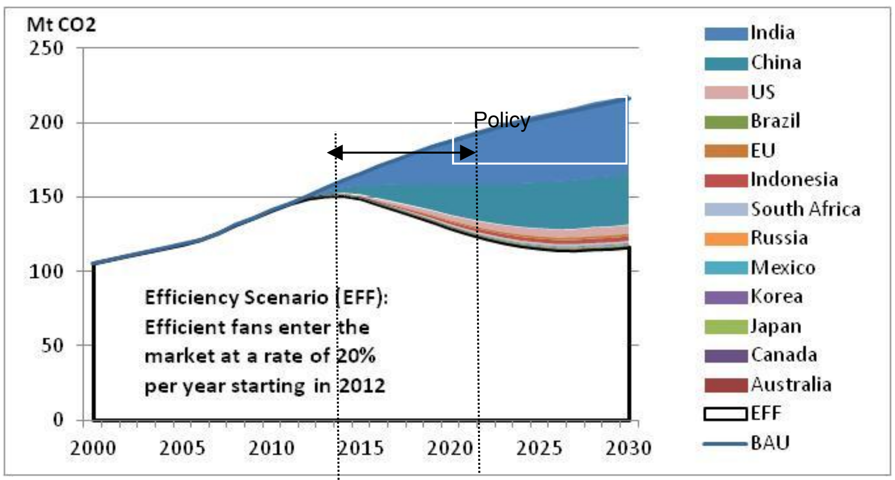

Figure 3. Potential CO_2 emissions reductions resulting from introduction of efficient fans, 2000-2030

Efficiency Scenario

In the efficiency scenario, efficient fans with BLDC motors gradually enter the market, gaining 20% of market share starting in 2012. The market reaches saturation in 2017 when 100% of fans sold are assumed to be efficient. The unit energy consumption (UEC) for efficient fans is assumed to be constant throughout the forecast period. We evaluate energy savings potentials in 2016, 2020, and 2030. Table 5 shows the results of the energy savings potential analysis, and Figure 3 shows the corresponding CO_2 emission results. India represents almost half of the potential electricity savings and CO_2 emission mitigation potential in the economies covered in this analysis.

Table 5. Annual and cumulative energy savings forecasts

Realizing Cost-Effective Efficiency Improvements: Lessons for Market Transformation Programs

As discussed earlier in this report, there are several cost-effective options for improvement of ceiling-fan efficiency that would reduce fan energy consumption by more than 50%. Although highly efficient fans that incorporate most of the efficiency improvement options discussed in this paper are commercially available in certain countries (e.g., the U.S.), they constitute a very small percentage of sales. In some countries (e.g., India), fans with BLDC motors and efficient blades are not currently commercially available. Several barriers, including high purchase price and lack of information (e.g., lack of labels that recognize highly efficient performance), have been identified that contribute to the limited adoption of highly efficient fans [4]. In this section we discuss some broad insights for energy efficiency market transformation programs based on the earlier discussion.

General Insights

Some of the insights that can be drawn from the preceding discussion apply across various types of market transformation programs and policies. We discuss some such general insights with respect to key fan characteristics such as fan size and speed, and with respect to blade design.

It is important for market transformation programs to classify fans by size and take into account the effect of fan speed on efficacy. First-and-foremost, size categories are important in market transformation programs to preclude the possibility that simply increasing blade length, without necessarily delivering better service, could circumvent a policy based merely on efficacy. For instance, although airflow increases with larger blades the amount of cooling felt by the user may not. This is because the service delivered to the final user (in this case, cooling) depends not on the total volume of air moved, but also on the velocity of the air[11]. If market transformation policies classify fans by size, fan manufacturers will not be able to simply install longer blades to improve efficacy nominally without competing with other manufacturers in a separate size category or improving the service delivered to the final user. Second, operating speed is also an important criterion in designing market transformation programs because efficacy varies inversely with increasing fan speed [39]. This effect can be addressed either by using standard speed or minimum airflow in the test procedure for the program, such as in India's standard and labeling programs, or by changing the efficacy requirement at various speeds, such as in the ENERGY

[11]The coefficient of convective heat transfer off the human body depends on the velocity of the air [75].

STAR program. It should be noted that the testing burden would be lower in the first case, with a tradeoff on the accuracy of the test procedure at various speeds.

The literature discussed earlier indicates that there is remarkable potential for energy-efficiency improvements from changes in fan blade design. We also find that blade design improvements have greater efficacy/power consumption savings impact at higher speeds. This implies that market transformation programs in economies with hotter climates and higher average airflows (e.g. India) will benefit proportionally more from blade design improvements than economies where average airflows tend to be lower. (e.g. the US). For example, the most efficient blade designs discussed in the literature will improve efficacy by 86% at lower speeds (airflows), versus 111% at higher speeds (airflows) compared with conventional blade designs [30].

Standards and Labeling Programs

Efficiency levels specified by standards and labeling programs are far below what can be achieved by implementing cost-effective energy-efficiency options in ceiling fans (see Figure 4). For example, as seen from data on the efficacy of fans meeting the US ENERGY STAR requirements, fans using BLDC motors and efficient blades are significantly more efficient (with efficacy as high as 15 $\frac{m^3}{min}/W$) compared to efficiency requirement for qualifying for ENERGY STAR (efficacy of 2.1-4.2 $\frac{m^3}{min}/W$). Furthermore, the Indian Bureau of Energy Efficiency (BEE) voluntary star rating program for fans only covered 2% of the Indian market and only 18% of fans (without a light kit) on the US ceiling fan market were compliant with ENERGY STAR, indicating significant room for efficiency improvement [25], [3].

The standards and labels levels for BEE's star rating program in India are presented in Figure 13. These efficacy levels are tested under different conditions (notably airflow requirements/speeds) than standards and labels in the US, Europe and China so they cannot be directly compared against each other without accounting for this.[12] However, the improvements in efficacy discussed in this report are applicable across the range of commonly encountered airflows. This means that these improvements will offer significant energy savings of a similar order of magnitude regardless of airflow or test procedure alignment. For comparison, the US ENERGY STAR label has an efficacy requirement of 4.2 (m^3/min/W) at low speeds and 2.1 (m^3/min/W) at high speeds while the lowest standard for efficacy in China varies by fan size from 3.47 (m^3/min/W) for 1800 mm fans to 2.75 (m^3/min/W) for 900 mm fans [3], [5]. Figure 13 makes clear the significant potential for improvement in fan efficacy through increases in specified standards and labels.

The highest efficacy level recognized by labels in several countries is significantly lower than what can be achieved by adopting cost effective efficiency options. Hence current efficacy label levels need to be revised significantly to encourage deeper penetration of efficient ceiling fans at the top of the market with efficacies achievable using BLDC motors and efficient blades that are already on the market in the US, and that are cost-effective in other countries. The low penetration level of efficient ceiling fans in both India and the US seems to indicate the presence of barriers to efficiency other than information, such as first cost, that may not be able to be addressed within a standards and labeling framework.

[12] See [39] for a discussion of the effect of fan speed and motor speed on efficacy. Increasing airflow from 5000 CFM (the US high speed) to 7415 CFM (i.e.210 m^3/min, the minimum airflow for star rated fans in India), i.e. A 48% increase will yield a decrease in efficacy of at most 35%.

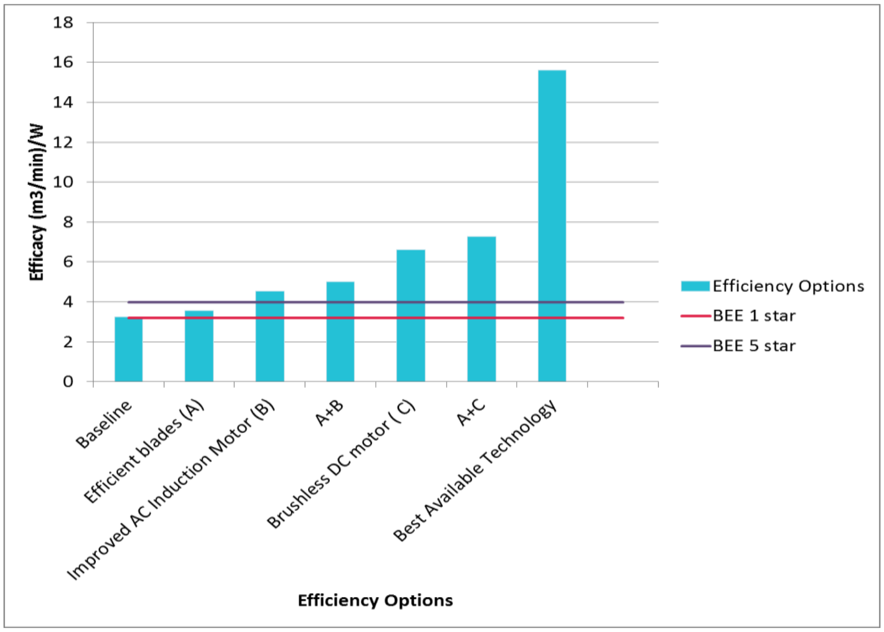

Figure 4. BEE (India) star labels compared to estimates of potential ceiling fan efficacy[13]

Incentive Programs

Incentive programs for efficient fans could accelerate the penetration of superefficient fans for the following reasons. First, adoption of cost-effective efficient appliances is often hindered by high first cost, e.g. as discussed in [6]. In emerging economies, consumers are highly sensitive to high first costs [4]. Second, due to the importance of aesthetics discussed earlier, it is not practical or desirable to mandate efficiency improvement from blade design through MEPS. However, the full existing potential from more efficient blades, as well as from BLDC motors, could be exploited through incentive programs for superefficient fans. Such programs could cost effectively target efficacies of up to 15 $\frac{m^3}{min}/W$, as discussed earlier. There are several examples of financial incentive programs that lower the first cost of cost-effective energy efficient appliances and equipment to accelerate their adoption. However, despite the large saving potential, financial incentive programs to promote the adoption of highly efficient fans are not common.

Conclusions

This paper presents an analysis of the potential for improvement of ceiling fan components to reduce global energy consumption and GHG emissions. Improved blade design and AC induction motor materials, and the increased use of BLDC motors, are identified as cost effective options to improve the efficiency of ceiling fans. Adaptation of these technologies could provide ceiling fan power consumption savings of more than 50%. Out of the several types of policies typically used to accelerate adoption of efficient products (e.g., awards, incentives, and standards and labeling programs), standards and labeling programs are most commonly used to accelerate the market penetration of efficient fans.

Efficacy levels are tested under different conditions (notably airflow requirements/speeds) in various countries so they cannot be directly compared against each other without accounting for this fact. Nevertheless, the improvements in efficacy discussed in this report are applicable across the range of commonly encountered airflows. Meaning these improvements will offer significant energy savings of a similar order of magnitude regardless of airflow or test procedure alignment.

[13] Note: The baseline efficacy value is based on the average values reported as 'National Player's Models' presented in (Garg & Jose 2009). Incremental improvements correspond to those presented earlier. The efficacy level of the best available fan corresponds to the fan with the highest efficacy in Figure 8.

The highest efficacy level required by standards and labeling programs in several countries is significantly lower than what can be achieved by adopting the cost effective efficiency improvement options discussed here. Hence current efficacy label levels need to be revised significantly to encourage deeper penetration of efficient ceiling fans at the top of the market.

The low penetration level of efficient ceiling fans in both India and the US, even with labeling programs in place,[14] seem to indicate the presence of barriers. These barriers to efficiency, in addition to information, such as first cost, may not be able to be addressed fully within a standards and labeling framework, particularly in emerging economies with price sensitive consumers. However, despite the large saving potential, financial incentive programs that promote the adoption of highly efficient fans by removing the first cost barrier are not common.

One notable example under development is the Super-Efficient Equipment Program (SEEP) in India where financial incentives will be provided to fan manufacturers to produce and sell highly efficient fans; fans that consume less than half of the energy consumed by fans typically sold on the Indian market [4]. Even if the entire incremental cost of the highly efficient fans is covered by the financial incentives, the cost of the conserved electricity for efficiency improvements over 50% is just 0.7 rupees per kWh (US$0.014/kWh) which is about one sixth of the cost of supplying electricity in India [6]. SEEP or a similar upstream incentive program for ceiling fans would be cost-effective even assuming higher costs and lower hours of use as discussed earlier. Therefore there remains significant scope for improved policy design and implementation for aggressive and cost effective ceiling fan efficiency improvements.

Abstract

The main objective of this initiative – co-funded by the EU programme Intelligent Energy Europe Programme of the European Union and conducted by a consortium of 12 partners – is to support consumers in their purchase decisions by providing up-to-date information about the most energy efficient products on the market.

The way consumers access information has changed rapidly in recent years; this, in turn, has significantly influenced the purchase decision-making process. Information published online makes it possible and easy for consumers to directly search and compare products; superseding traditional in-store sales advice to some extent.

This initiative reacts to mainstream trends for smartphone use as well as for adoption social media like Facebook or Twitter and provides the roll out of an “Efficiency adviser” smartphone app (available from late autumn 2013). The guidance app will be easy to use and accessed through mobile devices as smartphones and tablets for product identification and in-store advice, covering the most relevant consumer decision-making criteria, namely: cost, product quality and energy efficiency. Smartphone optimized consumer web portals will be used to raise awareness of the benefits of energy efficient and sustainable products and social media channels will encourage users to share the information with friends and family.

This project will specifically target the online ‘early adopters’ and ‘early majority’ (also called internet natives) but will also serve the more than 70% of European households that are connected to the Internet aiming at energy aware purchase decisions and effective change of user behaviour regarding every day energy use.

Starting point

Household electricity consumption

The electrical energy consumption in the domestic sector in EU countries has risen significantly for more than two decades (e.g. in Austria increase by 30 % within 1990 and 2006, since then almost stagnating [1], for EU 27 the overall situation is quite similar with an increase by 35 % within 1990 and 2006 and a reduction by 1.5% onwards from 2006 to 2011 [2]). First of all raised saturation levels for appliances in households as well as demographic trends were effective as main influencing factors for the growth in consumption. An enormous energy efficiency increase plays a crucial role in many scenarios in the context of energy politics to exploit all potentials for energy savings and to maintain a significant reduction of electricity consumption in the household sector.

Spontaneous purchase decisions and lack of sufficient guidance in shops

In the vast majority of purchase decisions, "energy efficiency" is not usually a key deciding factor. Purchase decisions are sometimes made spontaneously (this applies especially for cases where a certain – individually different – price limit is not exceeded).[3], [4]

Only a very limited share of people are willing to or capable of investing a significant time for gathering information and comparison of different products prior to the purchase decision. More likely people will search for the cheapest price of a certain product, possibly preselected in a more or less arbitrary manner. A decent share of consumers only relies on advertisement information and marketing oriented messages beside the price tag to select appliances.

Advice in shop is a crucial element in guiding consumers, but unfortunately quite too often sales personnel is not sufficiently trained or willing to explain the benefits of higher efficient (and sometimes more expensive) products. As a consequence the situation where thorough guidance of customers in shops takes place is definitely not common, as this service most likely, but still limited will be offered in specialist shops. The benefits of more efficient products in terms of lower running costs and possibly higher product quality will be overlooked or underestimated. As a consequence customers would purchase appliances with rather poor efficiency even if they were willing to choose high efficient products.

Major retail chains in the sector "electric and electronic products" are apparently understaffed; hence customers have to rely on information printed on product packages or on labels only. The situation in terms of appropriate customer information is even worse in the case of mixed food/non-food markets selling appliances as part of their assortments.

Especially young customers expect to find information concerning product purchase online or even by mobile access to the Internet. Classic means of information, like printed articles, flyers, etc. are getting less relevant. This obvious trend is actually hitting the overall mainstream thus forcing market players to establish and promote appropriate information services online.

The long tail of disadvantageous (purchase) decisions

Appliances partly have long product lives – up to and beyond 10 years, depending on the product category. Inefficient products will cause high accumulated running costs.

The revised EU efficiency label improves the market transparency in terms of energy efficiency again; but will challenge the consumers' understanding of labelling classes and their interpretation regarding the product's life cycle costs.

Consumers' perceptions of labels and efficiency classes

Learning from previous experience gained from the Eurotopten-Network, people will need some time to actually learn how to consider the information displayed on the label. As classes of the European Energy efficiency label have not been readjusted, thus new products will likely populate classes from A upwards, many consumer will expect no real improvement by choosing classes beyond A (being for very long time the best class available)[5]. For example only a very few consumers will expect a 40 % energy saving, choosing an A+++ fridge instead of an A+ (actually now representing the minimum efficiency standard stipulated by Regulation 643/2009). The revised labelling scheme for directional and non-directional lamps valid by September 2013 will again challenge customers to really understand differences in running costs and efficiency. The relatively newly introduced label for TVs covers an important section in consumer electronics segment, but will have to be moved to the customers' focus.

Green commercial messages vs. factual label data

In the light of this, there is significant need for complementary measures targeting the choice. Considering the huge diversity of (non standardized) product declarations and labels introduced by manufacturers on the market, uncertainty on different levels will challenge consumers making an informed decision.

It is very obvious that consumers risk confusion between official labelling schemes and multiple green commercial messages. Quite understandably consumers do not want to focus on efficiency only but would consider quality related aspects as well. Merging the levels quality, efficiency and price in an easy accessible service, especially on the point of sale, even independent from sales personnel, will be seen as significant advantage and added value from the customers' view. Concluding from the aspects mentioned above developing and disseminating an easily accessible information service on EU level - meeting crucial requirements as high quality, neutrality, timeliness, will be obligatory to significantly increase the share of sustainable and energy efficient products.

Purchase of efficient products AND efficient use – need for day to day behaviour change

Aiming at effective energy savings, the purchase of efficient products is an important precondition. However the efficient use of appliances in day to day life is important either. People e.g. need to understand how to enable power management features, to be aware that eco programmes will take more time and thus save energy according to Sinner's circle (as a composition of the factors temperature, chemistry, time, mechanics) opposite to express programs, most likely consuming more energy but finishing sooner, and so on. To exploit the full potential of energy savings efforts have to be made to effectively change energy use behaviour as well. This support of course has to be helpful, relevant, low-threshold and easy to use, to be appreciated and accepted by consumers. Thus ideally guidance regarding selecting efficient products will be accompanied by specific advice for energy- and cost efficient routine use.

Social media and the role of smartphone use

Internet User in Europe

Access to Internet media is a standard for most of European households, actually independent from social stratum, purchase power and age. For the region directly covered by the partners in the consortium almost 175 Million adults (older than 14 years) are using the Internet, these are already two thirds in average of the overall population.

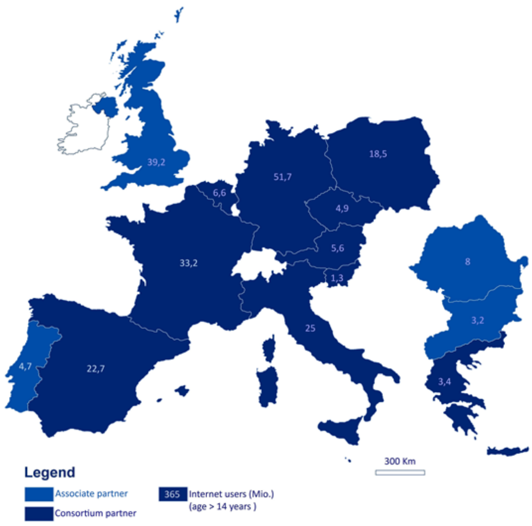

Figure 1: Coverage of "Efficiency 2.1" (Source: Austrian Energy Agency, 2013)

Table: Internet Use in Europe 2011 / Markets directly covered by initiative "Efficiency 2.1": (Source: GfK Online Monitor, GfK Austria, January 2012)

	Internet users (age > 14 years) [Mio]	Internet users (age > 14 years) [%]
Austria	5,6	79
Germany	51,7	73
Czech Republic	4,9	57
Italy	25,0	50
Spain	22,7	57
Poland	18,5	61
Slovenia	1,3	79
Greece	3,4	49
Belgium	6,6	78
France	33,2	60
Total	**172,9**	**Avg. 64,3**

Social media reach

Amongst many social media, Facebook is the most widely used one. The EU average monthly penetration of the Internet user population amounts to 63.6 % (data for 2011). Despite the fact that Facebook has been available for years, trends still indicate increases in use, for example, in Germany Facebook accounts grew by 43 % from March 2011 to March 2012. [6]

Smartphone penetration in target region and trend

Smart phones are already widely used in Europe. Within one year the share of smartphones compared to total mobile phone users grew from 31 % to 44 % (Dec. 2010 – Dec 2011). In December 2012 all European countries crossed the 50% mark for smartphone penetration. The highest adoption of smartphones is documented for Spain with 66%, followed by UK with 64 %, while the EU average lies at a level of 57%. Even 75 % of phones were smartphones acquired in December 2012. [7]

Quite interesting and being an important factor for success regarding the "Efficiency 2.1" strategy the smartphone use is not limited to a certain age range. However the age segment "25 – 34 years" is insignificantly dominating (averages for Germany, Italy, France, Spain and UK).

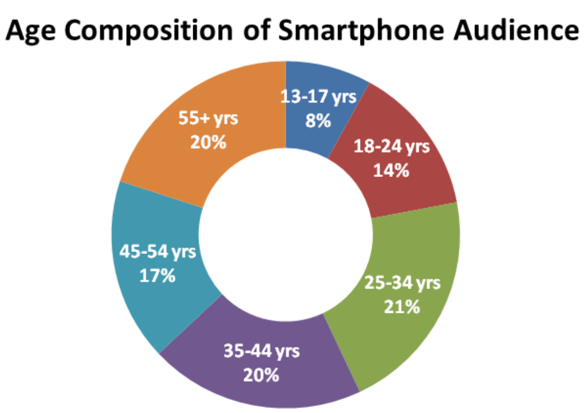

Figure 2: Age Composition of Smartphone Audience

(Source: Comscore, Europe Digital Future in Focus 2013, March 2013)

Smart phone use related to purchasing products

Until now there is limited evidence-based data on the interaction of smartphone usage/penetration and mobile consumer behaviour. But in "Our Mobile Planet: Austria, Understanding the Mobile Consumer" (May 2012) Google points out, that 67% of smartphone users do not leave home without their device, 98% use smartphones at home and 71% while being in a store.

The same study (which is also available for US, Denmark and Ireland with more or less similar results) highlights that smartphone users seek information concerning daily life on a regular basis: 58% of smartphone users search for product info, followed by items "Restaurants, Pubs" and "Travel".

Again the outcomes of this user survey prove that smartphones are primary shopping companions for a significant share of users: 20 % agree to the statement "I intentionally have my smart phone with me to compare prices and inform myself about products. Even 16 % commit to the statement "I have changed my mind about purchasing a product or service in store as a result of information I gathered using my smartphone."

The Initiative "Efficiency_2.1"

In designing the initiative "Efficiency 2.1" (funded by the Programme Intelligent Energy Europe) the following important aspects have been kept in mind, summing up framework conditions discussed above:

- The share of adults who are using the internet is considerably high: in average two thirds, in some EU countries almost 80 %.
- Social media (Facebook, Twitter, etc.) have been attractive for a huge share of internet users; the number of accounts is still increasing.
- Smartphone penetration is growing rapidly, showing an increase of 40% within one year. Especially the age segment 25 – 34 years represents the biggest share. Smartphone apps and their regular use represent the day to day standard.
- Online information sources linked to product data and sources of supply like price comparison portals are extremely popular. Moreover, smart phone apps being designed for accessing detailed product data are in demand. This e.g. is proven by the download statistics for the comprehensive shopping app Barcoo, which has been installed more than 2.5 million times in Germany.
- Nevertheless the above mentioned online channels and services are seldom linked to energy efficiency or aspects of consumer behaviour change.

Assuming that the daily time for using communication and information media (for private purpose) is limited to some extent, it seems to be obligatory to focus information and promotion regarding purchase and use of sustainable and efficient products to the channels with priority right from now. Otherwise, there is a risk that awareness and information regarding efficiency could lose ground again.

Thus the main objective of this project is to support consumers in their purchase decisions by providing up-to-date information about the most energy efficient products on the market by using this new means of information. This will be done through the development of an "Efficiency Adviser" smartphone app that is easy to use and access through mobile devices as smartphones and tablets. Smartphone optimized consumer web portals (including Euro-topten sites) will be used to raise awareness of the benefits of energy efficient and sustainable products and social media channels (e.g. Twitter and Facebook) will encourage users to share the information with friends and family.

Consequently the main project objectives of “Efficiency 2.1” are

- Drive demand for higher efficient and sustainable products and solutions, by providing user-friendly mobile accessible information that will help and encourage consumers to choose these products.
- Fill the current gap in the retail sector by providing up-to-date advice about energy efficient and sustainable purchase and use of products directly at the point of sale.
- Support awareness of especially younger consumers for energy efficient purchase and use of products and enhancing energy aware and ecological sound behaviour in everyday life.
- Support the effective implementation of labelling regulations for white goods, (replacing the existing well-known efficiency label), TV sets and domestic lighting as well as established product declaration schemes for office equipment by implementing information measures, which help over viewing the overwhelming number of multiple green commercial messages.

The following major outputs lay the basis for striving the goals described above

- An “Efficiency adviser” smartphone app will be rolled out for product identification and in-store advice, covering the most relevant consumer decision-making criteria, namely: cost, product quality (if data from third party sources are available) and energy efficiency.
- web portals and social media channels (Twitter, Facebook) will be established dedicated to sustainable and energy efficient products and their energy- and eco-conscious use, benefitting from synergies with existing initiatives and programmes (e.g. top lists, independent product testing sites, labelling programmes, etc.).
- A broad involvement of stakeholders and experts is maintained, keeping experts informed through an news feed (Twitter) fed into an EU-level platform, serving as hub for all activities at a national level.

Consequently, it seems quite clear that the initiative “Efficiency 2.1” can effectively support closing the common gap in very popular online information sources regarding easy to use guidance for efficient purchase and use by establishing a high quality, neutral, up to date and EU wide aligned information service. Concluding from the observation mentioned above the EU initiative “Efficiency_2.1” preliminary insights the app “Efficiency Advisor” can effectively impact the day to day live user behavior of the addressed target group concerning consumption and energy usage on two levels – as source of inspiration and incentive in the “day to day” mode as well as backing guidance in the selection and purchase of devices in shops.

Basic concept for EU-wide app “Efficiency Advisor”

Generally the smartphone app “Efficiency Adviser” will guide consumers on two different levels:

- Shopping mode: assisting the selection of energy efficient and sustainable products on the point of sale
- Day to day mode: supporting consumers in leading an energy efficient and eco conscious lifestyle aiming at a stimulation of behavioural changes.

In the following both service levels are briefly described. The actual implementation of the app, available in autumn 2013, will be based on design process, including thorough evaluation of user needs and expectation as well as usability testing.

Shopping mode:

- App offers support for selecting products in a certain product category, based on user input (relevant product category plus size of household for cold appliances, view distance for TV) including relevant information regarding features (interfaces, protocols, low power modes)

- Show data for best performing products in given category (TV 42/48 Inch screen size, On mode XX / YY Watt) providing an added value for comparison of different products
- Provide a list of up to date actual available best performing products (topten product lists)
- Based on the database entry the app delivers an info regarding product test from independent testing institutes showing test result and providing link to test report (with costs if applicable)
- The app offers a simple cost calculator for comparing different products (two TVs, A resp. B class) evaluating total costs (purchase price and running costs for project lifetime) to assist eco-conscious purchase decisions (based on default settings).
- Show user generated content to related product features, (only if defined quality criteria are met)

Day to day mode:

- App presents key word filtered (filter on hashtags, e.g. "#LED") content from social media channels provided by partner portals.
- The App offers a direct communication channel to social media sites as well. The User is able to post messages to Facebook, Google+ and Twitter and is able to upload pictures to the social media sites.
- App shows energy advise at least once per week ("tip of the day", "did you know?")
- In the case of co-branded version: App delivers appropriate topic oriented content from cooperating key market actor

Especially implementing the feature "Continuous news feed / social media link" will be essential as it makes sure that smartphone users are encouraged to actually download and use this app as it has the capability of delivering a daily basis service and helps keeping in mind, that the app is installed once a product will be purchased. Consequently this specific feature has to be highlighted in promotional tasks. Thinking of a smartphone app without this feature customers could be reluctant regarding the installation as then they expect a rather seldom everyday use.

Figure 3: dummy front end of smartphone application "Efficiency Adviser"

Relation to Euro-topten-Network and other related initiatives

It's worthwhile to emphasize that the initiative "Efficiency 2.1" considers two crucial aspects concerning scope and objective:

First it's not intended establishing a new brand, which would have to be communicated to consumers. However the project will focus on coupling and connecting to existing successful and already known initiatives at the national level, hence enhancing the service for consumers.

Second "Efficiency 2.1" will complement existing activities and avoiding duplication: The logic of this activity is consciously designed to preclude any duplication with existing activities. Instead, it will appear joined up from the consumers' perspective by transferring relevant information to attractive, up-to-date channels (via social media and accessible at the point of sale.) The project will make use of, and further promote, the outputs and synergies provided by the Euro-Topten-Max and other relevant IEE projects.

Especially this initiative is implemented as a complementary service to the Eurotopten-Network. Euro-topten is a consumer-oriented online search tool, which presents the best appliances in various categories of products. The key criteria are energy efficiency, impact on the environment, health and quality. Topten was launched in 2000 in Switzerland. Since then, sixteen other national Topten sites have been established, thanks to the European IEE-projects Euro-Topten, Euro-Topten Plus and today Euro-Topten Max (Intelligent Energy Europe). Each Topten website provides a selection of best appliances from the energy point of view. Topten information targets consumers (pictures, functions, price, no complex calculation, for products available locally in their country) and large buyers. Topten is rigorous and transparent, independent from producers and commercial distributors. Topten relies on neutral tests and analysis of independent institutions, labels and on standardized declarations of manufacturers (e.g. EU-directives for household appliances). www.topten.eu serves as a portal to reach all sites of participating countries. Beyond that "Efficiency 2.1" will collaborate with other EU projects and initiatives like Coolproducts, PremiumLight, Marketwatch, etc.

Role of key actors and co-operation partners

An intense cooperation with key actors is indeed a core activity within this initiative aiming at significant increase in promotion coverage and lay the groundwork for a permanent maintenance of the provided services – various smart phone app versions and social media channels – even beyond the project lifetime.

Beyond the roll out of an independent smartphone app "Energy Adviser" the consortium further aims at implementing co-branded apps jointly with key market actors as well as incorporating core functionalities in already well-established apps. This activity will ensure gaining the widest possible outreach of this point-of-sale (POS) customer service. Several stakeholders have already expressed their interest for cooperation (energy utilities, price comparison platform, online advertisement portal, app provider, etc.)

For many market players (e.g. energy utilities, NGOs, etc.) it potentially will be a very appealing situation to use a semi-final smartphone app (white label version) and promote this service as their own product (ensuring that the IEE funding background will remain visible for users). Beyond the approach to establish and disseminate a pure IEE branded app the partners will aim at involving key players committing to use and widely promote this app in their branded version too. This will also lay the essential groundwork for the service provided beyond the project's time horizon.

Outlook

After the project start in April 2013 the preparation and design process as well the implementation of all social media channels will be finalized by summer. The smart phone app "Efficiency Advisor" as jointly developed service will be available by autumn. In September all results from the evaluation of user needs and experience gained from European wide usability testing will be presented to professional audience.

Co-funded by the Intelligent Energy Europe
Programme of the European Union

What is the price of energy efficiency or which appliance efficiency class is the most suitable?

Miha Tomšič MSc, Anja Glušič

Building and Civil Engineering Institute ZRMK, Ljubljana, Slovenia

Abstract

Electricity used for household appliances can represent an important part of the overall building energy balance and operational costs. Increasing electricity prices force our purchasing decisions to be more elaborated, and energy efficiency is their vital element. An important question is: can an average consumer get a comprehensive impression about long-term effects of the purchase based on data currently available at the point of sale?

An indicator showing average annual operational costs for a particular appliance can be a helpful tool, helping consumers to make reasonable decisions for the long-term framework. This type of information also fosters transition in consumer behaviour from the lowest cost orientation to economically most viable option, thus providing firm reasoning for green decisions in private and public procurement. It can also help in transforming the market towards a consumer-friendlier one. In this context Slovenia is taking part in two Intelligent Energy Europe projects entitled Yearly Appliance Energy Cost Indication (YAECI), and (green procurement-oriented) BuySmart+.

The relevance of elaborating energy cost indicators for the Slovenian appliances' market is underlined in the paper, the market itself is analysed and typical energy use data are presented. Aspects of energy cost indication are shown, among other the retailer point of view and reasons for cooperation (e.g. upgraded service for customers, market competition, improved company profile), and the consumer point of view received as feedback to two polls conducted by ZRMK (e.g. energy costs indication at point of sale, eventual influence upon change in purchasing practice and decisions).

1. Slovenian market of household appliances – past and current situation

Slovenian market of household appliances is well developed with regard to both variety of brands and models available as well as their technical and environmental quality. Also, as all the major international manufacturers are present in Slovenian shops it can be said that during the last two decades the situation has evolved to a level quite similar to other EU countries.

Households are a significant consumer of electricity, where the appliances play a very important role. Official statistical data for Slovenia [1] show that until the year 2007 electricity consumption was increasing fast. The global crisis hitting also many segments of Slovenian economy discontinued this trend. However, the household sector has some particular characteristics. In 2010 the share of electricity consumed in the household sector was 27%, nominally being the largest since 1991 and exceeding the figures from 2000 by almost one quarter.

This situation can be viewed at from different angles. On one hand it is related to the rising number of apartments, which brings along a higher number of household appliances. For example, comparison of inventories from 1991 and 2002 shows an increase in the number of apartments by almost 95000. The national statistics quotes that around 92% of residential buildings or apartments are owned privately. On the other hand, the number of building permits issued has been decreasing since 2007; in 2010 14.6% less permits than in 2009 were issued, and in 2011 6.8% less than in 2010. This means fewer purchased appliances for new apartments, with the sales reflecting a shift towards a larger share of appliances bought to replace old ones.

It can be reasoned that not only a higher number of appliances, but also their more frequent and intensified use related to changed living habits and patterns contribute to higher electricity consumption, although contemporary products have a significantly improved energy efficiency. According to estimations on an average around 1000 large household appliances are being sold annually in Slovenia [2], which has a population of slightly over 2 million.

The latest Energy Efficiency Status Report by JRC [3] states that final residential electricity consumption accounted for 29.71% of total final electricity consumption in the year 2010. Compared to this figure the final electricity consumption in the Slovenian residential sector is slightly below the EU-27 average.

It is interesting to observe the shares of some of the more significant appliances in the annual electricity consumption as included in the report. If we focus on the ones with a nearly 100% market saturation in Slovenia, namely refrigerators (usually as a refrigerator-freezer combination) and washing machines, we see that they fall into the "cold appliances" category with a 14,5% share, and "washing and drying" category with a 7,2% share on the EU-27 level, as illustrated in the figure below.

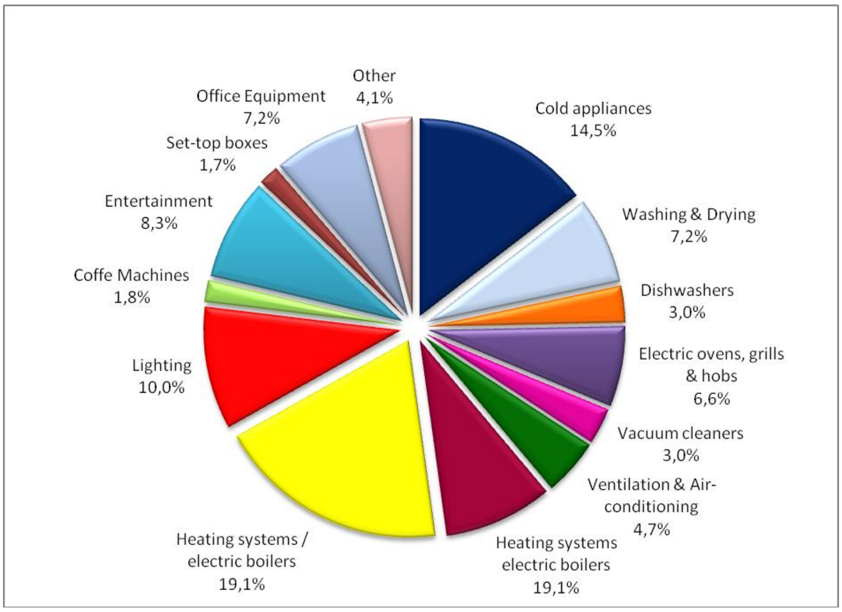

Figure 1: Residential electricity consumption breakdown in the EU-27; status 2009. (Source: [3])

The report brings an important conclusion, which confirms the above discussion about the situation in Slovenia; quote: "Residential electricity consumption is still rising. Although many appliances are becoming more efficient, the number of appliances is rising, appliances are used more often and for longer periods of time, and many appliances have more functions or special features that require more energy. The general trend in the residential sector is therefore an increase in electricity consumption."

In the Slovenian non-residential sector trends related to appliances are similar, although not that dynamic. Since 2012 the public sector has to comply with specific rules for green public procurement, which will be presented in more detail below.

The most recent (2013) Energy Efficiency Watch report for Slovenia [4] states that the policy package for appliances is to a large extent based on the implementation of the EU Directives on ecodesign and energy labelling. Currently there are no public subsidies available for purchase of energy efficient household appliances, but some commercial banks offer favourable loans with lower interest rate for such purpose.

2. Energy efficient appliances in the Slovenian strategic framework

National short- and mid-term energy and environmental strategies and goals in Slovenia are in line with the EU framework and related targets, for instance with the Directive on Energy Efficiency 2012/27/EU requesting purchase of products, services and buildings with high energy efficiency performance. For the appliances' sector labelling of products and gradual phasing out of inefficient models represent the starting point for improvements and progress. The public sector is supposed to play the leading role and represent a good example to the private one, based also on the requirements of the Decree on Green Public Procurement.

2.1 Decree on Green Public Procurement

Green (public) procurement has been identified as one of the crucial elements of national strategies oriented towards sustainable growth, low-carbon society and nearly zero energy buildings. Slovenian authorities have in the recent past taken more concrete steps for improvement of the usual procurement practice using solely the lowest price as a predominant selection criterion. In the year 2007 the lowest price as the only selection criterion was used in 79,81% of all procurement cases by value, and in 73,48% of all procurement cases by number. The national Action Plan on GPP 2009-2012, AP GPP [5], set targets in accordance with the EU ones, and it was followed by development of a specific decree bringing forward requirements and selection criteria for 11 product groups. The Decree on Green Public Procurement [6] prepared on the basis of AP GPP strategy has been in use since March 2012. It is a mandatory operational document and has the status of a regulation.

The decree sets basic (core) environmental requirements, which are the mandatory level, and additional environmental requirements in the primary sense of recommendations. Procurement bodies have of course a free choice of shaping further, more rigorous requirements. One of the product groups where consideration of these legal obligations is mandatory comprises refrigerators, freezers, combined refrigerators and freezers, washing machines, dishwashers, and air conditioners.

The technical specifications and selection criteria for the above mentioned appliance types all follow the same principle of using the energy label as the starting point. Technical specifications used as minimum requirements are: class A+ or higher for refrigerators, freezers, combined refrigerators and freezers, washing machines, and dishwashers, and class A or higher for air conditioners. Selection criteria are based on the bonus points principle, i.e. the offer is given additional points for A++ and A+ class (or higher) appliances, respectively. The procurer shall define the method for bonus calculation and the share of these criteria in the overall set. There are additional bonus points possibilities included in the decree regarding the selection criteria: class A or higher for the wringing cycle (washing machines), and class A or higher for the drying cycle (dishwashers).

The ZRMK institute representatives cooperated in the work of a special expert group appointed by the Government, with a task of preparing draft structure of the decree and its product appendices, and of defining the core and additional criteria and technical specifications. Here our experience from the Intelligent Energy Europe project Buy Smart+ (and its predecessors Buy Smart and GreenLabelsPurchase) proved to be very useful [7]. The project addresses both private companies and public authorities, and offers free consultation, guidelines and procurement tools, information about procurement directives and labels, good practice database and other materials of interest. The product groups considered are building components, green electricity, lighting, office equipment and vehicles, and also household appliances.

The decree will certainly go through changes and be upgraded in the future, especially concerning the product groups where technological development is fast or where the labelling scheme undergoes amendments. The national GPP legislation directly relates also to some other fields, one of the more important being EPBD-based regulation on energy efficiency of buildings. At first sight maybe not very obvious, but potentially important can be the range and type of input data for future building energy performance calculation method. Namely, a very important topic which all Member States need to deal with already at this moment is the national definition of a “nearly Zero Energy Building” (nZEB). To formulate the most appropriate nZEB criteria several questions need to be answered, one of them touching also the appliances’ sector: where will the system border be set and how detailed will the “energy” definition be, i.e. will the appliances be included in it. If yes, then the demand for most efficient products will grow faster, fostering also the development and manufacturing of new advanced products, and provision of additional information. Not only that, as the nZEB level will be mandatory for new public buildings already from 2018 on, the green public procurement criteria could need to be amended also considering this aspects. From this brief overview of a particular Slovenian regulatory segment it can be seen that many topics are interlinked and that in the future an instrument such as the YAECI indicator can play a noticeable direct or indirect role beyond the current one.

3. Energy efficiency versus investment and operational costs of appliances

Electricity used for various domestic appliances as reflected on monthly bills for operational costs can represent an important part of the overall building energy balance. The more efficient a building is the larger is the relative share of electricity consumption in the delivered energy score. It is somehow understandable that a highly energy efficient building is equipped with highly efficient products. But, as a consequence of increasing living costs related to electricity prices the purchasing decisions need to be more elaborated, and energy efficiency is becoming a logical yet sometimes not clear enough criterion. A very important question is: can an average consumer, be it private or public, get a comprehensive impression about long-term effects of the purchase based on data currently available at the point of sale?

For the appliances the same basic principle is to be followed as for the building energy efficiency itself. An analysis of long-term effects of individual choices and their impact on the overall performance is needed to gain the most profit out of the investment. At the same time another important fact has to be taken into account: electricity consumption and related operational costs depend also upon user behaviour, and patterns, frequency and duration of use.

It is fair to assume that data about average annual operational costs calculated according to a uniform method for a particular appliance can be one of the most helpful tools for the consumers, helping them to make reasonable decisions and bringing forward long-term advantages of buying a maybe somewhat more expensive yet much more efficient appliance in terms of energy use. This type of information also fosters transition in consumer behaviour from the lowest cost orientation to economically most viable option, and thus provides firm and clear reasoning for green procurement decision-making process in private as well in the public sector. Such an instrument can gradually bring further improvements and help in transforming the market towards a greener and consumer-friendlier one.

3.1 Indicator of operational costs as additional consumer information

Experienced partners from 11 European countries, including Slovenia with the ZRMK institute, have formed a consortium under coordination of the NL Agency and started developing a voluntary indicator as described above [8]. The project (Yearly Appliance Energy Costs Indication; YAECI) has been supported by the Intelligent Energy Europe programme. It is based on a successful Dutch practice EnergieWeter. The main objective of the project is to provide customers with information at the point of sale on the yearly energy cost of products with an energy label, in order to stimulate the uptake of affordable efficient products.

As discussed above, the EU energy label currently provides the consumer with information on the energy efficiency (energy class), energy consumption and several other energy-related aspects. However, it lacks the information about an aspect that many consumers find very important, i.e. the product´s (yearly) running costs. The calculation of costs follows a common method based on data from the energy label and average national electricity and water prices. For products with the old energy label the method has been modified to allow for comparison with the new labelling.

There are at least two major yet slightly different aspects of presenting these data at the point of sale (shop, catalogue, Internet). Firstly, consumers are able to better comprehend the difference between more and less efficient products when it is illustrated by lower operational costs for the first group. In this way the usually higher price of a more efficient product seizes to be perceived as a disadvantage frequently posing as an obstacle for a purchasing decision in favour of such items. Secondly, there may be cases when some product would for one reason or another be only seldom used, i.e. with much lower frequency than in a “standard” pattern of use. In such a situation the cost indicator would show that purchasing a more expensive and more energy efficient appliance would not bring long-term advantages as the operational costs’ savings would not cover the price difference. This can be done in a simple way by checking the ratio between price difference and annual energy costs difference.

An example: a customer compares a highly energy efficient but more expensive (price: 400 EUR) appliance with a less efficient but cheaper (price: 350 EUR) one. Let us say that with “average (standard, normal, ...) use” the energy costs are 30 EUR/a and 39 EUR/a, respectively. The price difference would be covered by a reduction of energy costs in ca. 5 years (50 EUR/9 EUR), so the purchase of a more efficient appliance seems completely rational and beneficial. However, in a case when the intended use is only occasional, for instance only one third of the “average” one, the energy costs would be only 10 EUR/a and 13 EUR/a, respectively. In this case the price difference would be covered by reduction of energy costs only in ca. 16 years (50 EUR/3 EUR), which may even be past the technical lifetime of a particular appliance.

Of course, points of sale will be equipped with simple but clear information for customers about the considered average use patterns of appliances fitted with indicators. These data and the calculation methodology behind the YAECI indicator are for each appliance type presented in detail in a report publicly available at the YAECI website (http://www.appliance-energy-costs.eu/eu/library/library).

It may be argued that the second case does not represent green purchasing decisions, but only if we look at the subject in a very narrow way, not taking into account the principle of searching for an economically most viable offer and the fact that lower usage rate also means lower electricity consumption and related lower negative environmental effects.

Although the visual appearance of the indicator has not been defined within the YAECI consortium to allow for customisation for different use options such as on a price tag, as an individual label and similar, in Slovenia the decision has been made to prepare a unified design. This initiative came in fact from the side of the largest retailers, pointing out that such an instrument needs own graphical identity so that the buyers will recognize it and accept it more quickly. Therefore the indicator carries the project logo and the text “Yearly energy costs” followed by the value expressed in EUR as illustrated in the figure below.

Figure 2: An example of the YAECI indicator for the Slovenian market. (Source: ZRMK)

4. Selected statistical data for Slovenia

The Statistical Office of the Republic of Slovenia provides access to statistical data from various sources and about various categories on its web portal [9], also about electricity consumption in households including information about electrical appliances and the shares of labelled ones. If we take a look at washing machines, refrigerators (also combined with freezers) and dishwashers we can see that in the year 2010 there were about two thirds of these appliances equipped with an energy label: washing machines, 65,3%; refrigerators (+freezers), 64,7%; dishwashers, 72,2%. Having in mind that in Slovenia energy labelling started in practice about a decade ago we can estimate that over two thirds of the mentioned appliances in use in Slovenian households are not older than ten years. The above mentioned statistical source offers further interesting data, some of which are presented in the figures below.

There are no official cumulative statistical data available which would allow for an estimation of the share of household appliances in the electricity consumption in the non-residential sector. This sector is very specific and the figures can vary significantly, for example between schools and hospitals on one side and office buildings on the other side. However, in relative terms the status can be estimated as being similar to the residential sector: continuous uptake of more efficient appliances both as first buy and as a replacement of old ones, increasing number of appliances or at least of some of the types due to technological upgrade, intensified and more frequent use.

Municipalities in Slovenia have an obligation to prepare local energy concepts (LEC), where the baseline conditions are established and various technically and economically feasible strategies for improvement of energy efficiency on the local level are defined. Current practice touches the share of electricity consumption as discussed in this paper only seldom, but with respect to the strategies for sustainable growth this aspect will probably have to find its place in the LECs as well.

A clear picture of electricity consumption range evolving from different sources can be established during energy audits, which are being carried out for example in Slovenian hospitals, schools and kindergartens as a precondition to apply for state funds for improvement of energy efficiency. Here again not only an estimation of improvements in technical terms is important, but also from the financial aspects. An indicator of operational costs for large appliances can offer valuable help as an input to mid- and long term financial flow projections and planning of necessary budget.

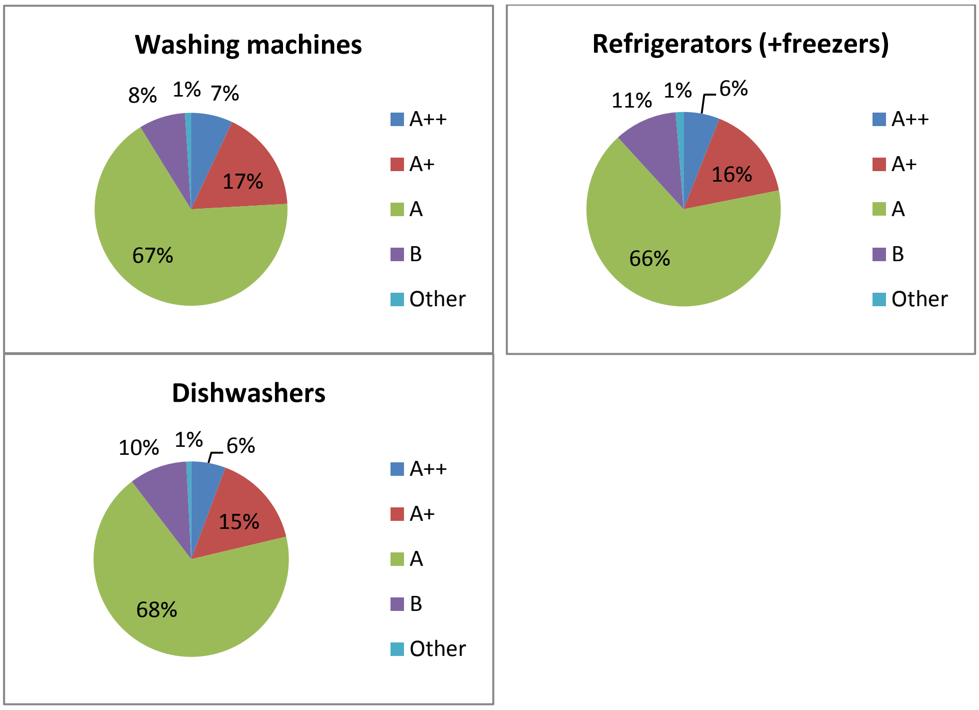

Figure 3: Energy label class shares, residential sector: washing machines, refrigerators (+freezers), dishwashers; status 2010. (Source: [9])

We can also observe (Fig. 4) that in the residential sector in the period between 2009 and 2011 the total electricity consumption for washing machines and refrigerators was slowly decreasing, which is probably due to uptake of more efficient products, not due to a reduced total number of these appliances. As opposed to this trend the consumption of dishwashers was slightly increasing, which can be related to a larger number of households, both old and new, equipped with this appliance.

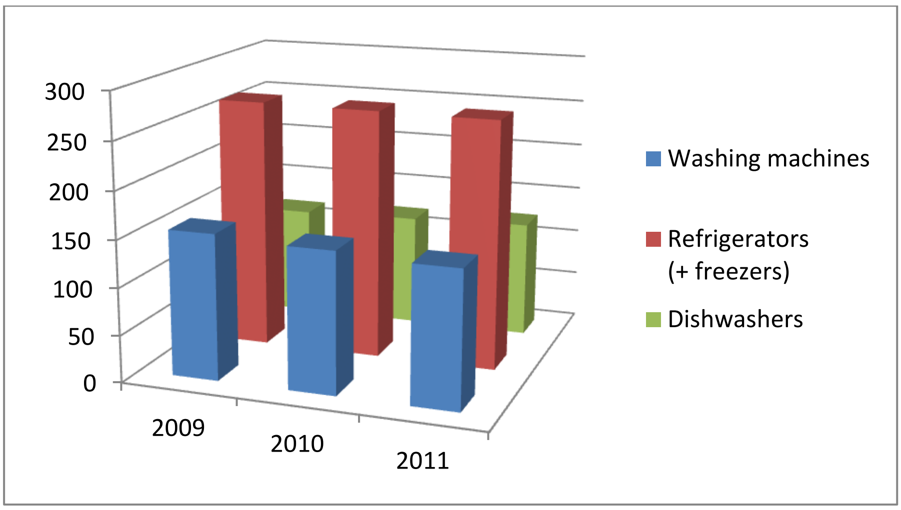

Figure 4: Annual electricity consumption for three selected products in GWh. (Source: [9])

5. Consumers’ and retailers’ point of view

Since the beginning of the IEE YAECI project in spring 2012 many promotional activities have been carried out in Slovenia by ZRMK, including presenting the indicator two times on the first programme of the national TV.

On the February 12, 2013 ZRMK presented YAECI project on the 1st programme of the Slovenian national TV in prime time just before the evening news. The additional information to consumers - appliances' operational costs was presented and explained at the interview. The second TV appearance was on March 5, 2013, when the Slovenian YAECI partner, ZRMK, went live into the national morning TV programme. The meaning and importance of energy labelling, and the idea of the yearly energy costs indicator for domestic appliances ware presented in the Merkur retailer trade centre in Ljubljana.

To obtain the consumers point of view about the energy labels, understanding of the appliances’ operational costs and about key aspects when purchasing a new appliance, two polls were conducted by ZRMK. The first one was distributed after the workshop about the energy efficiency of appliances at the DOM Fair, Ljubljana, from March 13 to 17, 2013. The second one was an electronic version sent randomly to different costumers who just recently made the purchase of an appliance or are planning to do so in the near future. Altogether 204 opinions were collected and are presented in the figures below.

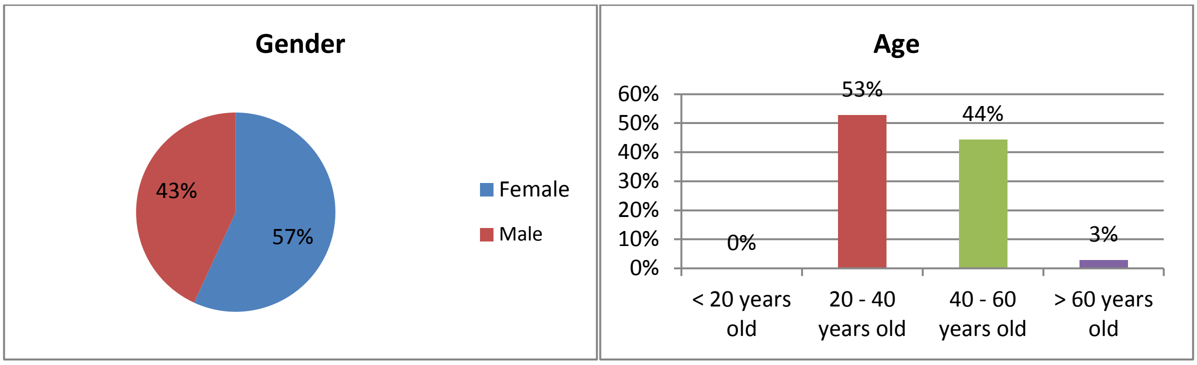

Figure 5: 114 female and 88 male persons mainly of the age from 20 to 60 years responded to the poll. (Source: ZRMK)

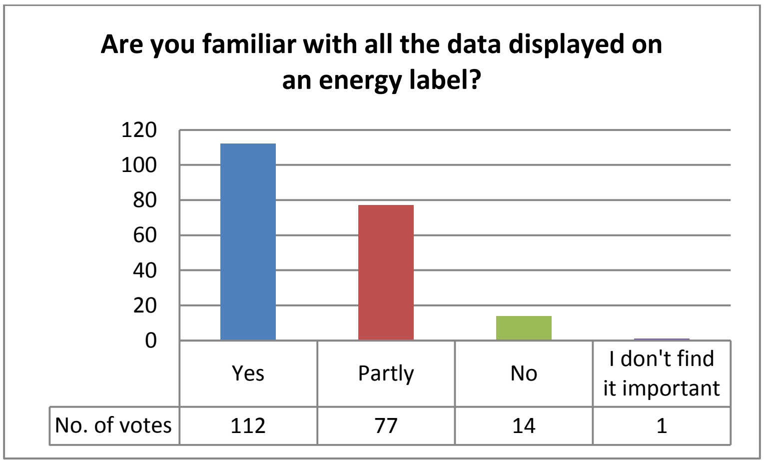

Figure 6: As seen from the chart the awareness about energy labels is quite high in Slovenia. (Source: ZRMK)

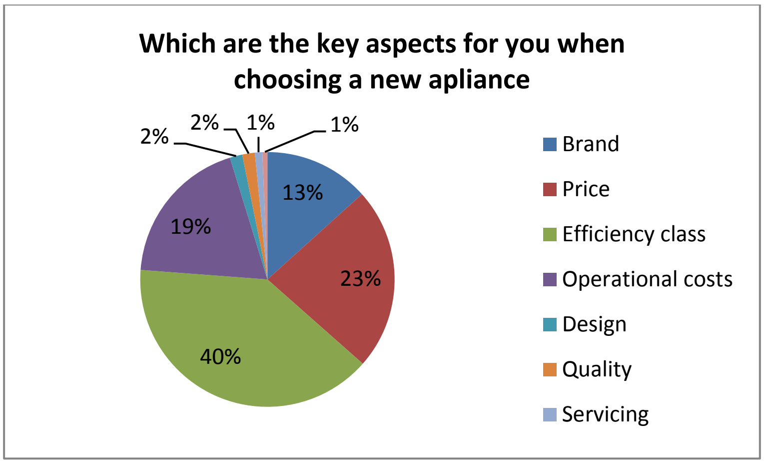

Figure 7: According to received answers the efficiency class followed by the price and operational costs are key elements when purchasing a new domestic appliance. (Source: ZRMK)

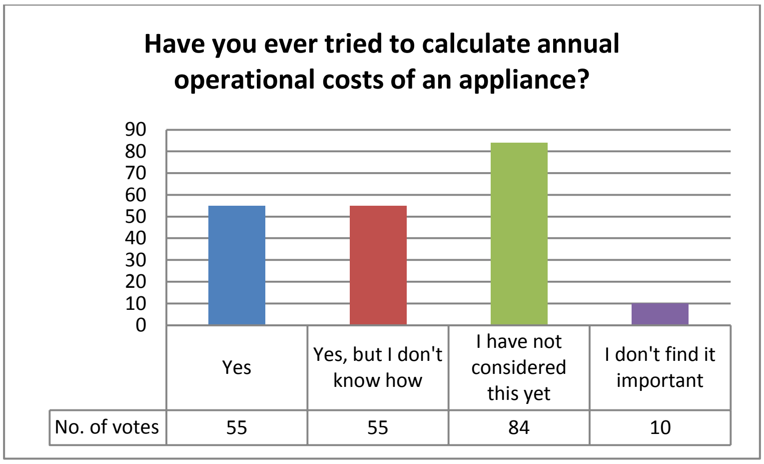

Figure 8: The calculation of annual operational cost of an appliance has proven to be a problem. The consumers are either not familiar with the calculation process or haven't considered it yet, basically for the reason of not knowing the methodology of calculation. (Source: ZRMK)

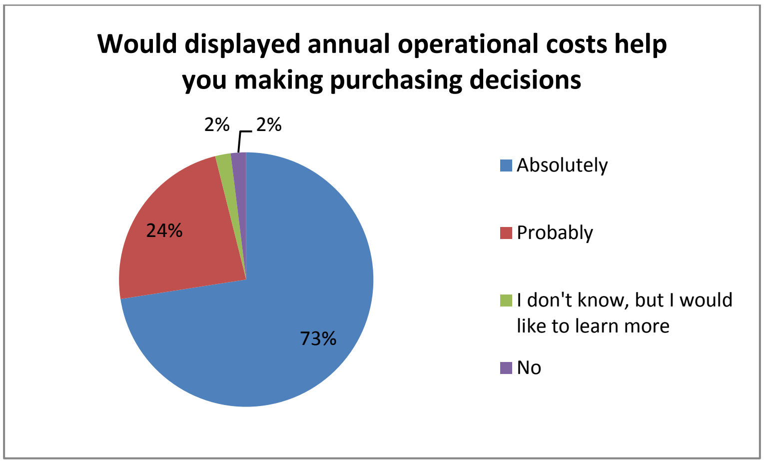

Figure 9: The final part of the poll shows that Slovenian consumers would highly appreciate additional information about the operational costs of an appliance. (Source: ZRMK)

The major Slovenian retailers contacted by ZRMK about YAECI so far underlined that one of the key elements of their approach to consumers is providing relevant and adequate information, be it in shops, catalogues or on their web pages. They confirmed great care of proper display of energy labels and showed interest in the cost indicator idea as an additional information for the buyers. The prevailing positive aspects seen from their side can be summarised as building up the company image of being environmentally aware and consumer friendly, keeping up with current EU and national standpoints, and using the indicator as a marketing tool to strengthen their position on the national market.

6. Conclusion

Electricity consumption and related costs used to be somehow in the shadow of consumption and costs for heating. With the rising thermal standard of buildings (new construction and renovation) and with increasing energy costs in general this segment is quickly gaining importance. Building owners and users are more attentive to the possibilities of reducing related operational costs. Household appliances can contribute a significant share to the overall expenditure of energy and financial resources.

Based on these facts it would be logical that the fundamental decision making process when purchasing a new appliance is similar to the one when selecting for example a new boiler: defining the actual need in technical terms, choosing an appropriately high level of energy efficiency, comparing prices, and estimating long-term effects and payback time. We are talking about green procurement here, irrespective of the fact that especially in the private sector many buyers don't actually think about such a definition, but do it in a self-evident way simply because they are looking for the most rational solutions according to their available budget.

As shown in the paper the general awareness about the energy label for domestic appliances is high, meaning that buyers know how to differentiate between more and less energy efficient products. Knowing how to use data from the label to calculate long-term costs related to operation of appliances is another question. According to our survey an indicator presenting these facts at the point of sale as developed within the IEE YAECI project will be warmly appreciated not only by buyers, but also by retailers. The advantages are obvious and manifold: additional information for the consumer, a transparent picture of the relation between product price and its operational costs, clearer advantages of selecting more efficient products and better basis for planning of future budget expenditure. These facts are important both for private and for public purchasers and contribute to meeting individual as well as local and national environmental targets combined with cost savings.

ABSTRACT

Nowadays, there is a wide interest in the transformation of electric grids into smart grid, especially in the residential sector. This technology change provides the basis for a more efficient use of the electric power infrastructure at a global scale. Since electricity is an indispensable commodity for people, which has its own trade market, there is a growing need for technologies that make a sustainable, intelligent and optimized management of electricity. Thus, technologies have been presented based on demand-sensitive pricing strategies that already have proved to be effective for load profile changes such as the one mentioned in this paper, which is designated as Energy Box (EB). This is a benefic technology not only for the environment, but also for utilities and especially for the end users by referring to the domestic sector and their respective loads, emphasizing one “special” domestic load, which is the Electric Vehicle (EV).

Therefore, in this paper the EB technology, the demanding EV charger characteristics and the associated benefits regarding end users and utilities are examined. This paper also compares several case studies based on daily EV usage, electricity price evolution and EV batteries State-of-Charge. The presented results are based on ECE 15 standard driving cycle and different electricity tariffs, such as, single and two rate tariff, and dynamic tariff based on *OMIE* market prices which considers the access to networks tariffs for January 2013 in Portugal. For each case study, possible EB decisions concerning one random end user are presented and fully discussed. The battery life impact for the proposed application and the achieved monthly handling cost (€) are also approached.

Keywords: Electric Vehicles; Charger; Energy Profit; Vehicle to Grid; Energy Box.

INTRODUCTION

Currently the optimization of energetic resources usage, beholding the associated costs, is one of the most discussed hot topics, mainly when the crude oil and respective arising products are considered. The global aspects concerning the energy supply, leads to economic, ecologic and geopolitical issues, which are gaining today’s political and scientific attention. Contemporary society is increasingly dependent on energetic resources, with the fossil fuels being (e.g. coal, natural gas and crude oil) the most problematic, due to their limited existence and currently attained importance, which leads to their price instability. Only in Portugal during 2011 approximately 5.5 million tons just in fuels for the public transportation sector was expended [1].

The resulting emissions from thermoelectric plants and the massive utilization of internal combustion engine (ICE) vehicles, mainly in the transportation sector, substantially increase the global gas emissions. Carbon dioxide (CO_2) is probably the most famous greenhouse gas emitted to our atmosphere. During 2010 in Portugal, only from fossil sources approximately 53 thousand tons of this greenhouse gas was released [2]. ICE vehicles emissions are one of the major urban pollution sources, especially in medium and large cities, leading to public health issues, as air pollution contribute to mortality and morbidity [3]. Thus, it is easy to understand why pollution coefficients must be reduced in order to increase planet sustainability and life quality. The reduction of greenhouse gases emission could be achievable through losses reduction from generation, transmission, distribution and consumption of electrical power. This reduces the amount of produced energy needed, as well as the resulting pollution and greenhouse gas emissions, being achieved more efficient energy production systems. For this purpose, renewable resources and Electric Vehicles (EV) are considered good alternatives [4].

On the other hand, the smart grid applicability in the residential sector provides technological basis for a more efficient use of the electric power infrastructure at a global scale. Since electricity is a good indispensable for people commodity, which has its own trade market, there is a growing need for technologies that make a sustainable, intelligent and optimized management of electricity. Thus, technologies have been presented based on demand-sensitive pricing strategies that have already proved to be effective in altering patterns of electricity usage as the one mentioned in this paper, which is designated as Energy Box (EB). In fact, demand-sensitive pricing of electricity is expected to become the standard pricing mechanism in smart grids, maintaining electric system security and reliability at least cost. This is a benefic technology not only for the environment, but also for utilities and especially for the end users by referring to the domestic sector and their respective loads, emphasizing one “special” domestic load, which is the EV. These end users benefits are assigned based on their willingness in the assistance to the utility in several energy exchange scenarios, as the ones described further in this paper. Recent concepts and developments in EV philosophy and technology not only point for the need for charging (Grid to Vehicle – G2V) but also on delivering storage energy back to the grid (Vehicle to Grid – V2G), providing economic benefits for EV owners (end users) and utilities, decreasing the environmental impact through electricity generation plants and pollution reduction. Accordingly to this, technologies like the EB when attached to EV bidirectional and power adaptive chargers, as mentioned in this paper, will allow exploiting all the capacity and benefits of EB technology. This is possible by managing the EVs energy as they represent important loads or supplies in the end user and utilities perspective [5] [6]. Therefore, in this paper the EB technology is examined, including the demanding EV charger characteristics, how both are related, and the end users and utilities associated benefits are also discussed. Facing the enormous challenge of energetic exchanges between the EV and the grid, this paper approaches the importance of energy management, while maintaining the end user satisfaction level. Maintain electrical energy quality service without neglecting the dynamic electricity price changes is also highlighted. This paper also compares several case studies based on daily EV usage, electricity price evolution and EV batteries State-of-Charge (SoC). The presented results are based on ECE 15 standard driving cycle and different electricity tariffs, such as, single and two rate tariff, and dynamic tariff based on *OMIE* market prices considering the access to networks tariffs for January 2013 in Portugal. For each case study, possible EB decisions concerning one random end user are presented and fully discussed, as well as battery life impact for the proposed application and the achieved monthly handling cost (€).

ENERGY BOX CONCEPT AND ELECTRIC VEHICLE INTERACTION

The EB is proposed as a 24/7 operating technology for home or small business electrical energy usage management, which could take new actions within small step times (e.g. minute). EB is designed to operate in a demand-sensitive real-time pricing environment, which is feasible through smart grids technology evolution (see Figure 1). Thus, under this purpose it is assumed that, every electrical device in a home or small business will be controllable from one EB [6] [7].

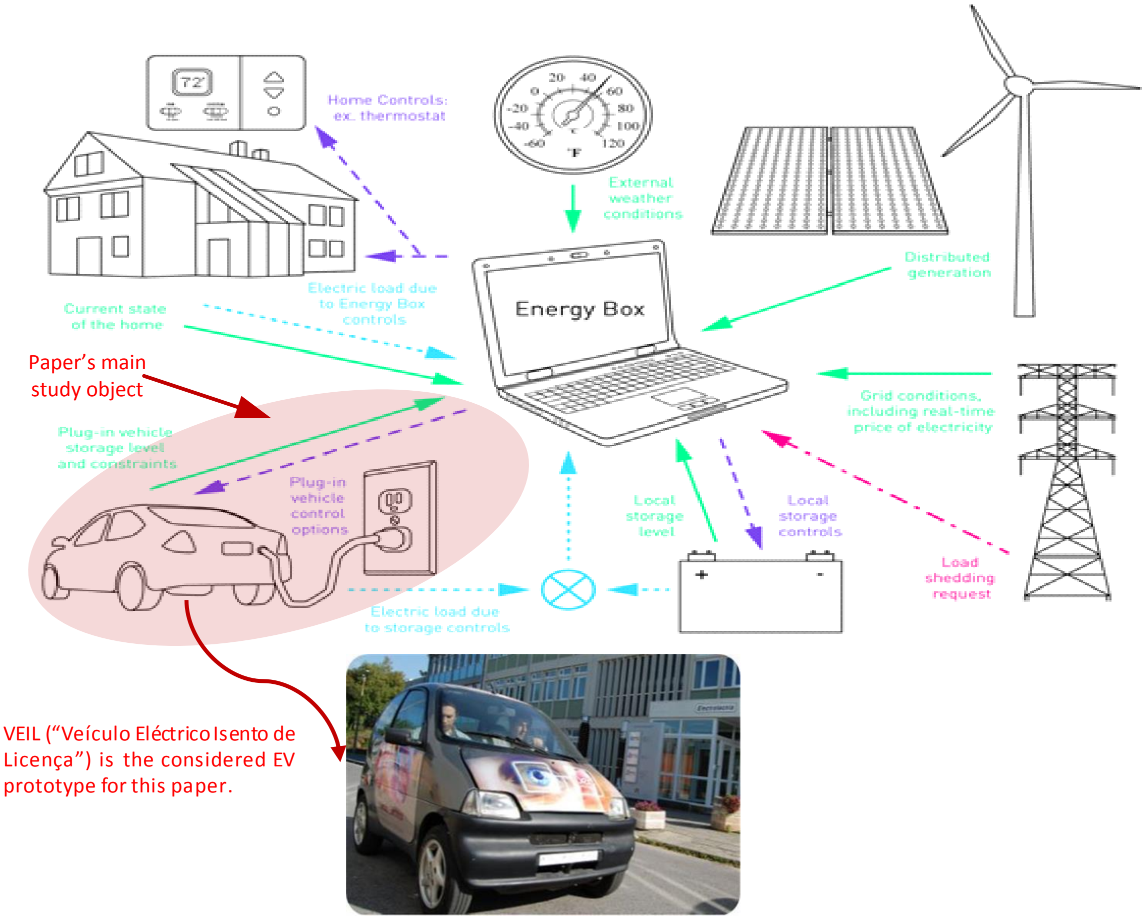

Figure 1: Energy Box concept illustration [6].

The current transformation of the electrical grid according to the smart grid concept generates opportunities for implementation of demand-side energy management systems technologies based on different pricing strategies that will allow a more efficient use of the electric power infrastructure. These strategies, already demonstrate that they are efficient in the application of electricity consumption alternative patterns. This kind of approach means benefits for the end users (e.g. reducing their electricity bill without degrading comfort levels) and for utilities as well (e.g. by the assistance that end users might provide in order to have better management of energy peaks, flattening the aggregate demand curve, and meeting supply with demand), leading also to environmental benefits [5]. Concerning EB technology, the most relevant aspect approached in this paper is the capability to manage the energy of one residential specific load, the EV. Thus, to obtain profitable electricity exchanges between end users and utilities, the EB will have the ability to store and learn about the end users profile. This allows taking cyclical decisions of storing or selling electricity from and to the grid, given dynamic variables such as, the price of electricity, weather conditions, comfort requirements, and electricity availability from decentralized renewable sources, without need human intervention.

In terms of command signal trades among utilities, end user's EB and the EV, a bidirectional communication system will be need. These involve communication devices, which will send and receive information signals about energy price, peak demand, reduce power demand curve and unused renewable energy. Then, according to the EV user cooperation capability and their respective storage energy or power supply capacity, can behave as a support system. With this technology, the decision about storage energy or selling electricity to the grid is based on the specific user profile and other dynamic variables. This is a quite interesting challenge that will require some sort of autonomous support based on decision support tools and adequate algorithms, where EV has a benefic and important role. Thus, technologies similar to EB are crucial for meeting the several opportunities and challenges offered by evolution through smart grids. However there is still needed investigation and pilot-projects in order to archive an energy management system of this kind [5].

Main Benefits and Drawbacks in End User and Utility Perspective

The G2V and V2G operation modes allow that all the EV can be seen as load, distributed energy storage system or as isolated electrical energy supplies. Thus, with a large EV and respective chargers integration (similar to the one presented in [8]) the electric grid will make possible the offer of several services which will differ in control regime, response time, terms of contract and price, having different benefits and drawbacks in the end user and utility perspective. Some of these services are related with peak power response capacity, storage for renewable energy, backup ability, peak shaving, spinning reserves and voltage and frequency regulation in order to improve quality service. One common benefit for each one of these services is related to energy acquiring possibility at the lowest prices, being the main drawback related to the still limited EV Energy Storage Systems (ESS) energetic capacity of [8] [9] [10].

Electric Vehicle Charger Characteristics

In order to accomplish the desired interaction between the EV and the EB, is important notice that the EV need to be associated a charger designed accordingly some specific features. Those are bi-directionality in power flow for charge and discharge operation modes (G2V and V2G respectively), capable of establish unit power factor and low Total Harmonic Distortion (THD) in order to not degrade power quality. The EV charger should also perform power control, have low construction complexity, if possible be classified as an on-board charger and be compatible with a regular 16 A plug. In order to fulfill these requirements the considered charger topology is the one presented and fully discussed in [8]. Regarding the battery technology, also in [8], are presented the considered battery pack characteristics. LiFePO4 is the deemed technology, because based on recent studies for energy storage systems applicability in EV, this is the most appropriate nowadays for EV powertrain purpose [11] [12].

ELECTRICITY TARIFF SCENARIOS

As previously mentioned, in near future demand-sensitive electricity pricing is expected to become the operative standard for energy tariffs mechanism. Since this paper intends to focus the importance and benefits of energy management technologies, mainly for the residential sector, is mandatory set all the pricing options in the end user perspective. Therefore, in this paper are considered three pricing methodologies presented in Table 1.

Table 1. Considered electrical energy tariffs.

Tariff	€/kWh
Simple	0,1418
Two Rate (peak period)	0,1674
Two Rate (off-peak period)	0,0878
Dynamic pricing (based on market)	Average hourly for week and weekend days

The two first methodologies, stated in Table 1, are designated as simple tariff and two rate tariff, being these established by "*Entidade Reguladora Dos Serviços Energéticos*" (ERSE) in 2013. The third is the dynamic tariff based on *OMIE* market prices (€/MWh) considering the access to networks tariffs, for each hour in January 2013 for Portugal [13]. To obtain the same price evolution to the end user, this hourly dynamic tariff was divided by a thousand in order to achieve an €/kWh relation. Lastly, this final daily electricity dynamic energy pricing was obtained by adding the access to grid tariff accordingly to the ERSE electricity price structure presented in Figure 2. The considered access to grid tariff value, was 0.0654 €/kWh for end users with power contracted under 20.7 kVA, accordingly to ERSE 2013's grid access tariff tables [14].

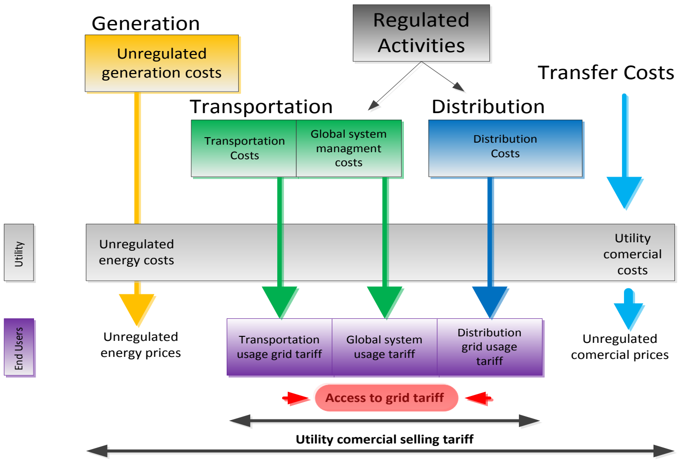

Figure 2: ERSE 2013 dynamic energy pricing tariff architecture.

In order to achieve more accurate results analysis, the 2013 January month was split into week days (twenty three) and weekend days (eight), being obtained two different dynamic tariff curves. These are the used price curves, for variable tariff case. These evolutions are the most updated electricity price values in Portugal for dynamic energy pricing, in order to obtain a less erroneous approximation facing the future of electricity market operation system.

In this paper is considered for the variable tariff, that each hour price is also the same for the utility to pay to the end users for their sold electricity. For the simple and two rate tariff is no admissible sell energy to the grid.

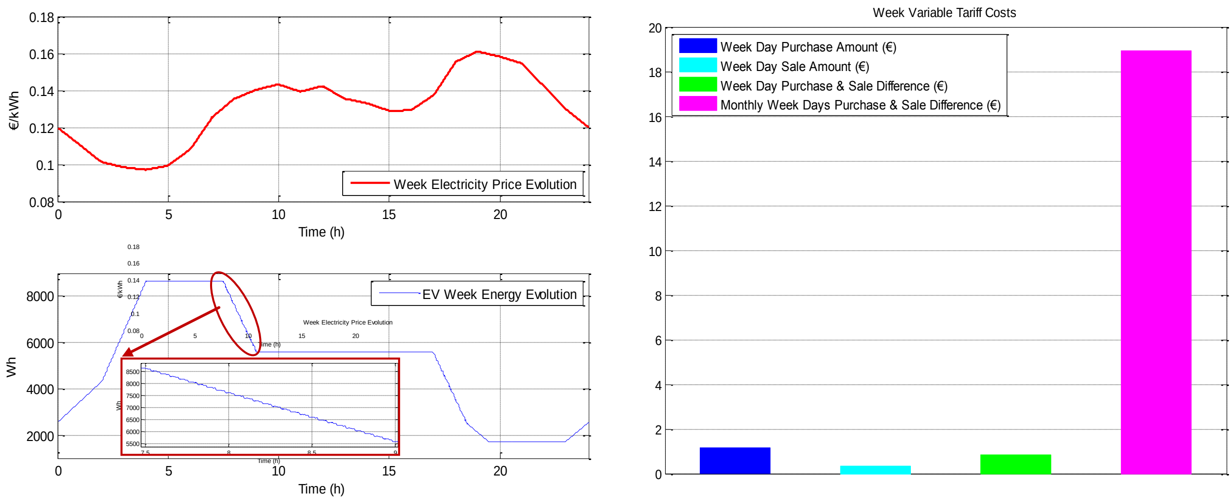
CASE STUDIES

This section introduces the approached scenarios in this paper. Four case studies will be next presented, where for each one of these, should be noted that the expectable life time conservation and safety levels preservation demands for 80% of the battery pack SoC utilization (for LiFePO4 batteries technology). The batteries operation temperature is considered constant (around 25ºC), and the proposed charger for this application ensures that the permissible voltage and current limits are not exceeded [8] [15]. Thus, for further understanding of EB possible decisions facing each scenario is a relevant remark that the maximum SoC level (100%) is equal to 8.640 kWh while the minimum (20%) equals to 1.728 kWh. For all presented scenarios it is considered that the EV is the family 2nd car, used at working days (week) for travelling and grid energetic exchanges participation, and at weekend days essentially for the grid energetic exchanges, being associated at one random residence.

The adopted strategy for buying or selling electricity is based on knowledge of the maximum and minimum electricity price along the daily 24 hours for each case. One third variable located between this maximum and minimum, will define the price slots for buying or selling electrical energy. Finally is established a linear relation between the current price and the power level applied in that instant, in order to valorize the flowing energy. Therefore, for the instants with the lowest and highest price, the EB will command purchase or sale operations respectively, using the maximum charger power level (2.3 kW), if none of the SoC limits is reached. For the further presented scenarios regarding the week days, the EV is daily out from home from 7:30 AM until 6:30 PM. Along this daily time slot, the first drive time period (expended time to get to work) goes from 7:30 AM to 9 AM, then the EV stays parked from 9 AM until 5 PM where energetic exchanges (charge or discharge) are not allowed. Finally, the end user daily trip back home takes 1.5 hours (like the morning period), arriving at home around 6:30 PM. In the driving periods was considered a typical routine for mobility in big European cities with low average speed and frequent start and stop situations, designated as ECE 15. These were used according the tests presented in [11] for a small EV prototype only with the considered battery pack as ESS and with regenerative breaking capacity. Thus, both 1.5 hour drive periods was formed by 27 times the ECE15 drive cycle, which corresponds to approximately 27.35 km, being the daily considered total journey distance of 54.7 km.

In this paper it is also important remark that only one EV is considered. Therefore, the grid impact of several EV simultaneously connected for charge or discharge purpose is not addressed.

The first case study approaches the considered dynamic energy pricing for the week days (see Figure 3). Through Figure 3 analysis, it is possible notice that the purchase and sale energy amount is defined according to the involved daily price slot, in order to valorize the EV storage energy and minimize the EV charging cost as previous mentioned. The variable for the price slot definition was approximately the mean value of this price curve (0.13 €, in this case). Thus, the EV energy evolution slope is bigger when the price is lower and is smaller when the price is higher for purchase and sale situations respectively.

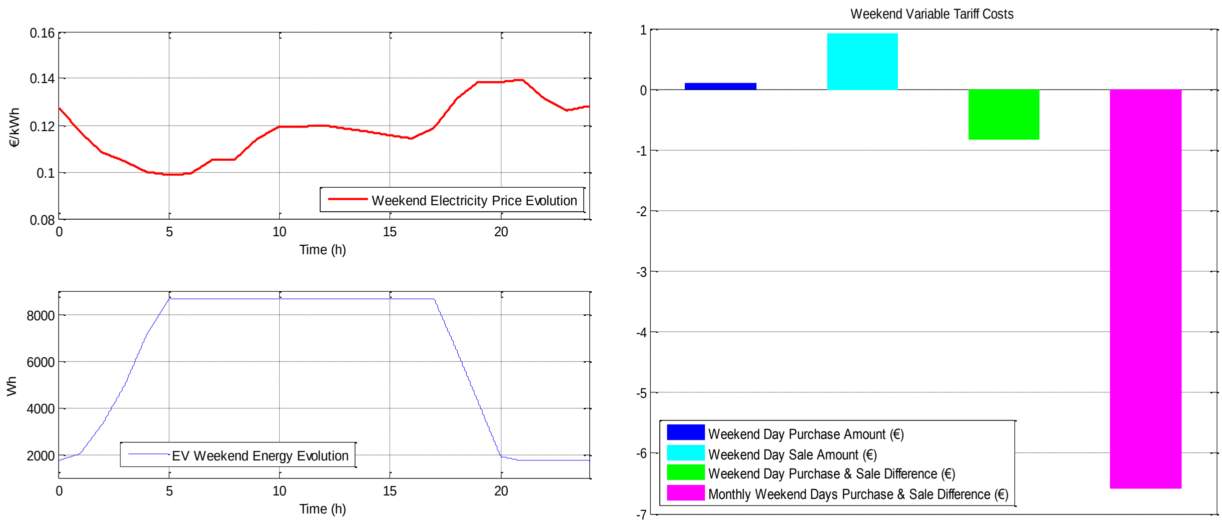


a) b)

Figure 3: a) Week days' electricity price and EV energy evolution. b) Dynamic energy pricing handling costs for week days.

As previously stated, for the week days from 7:30 AM until 6:30 PM is the daily time slot where the EV is out from home, therefore in this period exists energy consumption by travelling, as presented in Figure 3 a) zoomed area. In Figure 3 b) the handling costs are presented for the considered one week average day and the respectively total monthly amount, which is 23 (number of week days in January 2013) times the approximately 0.80 € value corresponding to the green bar.

In Figure 4 is presented the previous equivalent scenario analysis but for the weekend days.

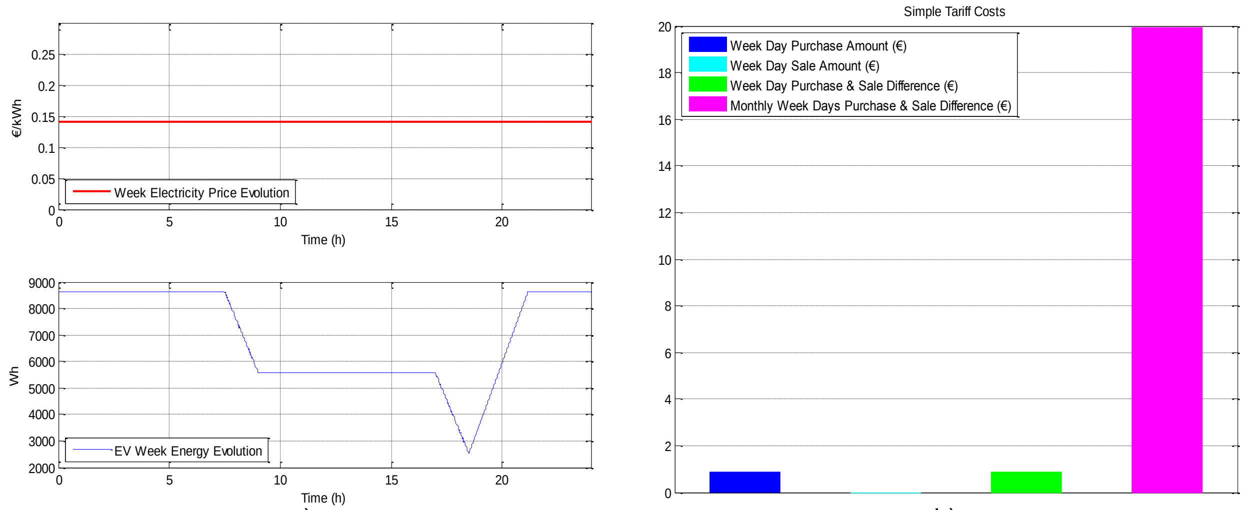


a) b)

Figure 4: a) Weekend days' electricity price and EV energy evolution. b) Dynamic energy pricing handling costs for weekend days.

Therefore in Figure 4 a) the purchase or sale energy price slots were defined using as reference value 0.12 €. This possible EB decision means to purchase electricity when the price was approximately under 0.12 € and only sell it back around 7 PM which is the beginning of the day period where the electricity price is higher. Thus, this is one possible decision in order to maximize the profit, being the monthly handling cost around 7 €. Notice that when the energy sold is higher than the purchase amount, the obtained difference between both is negative, which means profit in the end user perspective.

In Figure 5 and Figure 6 are presented the simple and two rate tariff scenarios respectively. For these, selling electricity back to the grid is not permissible, being only considered the January 2013 week days (23 days). As is possible notice, in the presented cases the EV fully charge level is attained before the end of the day, being minimized the partial or minimum SoC level time in the battery pack, which also increasing their life time expectance. Figure 5 presents single tariff scenario based on stated values in Table 1.

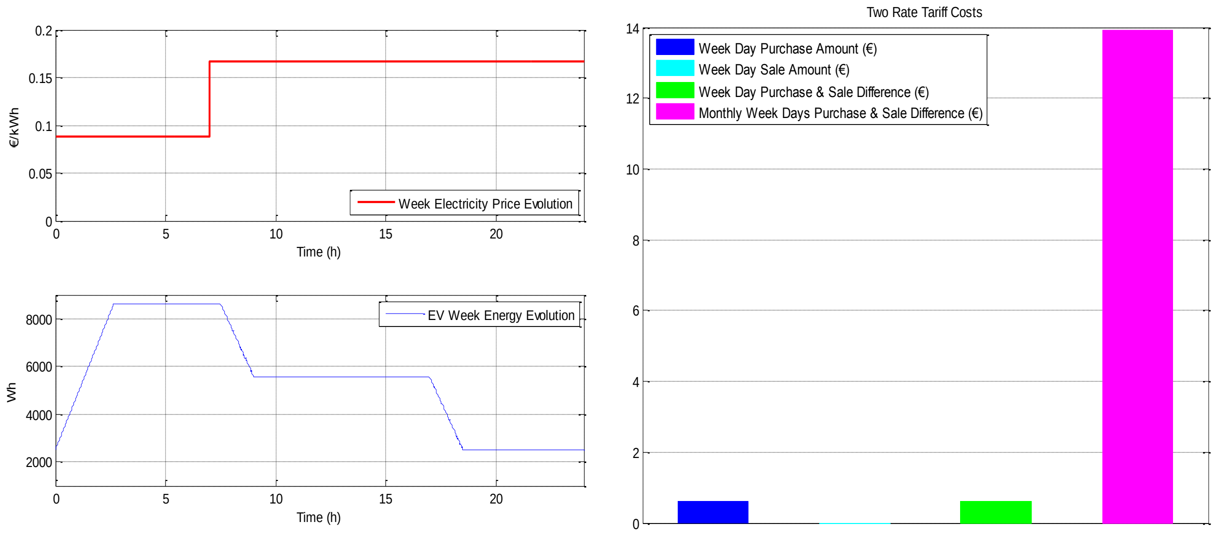


a) b)

Figure 5: a) Week days' simple tariff electricity price and EV energy evolution. b) Simple tariff handling costs for week days.

Through Figure 5 analysis and considering what was previously stated in this paper, is understandable the lack of sold energy amount, and the high monthly expended amount for EV charge purpose. In fact, is only possible buy energy following a constant and high price level when compared to the other case studies.

Figure 6 presents the two rate tariff scenario based on stated values in Table 1.



a) b)

Figure 6: a) Week days' two rate tariff electricity price and EV energy evolution. b) Two rate tariff handling costs for week days.

In the two rate tariff, the most profitable EV charging period is from 0 AM to 7 AM, which is the off-peak period having the lowest electricity price among all presented cases. Once is achievable a meaningful difference price between the peak and off-peak period, the EB decides to charge only in the off-peak, because that time slot is big enough for fully charge the EV before the beginning of the drive period, being minimizing the EV charging cost.

The final overview facing all presented scenarios is made through Figure 7 analysis.

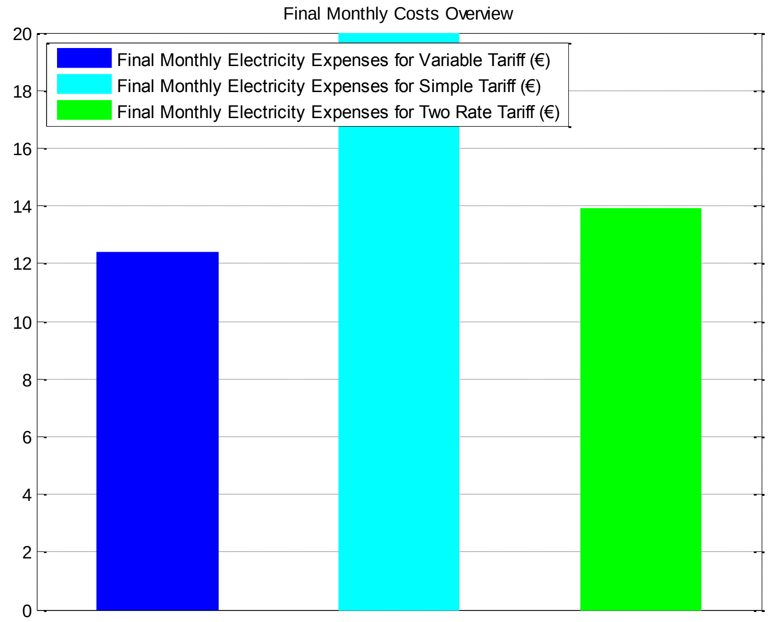


Figure 7: Final monthly handling costs for each approached tariff method.

In this figure are summarized all final monthly EV electricity expenses amounts for each considered case. The final variable tariff value is obtained by the sum of the monthly total amounts for the 23 week days and the 8 weekend days which totaling the first 2013 month. Obviously the other two case studies concern the simple and two rate tariff, being understandable their final bigger values. Thus in this cases is not possible sell back to the grid the EV storage energy and average electricity price value is higher than in the variable tariff case. The final two rate tariff monthly cost is close to the variable one due to the EV charging was performed in the off-peak period where the price is lower.

CONCLUSIONS

This paper tackles the end user achieved benefits in the exchange of electrical energy with the utilities concerning one EV. This is a dynamic process managed by autonomous support technologies like EB devoted to residential sector where the EV is approached as a load or supply identity. Thus, the EV may have a prominent role when associated to autonomous residential electricity management systems like EB, being mandatory to have associated EV chargers with specific features, which are fundamental for a more sustainable energy system.

Through the presented results analysis and authors considerations it was possible to conclude that the future of electricity dynamic energy pricing associated to the EB and EV technologies could allow to end users archive important monetary benefits. Hereupon, a good trade among EV energy needs given the electricity prices is always attained. Thus, among all presented case studies the dynamic tariff case associated to the mentioned technologies is the most profitable being its monetary profit of 7.6 € and 1.5 € when compared to the simple and two rate tariffs respectively. If we consider twelve equal months like the approached in this paper, one single end user will achieve approximately 91 € and 18€ of annual profit, given the previous presented comparison.

Due EB decisions for minimize the charging cost and maximize the sale price, the end user always obtains good tradeoff in the energetic exchanges. The fact of the charger being power “flexible” allows performing charge/discharge with different power levels, which benefits the power distribution among all domestic loads. The end user also has the advantage of not need to concern about price scheduling since the EB takes the better decision for him, he just needs to plug the EV once he at home.

It should be noted that in all of these cases and presented results several capabilities and characteristics of EB are not being taken into account, such as crossing power requirements of the other domestic loads or taking decisions in order to a specific user profile. Exploiting all the potentialities of EB technology is not the objective of this paper. The developed study cases were based on real energy price approximation, real battery technologies restrictions and logical random end user decisions concerning EV needs and price evolution, just to demonstrate what could be the end user economic benefits.

Thus, the controllable EV's charger under EB decisions will be crucial in the future of residential energy trades, being archived significant profits which leads to optimized energetic handling cost.

Abstract
The aim of the present research is to assess the cost-effectiveness of mixing and combining different energy retrofit measures for the several geographical areas of Italy. The research work is based on the analysis of the results supplied by the several Reports drawn up by ***ENEA*** - the ***Italian National Agency for New Technologies, Energy and Sustainable Economic Development*** - year by year since 2007. The work is centered on finding out a criterion, based on simple and available data, that is able to identify the most cost-effective retrofit measures to improve dwellings' energy efficiency.
With the final objective of adjusting and addressing the subsidies and the policy makers' decisions in the most profitable way, there were developed some comparative cost-effectiveness analyses and there were highlighted the most consistent kinds of renovation, both with the current economic outlook and depending on the specific geographical and climatic background.
This paper presents and discusses the consequences of the Italian government leaders' policies and purposes of reducing the energy demand in the residential sector, in order to facilitate the development of a consistent plan and extention of public incentives and tax deductions for dwellings' energy-saving retrofits.
Thence, it's designed to represent a reference point to help decision-makers and relevant stakeholders appreciate how targets have been used till now and how effective they could be, also providing evidence to be used in the upcoming policy development discussions.
Actually, as this paper proves, the earlier outcomes connected with the current National Energy Strategy reveal that some such adjustments and refinements are needed, in order to make it really effective and worthwhile.
Although the praiseworthy initiative and aim that underlies such a political-economic venture, it shows several gaps and faults that should be offset and filled up.

Nomenclature
OO: Opaque horizontal surfaces' insulation (floors and roofs);
OV: Opaque vertical surfaces' insulation (walls);
IN: Replacement of windows with low transmittance ones;
ST: Installation of solar thermal collectors;
CI: Replacement of boilers with condensing or biomass ones or with high efficiency heat pumps;

NW: NorthWest Italian macro-area (Piemonte, Valle d'Aosta, Lombardia, Liguria);
NE: NorthEast Italian macro-area (Trentino-Alto Adige, Veneto, Friuli-Venezia Giulia, Emilia-Romagna);
CE: Central Italian macro-area (Toscana, Umbria, Marche, Lazio);
ME: Southern Italian macro-area (Abruzzo, Molise, Campania, Puglia, Basilicata, Calabria);
IS: Islands Italian macro-area (Sicilia and Sardegna).

Introduction
The present research-work is a report and a review of the most representative financial instruments introduced in Italy since the enactment of the Finance Act 2007 (and its successive 2008 and 2010 edition), i.e. the Fiscal Incentives for Energy Savings in the Household Sector (a.k.a. "The 55% Tax Reductions for Building Retrofitting") .
It is in particular focused on those only kinds of building renovations related to the three last Commas (i.e. 345, 346 and 347) of the First Finance Act Article, that were carried out in private dwellings within

the time span of 2007-2010. With reference to the several Reports drawn up by the ENEA in order to relate the Authorities about costs and results of the above incentives, there were written and filled out different spreadsheets, schedules and graphs to collect and sum up all the data and information that could be the most significant to define an all-embracing cost-benefit assessment.
The main purpose of the present research is in fact aimed at the assessment of the results till now obtained in terms of their cost-effectiveness, resting on an amount of data large enough to take stock of the early stages of the Government Campaign.
Thanks to that it could be possible, in the foreseeable future, to adjust the Italian Energy Policies and address the politicians' decisions in order to encourage those kinds of renovation, where they should be more cost-effective, and instead give up and/or limit such a financial support, whereas some other interventions reveal their lacks and disadvantages.
Actually, the rising energy costs, the growing concern about environmental issues and the approaching exhaustion of world energy resources are urging the whole European Community and the several National Governments to improve their energy management.
With European overall policy being to significantly decarbonize its economy by 80% to 95% by 2050, the building's sector, which accounts for 40% of the region's energy consumption and almost the same level of GHG emissions, must undoubtedly play a key role [5].
And any strategy to tackle the challenge in the buildings sector will clearly require a significant amount of financial investments and therefore long-term political commitments.
Hence, the main goal of the present work is to gather key facts derived from the use of some such financial instruments as the next steps in improving the energy performance of buildings: this paper would like to show the Italian tax reliefs already in place and points out the main observations related to the impact of such a policy in an all-embracing assessment.
In general, a particular attention is usually paid to Public Administrations, as European and National Legislations often point out that these entities must provide energy efficiency measures, as well as for the reasons above indicated, also in order to represent an example for the entire community and for the citizens too [6].
But it's very important also to find out how to foster and encourage energy efficiency improvements and energy saving measures in private dwellings, in order to achieve the double advantage, both to reduce the global energy consumption level within the private sector, and to increase investments favouring the creation of additional cash flows too.
"Buildings are at the centre of our social and economic activity. Not only do we spend most of our lives in buildings, we also spend most of our money on buildings. The built environment is not only the largest industrial sector in economic terms, it is also the largest in terms of resource flow" [7] .
Hence, the possible combination of some such multiple benefits makes the building sector a crucial field for policy makers at EU and national levels. Therefore, a policy framework that can support the national markets in unlocking these potentials is strongly needed.
And moreover, most of the previous, several researches already developed, demonstrate that financial and environmental aims are not necessarily a contradiction, but can actually support each other [8].

The background of the previous knowledge and the potentialities disclosed by this paper

There were already depicted, at European International level, various reports and surveys that have taken a closer look at how financial instruments are currently being used in Europe, providing some evidence of their effectiveness too [5,10,17]. In particular, they have underlined a great variety of financial instruments available throughout the EU to support the improvement of the energy performance of buildings, but, although their undoubtable relevance, none of them has analyzed into details the respective implications at a "single-nation-level". As a matter of fact, this particular topic isn't thoroughly discussed, neither in scientific literature, nor in specific technical guidelines: thus, the example offered by the ENEA Reports could represent, at a national level, a very important instrument to develop a concrete strategy with the aim of creating some guidelines to optimize and address the challenge of renovating the existing building stock, keeping also pace with the ambitious aims of both the Italian Nation and the European Union.
Actually, all the data on costs and energy savings collected through the last four years by the ENEA and provided by such reports, represent a valuable source that should be used systematically to evaluate the financial policies' current approach and to give some guidance on the future. And moreover, since achieving energy savings in buildings is a complex process, policy making in this field requires a meaningful understanding of several aspects and characteristics of the building stock:

reducing the energy demand involves the deployment of effective policies which, in turn, make it necessary to understand what affects people's decision making processes, the key characteristics of the building stock, the impact of current policies etc…

As already mentioned in a recent article [9], many other authors have already pointed out that there are many obstacles to the spreading of good practices. One of the main problems is the cost-effectiveness of home energy retrofits that is rarely taken into account in national policy programs [27].

In particular, the literature review highlights some critical issues:

- National legislation can be too strict and prescribe energy efficiency requirements that make retrofits cost-ineffective for homeowners [22, 25];
- Energy price is fictitiously low because social costs of production are often hidden and not charged directly on users' bills [23, 24, 26, 27];
- Uncertainties on future energy price make the economic feasibility analysis of works really difficult [19, 20];
- Public subsidies are necessary to reduce payback time and increase economic benefits for investors [26, 27].

Taking account of some such remarks and focusing the attention on Italy and on its own financial policies and energy regulations, it reveals very important (after due considerations related to the previous, early stages of the public incentives established till now) to plan and address the future energy policies so them to be consistent and profitable.

Therefore, the Enea Reports and their analysis in depth could play a fundamental role to understand which and where some kinds of buildings' renovation reveal their cost-effectiveness (and thence should be encouraged with a suitable financial support), and when instead they display a lower all-embracing consistence.

The *ENEA REPORTS*: the so-called reports consist in all the information and data collections drawn up by the *Italian National Agency for New Technologies, Energy and Sustainable Economic Development* in order to test and assess the effectiveness of Italian laws and regulations related to the "55% tax reductions" for building retrofitting in Italy [1, 2, 3, 4].

The above reports were issued, year by year since 2007 (i.e. since the earliest incentives settled by the Finance Act of 2007), in order to monitorize the results of the financial policies adopted in Italy to increase the Nation's energy efficiency. They involve the entire country and, splitting it into 5 different geographical macroareas, allow to carry out an investigation and to develop an analysis centered both on the single macroarea's level and on the whole Italian level.

In line with the EU general objectives, and most of all in the light of both the recent 2006/32/CE and the 2010/31/CE Directives' enactment, besides the so-called *EU 20:20:20* energy saving planks, the primary goal of the Italian energy policy concerns the implementation of several measures addressed to liberalize and increase the overall efficiency of the energy sector [10, 17].

And in order to align with the above mentioned European policies and objectives, the Italian Government has in fact adopted a strategy aiming at the diversification and the penetration of new energy forms in power generation, with a concurrent improvement of energy efficiency and conservation in end uses, as well as with a wider eploitation of renewable energy sources.

Thence, on the one hand it is attempting to incentive mechanisms and methodologies for quantifying energy consumptions and energy savings in dwellings, and on the other hand, since the Finance Act issued in 2007 and in order to increase energy savings for winter heating in existing buildings, has established a system of generous financial incentives: they allow a tax deduction of 55% for all the investements sustained both by private, individual citizens and by companies.

Description of the method used

"If you cannot measure it, you cannot improve it "(Sir William Thomson, Lord Kelvin) [10].

The present analysis has been based on all the all the statistical data provided by the several Enea Reports issued in these latest four years. Actually, the above data consist in a huge set of statistical information related to the following main and most significant key-elements: the number of different kind of renovations respectively realized in the several italian macroareas, their relative average costs, and the consequent energy savings (and economical benefits) achieved. After the initial scanning and collecting of the most relevant results summed up by the reports issued in 2008 (based on the 2007 Energy Campaign results), 2009 (based on the 2008 results), 2010 (related to the 2009 Campaign) and 2012 (based on the 2010 results), there were in fact filled up several resume schedules, drawing the respective graphs and summary tables, in order to follow and outline the evolution and the statistical changes within the whole timespan analyzed (as below detailed). All the

assessments were carried out through excel, hand cost-benefit calculations and spreadsheets, and were developed basing such analyses on those which should be the most suitable lifespan values for the different kinds of intervention: thence, after a global review of the current European Standardization and of the Regulations related to this topic, there were introduced some adjustment factors which, due to the statistical nature of all the data processed and being the typological range of such renovations so wide and general, were assumed quite "widespread and global-fitting".
There were adopted the following reference intervals: 50 years both for the horizontal and vertical surfaces insulation (i.e. walls, floors and roofs), 30 years for the windows' replacement and 25 years both for the solar thermal collectors' installation and the heating plants' replacement [11,13,16].

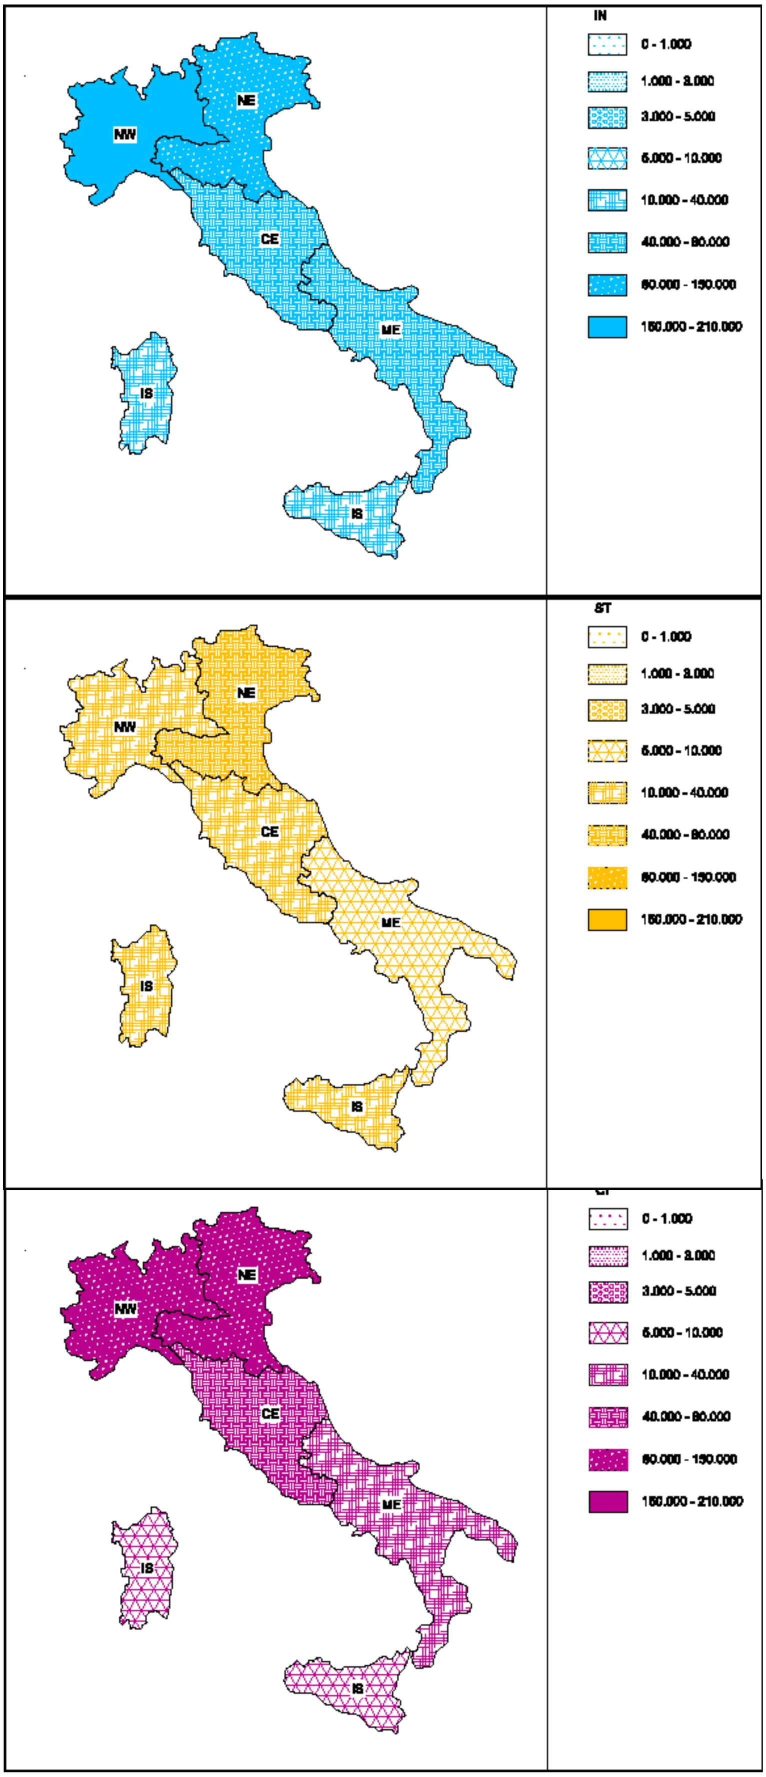

Fig.1: Time-span 2007 – 2010: Cumulative overall renovations' distribution along the whole Italy

As it's easy to note, there are a lot of differences and discrepancies among the several resume tables and the figures above shown, both related to the number of renovations registered along the entire country, and to their respective distribution. First of all, an evident gap is recognized between the global number of renovations reported during the first campaign year and the successive ones. And such a statistical phenomenon is essentially ascribable to the following main reasons: on the one side, it is due to the first venture's year being such an "initial, testing experience". Thence, despite the awareness campaign and the Enea's Helpdesk and informative venture, people hadn't enough experience with such an investment plan yet. On the other side, an error had occurred in the earliest version of the Budget Law issued in 2007 (and hence in the consequent so-called "Decreto Edifici"): due to an editing and drafting mistake, the U-Value, thermal transmittance limits to be respected in realizing the different kinds of opaque horizontal renovations, there were in fact reversed. Thence, one more reason that has made even fewer the already low rate of such a quite expensive kind of building's retrofit.

Research Results and Discussion

Also in the light of the above considerations, it's important to underline the difficulty of globally implementing a meaningful, exhaustive and fair comparison among all the different yearly reports analyzed. Beside that, a further alteration and data corruption that affects this global trend overlooking is made up by the sensible differences in the population's amount - and thence in the dwellings' number - among the different macroareas scanned (and above of all, in the case of Islands Macroarea).

Table 2: Cost-Benefit balance values reckoned for the several Italian macroareas within the time-span 2007-2010

COST-BENEFIT BALANCE SUMMARY 2007	NORTH-WEST	NORTH-EAST	CENTER	SOUTH	ISLANDS

THERMAL PLANT REPLACEMENT	55,93	74,93	86,59	94,45	108,35

The overall frame depicted by the above table confirms what right now outlined and provides much further, very interesting food for thought and research questions to delve into: first of all, it's important to appreciate the big effort required by such a survey and data gathering. Beside that, also the main aim and intentions which led this global campaign play a strategic role to realize the broad sweep and the weight of such financial and energetic policies, with the final target to improve and refine them.

And although the trends' analyses and data-processing implemented by the above cost-saving ratio values actually don't directly supply a clear indication about how to address and develop a future, worthwhile financial policy and investment plan, they reveal themselves fairly meaningful.

The cost-benefit balances were assessed, year by year and for all the several Italian macroareas, through the evaluation of the ratio between the weighted average cost (i.e. the actual average cost, given in €) and the weighted average energy saving (expressed in MWh per year) calculated for any kind of renovation, also considering the respective LCC factors before introduced.

Actually, those data provide a global frame quite patchy and uneven and, at first sight, could be seem affected by some such mistakes and/or evaluating errors.

But a deeper analysis and a careful examination of the boundary conditions and global background that lay behind that lead us to some reasonable comments and observations.

Beside the already highlighted appreciable differences in the population's amount and in the dwellings' number of all the macroareas, another reason of such a relevant results' gap and mismatching is ascribable to the substantially different economic conditions which make the northern areas more active and resourceful.
And a further element which doesn't help the survey to find out a global, common analyzing criterion and that concurs to such a result is closely connected to the distinct weather patterns that concern the entire Italy.
Actually, the whole nation involves a quite wide range of different Climatic Zones: 6 exactly - from the A Zone, till the F Zone - and thence 6 distinct weather contexts and environmental backgrouds.
But, despite all the above considerations, such a huge amount of data and informations however plays a very important role.
And although the earliest results till now outlined reveal themselves so much heterogeneous, it could reveal possible and quite worthwhile to base on them a final knowledge and an overall comprehension of which and why should be the most cost-effective kinds of renovation for any Italian Macroarea.
Thence it would be also easier to find out the most profitable adjustments and optimizations that should be applied to the already issued financial strategies.
However, it should also be remarked that, since all the previous years' analyses didn't allow us to detect any significant and reliable prediction or trend to base on and to develop the future steps of the research, it could be possible only work out some few, very rough assumptions to lead the work.
For example, it could be possible gathering that, in the future and with some such further technical developments, the average cost of the different energy saving solutions should decrease, but on the other hand, some new technologies are going to be probably developed and should increase and vary also the inflation rate, the interest rate and the price of money…
Moreover, although the ongoing global climate changes, the southern Italian areas are actually in general more warm and with a wider solar radiation than the rest of the country; but, besides the above considerations, we don't have any mathematical certainty regarding the future, unless the information and the data already collected.
Also the latest, lowest cost-benefit ratio value registerd in the Islands macroarea for solar panel installations (23,58) confirms the appropriateness of such an already registered trend, while it should be strongly recommended to enhance and encourage the solar thermal collector equipments in the south of Italy (due to the other two, lowest ratio values reckoned of 23,34 and 14,04).
But another, really important and more precise information is needed with reference to the already issued financial strategies and, most of all, in relation both to the current and to the incoming tax reduction criteria.
While it would be necessary to adopt a far-sighted policy in order to allow, in the future, such facilitations during a wider time-span, a lot of care is needed in order to plan them avoiding unfruitful investments.
Restrictive upper limit should be settled, also exploiting all the earliest cost-effective information already carried out. Moreover, turning towards both the latest, urgent European statements and Regulations, and towards the overall economic crisis, the standard-range to be respected in order to obtain such fiscal reliefs should be stiffened.
Thence, just related to the above last topic, it clearly turns out to be a suitable decision the hardening of U-value limit ranges to be respected along the different macro-areas, while it should be avoided the incoming decision to make no more binding the energy efficiency certification proofs for most of the kinds of renovation - i.e. with reference to windows' replacement, solar panel installation and thermal plant replacement.
On the other hand, it should be recognized that right this last kind of energy retrofit, in spite of its higher cost-benefit ratio value and thence its flimsiness, is also the most affordable measure (from an economic point of view), besides its most quick and easy feasibility.
Hence, recalling that a National Policy and Energy Strategy could be really worthwhile if enough balanced and widely exploitable by a large users' bracket, a reasonable and fairly-weighted financial support should be preserved also into boosting such outwardly fruitless type of renovation.

Conclusions

As this work shows, the building sector - and above all the residential private dwellings - can significantly contribute to mitigate and smooth over the ongoing climate change, while delivering many other social benefits too. Political courage and initiative, innovative investement tools, together with a

social awareness, are the real key factors that could contribute to a radical trasformation and improvement of the whole sector.
Thence, the already existing EU policies - and in this case the Italian financial programmes - should be implemented in a best practice manner in order to achieve the intended energy savings, while on the other side some new instruments are strongly needed to stimulate a deeper renovation wave across the entire country [5,16,17].
But another fundamental challenge is represented by the observation that good policy making requires a good knowledge about the *status quo* of building performances and thence, to contribute to the success of its main goals, it will be also necessary plugging some relevant gaps that make it difficult to develop targeted programmes, to monitor policy's implementation and to evaluate its progress.
Thus, the principal actors of the whole process should strongly invest all their efforts into fill up these data gaps, harmonizing the entire monitoring, reporting and evaluation process, in order to provide for the best resolutions.
On the other side, it's important to underline that, although these targets are fundamental, they should be definitively seen as only one among all the other elements that make up the global solution.
Only thanks to an all-embracing assessment it will be possible attending to a relevant renovation opportunity, both innovating products and services and building a well-functioning energy saving renovation market. Thence it will be also possible to offer at the same time attractive solutions to private and commercial customers, as well as making the highly efficient buildings a common standard for the entire Italian building stock.
Moreover, recalling the main goals and purposes that have led the earliest analysis, the future steps of such a work will be focused on the single study of all the several Italian Macroareas - one by one - in order to find out how it could be possible to define the future energy-saving strategies, refinining and calibrating the results already achieved.
The above process will be planned both in function of the previous results and the respective different climate conditions, and will involve a full exploitation of the linear programming analysis potentialities, implementing in particular the Dantzig's simplex method.

Future Outlook

As already intended and set out to do, the future studies would proceed and go on starting from the data and sentences already available and will be based on the same life-span ranges already assumed for the different kinds of renovation, but will also resort to such more advanced algorithms and calculation technics than the simple spreadsheet-hand computations.
And also in the light of the ongoing political financial strategies and policy makers' statements (which will globally involve an investment valued at around 180 billions of Euros till the year 2020), the main research goal to find out and encourage only the most cost-effective kinds of building retrofit has been confirmed [18] .
Moreover, the Italian Revenue Agency has recently published the New *"Guida sulle Agevolazioni Fiscali per il risparmio energetico"* (the New Guide about how to join the 55% Tax Deduction for energy-saving renovations). Since the Decree n. 83/2012 has been definitively approved by the Italian Government and transformed into the Law n.134 - 07/08/2012 - the 55% tax deduction has been extended until the 30th June 2013 while, with effect from July the first 2013, the 55% tax cut will be replaced by the normal 36% tax deduction provided for generic buildings' retrofits which, since the year 2012, had become definitively structural and never-ending.
And the most important aspect to underline with reference to the last proof of the *"Strategia Energetica Nazionale – National Energy Strategy"* is referable, besides to the lengthening of the 55% tax deduction, to the tax cut differentiation based on the real and concrete benefits renovations-related. They are also going to play a fundamental role into the future banks' plans of innovative, financial and contractual models focused on such a feature.
But on the other side, it's also important to observe that, as well as it happens in almost every context, a balance should be reached between the ideal and most profitable actions to plan and the real economic background of the people middle classes to deal with.
Whilst a different, best-fitting binding target is needed in order to address the future policy makers' statements, the risk that it would limit a certain flexibility of response should be recognized.
Furthermore, a binding target should be linked to a harmonized measurement method; but this should be both robust and flexible so that stakeholders have enough confidence that it will enable the demonstration of all the consequent, achievable progresses.

Such targets are very important in galvanizing action and understanding progress, but they also have to tread a fine balance between achievability and ambition [10].
They must be founded upon need and evidence of the energy saving potential, moderated by real-word expectations (in addition to economic and technical considerations) of what can realistically be achieved, as well as upon the progresses that can be credibly and transparently shown.
Undoubtedly, there will be necessary more innovative ideas and initiatives. Deep renovations are expensive, even if they are cost-effective. They require considerable up-front capital that is normally beyond the support of any single financial instrument.
Moreover, new strategies to secure sufficient financing for deep renovations of the whole building stock are needed, which ideally bring together private and public investment streams. The future targets need to balance achievability and ambition: in fact, if they are too low, they reveal themselves meaningless, but on the other side, if they are too much high-flying and ambitious, it is likely that key-stakeholders will not engage in the entire innovation process.
Thence, policy makers and all the relevant stakeholders in the building sector should elaborate which policy framework would enable the necessary investments: and this would, not only create new investment opportunities for the private sector, but would also reduce the global burden on public budgets.

Enhancing energy efficiency – Product related incentive schemes for the general public

Kathrin Graulich, Dr. Corinna Fischer, Ina Rüdenauer, Dr. Dietlinde Quack

Öko-Institut e.V., Germany

Abstract

Consumers are increasingly confronted with demands for CO_2 savings, increasing energy prices, power cuts and energy poverty. Especially low-income households do not have the financial means to buy energy efficient household appliances and they often lack the knowledge how to save energy in their daily life. However, from washing machines, refrigerators, lighting to outlet strips – in nearly every household there are appliances with relevant saving potentials.

By strengthening the awareness of private households through information and direct advice, consumers more likely adapt their use behaviour and thus reduce their energy consumption. Supporting the purchase of energy efficient appliances at the same time can also lead to a decrease of energy costs in private households.

Within the European project 'Common appliance policy – all for one, one for all – energy labels (ComeOn Labels)' [1], Öko-Institut has compiled an overview of a variety of informational tools and financial incentives with focus on replacement of household appliances to enhance the overall energy efficiency. The paper will highlight the overall benefits and results regarding energy savings and reduction of CO_2 emissions of the product related incentive schemes as well as discuss more detailed the different options and possible optimisations for the implementation of such programmes and initiatives.

Introduction - Underlying mechanisms of product related incentive schemes

White goods are generally being used for 10 to 20 years. Therefore, most private households still own a lot of old appliances with significantly lower energy efficiency than that of the best models on the market. And if they do purchase a new appliance, they often choose a product with a low upfront price (and higher follow-up costs); even if a highly efficient product would have the same or lower life cycle costs [2].

By promoting highly efficient appliances, i.e. devices of the best energy efficiency classes, a variety of ecological and economic savings can be achieved. According to [3] two general mechanisms can be distinguished that are briefly explained in the following.

Better replacement

Better replacement means that consumers choose a more energy efficient appliance than they would have chosen without the corresponding policy instrument. The fundamental decision to buy new equipment, however, has already been made. The environmental advantage arises from the lower power consumption of the "better" appliance. A class A++ refrigerator or freezer, for example, consumes about 45% less electricity than an A model of the same size and with the same technical and functional performance characteristics. An A+++ model consumes about 60% less [4]. Furthermore, highly energy efficient products can also be advantageous not only from an energy/environmental point of view. They can be also associated with lower operating costs, resulting in lower overall life cycle costs (i.e. the sum of all product-related costs affecting the consumer including the purchasing price).

Early replacement

Early replacement means the replacement of an (old) installed appliance although it is still working. Whether early replacement is environmentally beneficial or not, essentially depends on two factors: first, on the potential savings due to the reduced energy consumption of the new appliance, and secondly, on the environmental impact of the manufacturing and the disposal of the equipment, since the old equipment's useful life is not fully exploited.

In many product types, there is a large difference between the energy consumption of the average equipment in use and that of the most efficient new appliances available on the market. For example, an average refrigerator-freezer combination bought in 2000 in Germany, usually still quite functional today, consumes about 390 kWh of electricity per year. A class A++ appliance with the same storage capacity and technical and functional performance characteristics, however, only needs 180 kWh per year. Therefore, by replacing the old appliance with a highly efficient new one, around 210 kWh of electricity could be saved each year.

By contrast, the environmental impact (in terms of life cycle analysis (LCA) resulting from the production and disposal of household appliances is in general relatively small. Depending on the appliance and impact category, it accounts for 5-25% of the environmental impact throughout the equipment's entire life cycle (see Table 1).

Table 1: Global warming potential of selected household appliances in different life cycle phases

	Production	Use	Disposal	Source
Washing machines	25%	79%	--4%[1]	[5]
Tumble dryer (condenser dryer of energy efficiency class B	5,7%	94,1%	0,2%	[6]
Refrigerator/freezer combination (200 l + 90 l)	13%	89%	-2%	[7]

From an environmental point of view, therefore, early replacement often pays off. The "environmental payback period" denotes the time after which the environmental impact of the cumulative energy savings outweigh the additional environmental impact from the premature disposal of the old appliance. For the replacement of an average refrigerator-freezer combination manufactured in 2000 by a corresponding A++ appliance, this period is only about 2 years in terms of cumulative energy demand (CED) and global warming potential.

According to current information, valid for Germany, early replacement makes sense in particular for cold appliances, tumble dryers and circulators for central heating, as well as for electric and gas stoves. For other appliances like washing machines and dish washers an early replacement must be checked more carefully. There may be variations between EU Member States, though, mainly due to differences in climate conditions, consumer behaviour, the efficiency of the installed appliance stock and purchasing power.

However, even if environmentally beneficial, early replacement usually doesn't pay off in monetary terms – at least not in the sense that the purchase price of the new appliance will be completely compensated by the cost savings during its use phase. However, usually a noticeable reduction of electricity costs can be achieved. When replacing an average refrigerator/freezer combination built in 2000 with a corresponding A++ device, and assuming an average European electricity price of about 17 ct/kWh, about 35 EUR can be saved annually. It is difficult to compare the actual costs of "early" and "later" replacement though, since it is unknown for how long the old appliance would still have been serviceable in the "late" replacement case.

[1] The negative sign means that the disposal even has an environmentally beneficial effect, since the gains from recycling the material outweigh the negative impacts of the disposal and recycling process itself.

General choice of instruments to increase energy efficiency in private households

Overview

There is a variety of policy tools to increase energy efficiency in private households. According to [8] three basic categories of instruments can be distinguished:

1. Informational tools (such as labels, information campaigns)
2. Financial and fiscal incentives (such as direct subsidies, subsidized loans, indirect subsidies)
3. Regulatory tools (such as limit values or minimum requirements for new appliances)

Furthermore, there is the new category of cooperative tools such as voluntary agreements and network building.

In this paper, the focus is laid on the informational tools and financial incentives which will be explained into further detail.

Differences between instruments for better and early replacement

Not all tools and designs are equally suitable for all purposes. While measures to promote early replacements will always result in a better replacement, as they are also available to those consumers who just want to replace their old appliance anyway, the reverse is not true.

If early replacement is to be stimulated and the possible benefits that may be associated therewith are to be realized, certain criteria must be met:

- The measures must provide an appropriate financial incentive to consumers; otherwise there will be no reason to dispose of an old but still functioning appliance prematurely.
- The measures must be limited in terms of time or budget; otherwise consumers will just await the end of their appliance's technical life assuming that the incentive will still be in place by then. On the other hand, they must be long enough to support market transformation.
- The return and proper disposal of the old appliance must be part of the measure, otherwise it may continue to be operated as a spare device or supplied to the second-hand market.
- Also, the implementation of an effective system for the take-back of old appliances supports early replacement. In many EU countries, as a consequence of the WEEE directive, shops are obliged to accept any discarded appliances that customers bring back, independently of its brand or place of purchase.

The following sections list appropriate informational tools and financial incentives promoting particularly efficient household appliances. Labelling with the EU energy label as one example for an informational tool is taken for granted, thus only those going beyond the energy label are considered.

Informational instruments

In the domain of voluntary information measures, the credibility of the initiator or sponsor is relevant for their success. A high level of credibility increases the willingness of manufacturers to participate and the willingness of consumers to initially spend more money for highly efficient products or the early replacement of old appliances.

Communication of life cycle costs

This means consumers are given information on the financial savings they can achieve throughout the product life cycle by purchasing a highly efficient appliance. As we have seen, the argument is mainly valid for better replacement, and less so for early replacement. In contrast to a label only declaring energy efficiency, the communication of monetary information has the advantage that a general environmental benefit of a product is converted into an individual benefit for the consumer.

This is particularly advantageous when broader customer segments beyond the niche are to be addressed.

For example, Öko-Institut is participating in the European project 'YAECI - Yearly Appliance Energy Cost Indication' sponsored by the Intelligence Energy Europe (IEE) programme with the main objective to provide customers with information on the yearly running cost of products at the point of sale, in order to stimulate the uptake of affordable efficient products. [8] In the project running until March 2015, the following activities will be carried out in each participating country:

1. Development/ replication of a database with yearly running costs for the following products: cold appliances, washing machines, dishwashers, dryers, televisions;
2. Recruitment of retailers (in addition to the retailers who have already committed to participate at the start of the action);
3. Provision of information on yearly energy costs at the point of sale (shops) and on websites where the energy labelling class is shown of participating retailers;
4. Update of information on yearly running costs every 12 months;
5. Evaluation of the impact of the action.

Further on, there are several Internet platforms that present life cycle costs or at least operation costs/energy costs together with the presented products. One example, covering several European and non-European countries with specific websites is topten.info. In Germany the consumer information website EcoTopTen [9] presents the life cycle costs of energy efficient products in comparison to an average product of the same product category at its, see also next point.

Market overviews and product databases

Market overviews and product databases such as the German website www.ecotopten.de provided by Öko-Institut [10] or the European website www.topten.eu [11] facilitate the purchase process by providing potential purchasers with an overview of efficient products, their features and prices, and eventually their life cycle costs under average conditions. Hence, they are rather a tool for better replacement. They may be provided by different actors, such as national energy agencies, manufacturers' associations, NGOs or other independent bodies. An innovative element is the inclusion of a price competition, enabling potential customers to inform themselves not only about the average purchase price of the desired product but also about the cheapest supplier. With this method, the Danish site www.hvidevarepriser.dk achieved a major price reduction: Within three weeks, the recommended retail prices fell by 20% [12].

Additional voluntary labelling

In addition to the mandatory EU energy label, there are voluntary ecolabels both on EU level and in some national states (such as the German Blue Angel, the British label "Energy Saving Recommended" and the Danish Energy Saving Label.) The goal is to particularly reemphasize highly efficient products or products that, beyond the energy savings, meet further environmental and quality criteria. This measure can especially promote better replacement.

Voluntary labels can generally be quite cost-effective. A harmonization with other tools (e.g. GPP, incentive programs) and a regular update play a crucial role. So far, however, it could not yet be demonstrated that one of these voluntary schemes had a market transformation effect reaching beyond that of the EU energy label.

Information campaigns

Information campaigns must accompany many other instruments in order to draw consumers' attention to the existence of that instrument. Especially when aiming at early replacement, a comprehensive information campaign aimed at the general public is important in order to reach those consumers who are not currently facing a purchase decision and actively searching for information.

Information campaigns are relatively inexpensive. Their effectiveness, however, is difficult to assess. Just like voluntary labelling, they are generally more effective in combination with other tools (e.g. incentives for replacing an old appliance with an efficient new one).

Measuring energy consumption

The measurement of the energy consumption of appliances in private households is an appropriate measure to promote early replacement. Firstly, it may raise the consumer's awareness to an associated cost. Secondly, it can form an integral part of a broader programme. For example, in-house measurement may be used to determine the eligibility of a household / appliance to participate in a subsidy program.

Financial incentives

Direct incentives to consumers

The basic idea is to provide consumers who buy particularly efficient appliances (which are at the same time disposing of an old appliance) with a financial reward. This is one of the most popular instruments. Examples of national programmes abound, and there are even more examples of programmes set up by trade, manufacturers or energy companies.

If the measure is limited in terms of time or budget, rather early replacement will be stimulated. If it is planned on a long-term basis (i.e. over several years), better replacement is promoted more or less ad infinitum, thus bringing forward falling prices and a longer-term market transformation. Early replacement, however, is stimulated to a smaller extent, as there is no incentive to replace the old appliance unit as quickly as possible.

In the design of incentives, a number of conceptual questions need to be answered, impacting on the success of the measure:

- Target group (e.g. restriction to low-income households or households with particularly energy-intensive appliances?)
- Appliance groups to be promoted
- Criteria for incentive / requirements to be met by the appliance
- Amount of incentive (high enough to have visible effects; low enough to avoid free riders; differentiated according to appliance type and efficiency? differentiated for household income?)
- Duration of measure
- Organizational implementation of premium payment (e.g. by retailers or national agency?) and take-back of the obsolete appliances.

Incentives are often effective, but not always cost-efficient, which is due to free riders. To be cost-efficient, measures should focus on very innovative appliances currently still having high purchase prices, but a good potential for reducing them by economies of scale.

For example, in 2009 Öko-Institut was commissioned by the German Federal Ministry for Environment to develop an implementation concept for a product related subsidy scheme within the German Federal Climate Protection Initiative (NKI). [13] The project prepared concrete implementing measures and developed a master plan for the overall organization of the planned programme. Besides setting of ambitious criteria, the main responsibility of Öko-Institut was to coordinate and balance the different interests of the implementing organisations (Federal Ministry for Environment, the granting authority, the German Energy Agency, the Federation of German Consumer Organisations, the marketing agency) and the market actors (retailers, disposers, hundreds of thousands consumers) to ensure a smooth operation of the programme. Most of the challenges and arising questions could be clarified within the project, for example the advantages and disadvantages of different pay-out options, the proof of disposal, the requirements for products that shall be eligible, the amount of subsidies granted, additional electricity saving advisory services, possibilities for consumer information, as well as implementation of a database for products that shall be eligible. In the end, however, the German Federal Government decided against the implementation of the subsidy scheme.

A variant of the consumer subsidy is the “free giveaway”. For example, a popular measure in a number of countries has been the distribution of free energy saving light-bulbs. The effects are contested, however. First, free giveaways may destroy markets for these appliances. Secondly, free appliances are often not installed by consumers, limiting the effect. In the UK, this type if programme is therefore no more eligible as an energy saving measure under the Carbon Emissions Reduction Target (CERT) scheme.

In Germany, pilot projects (Stromsparcheck and Stromsparcheck Plus [14]) have successfully tested and applied the combination of energy checks and advice together with financial supporting the purchase of energy efficient appliances for low-income households. For example, they received free-of-charge appliances like energy saving lamps, water-saving flow regulators and outlet strips. By these direct installations, CO_2 and energy cost savings could be realized. Further, the project resulted in social benefits as long-term unemployed persons were trained to “energy savings assistants” implementing the energy checks in the households. [15]

A further variant would be to just offer an incentive for disposal of the old appliance, without subsidizing the new one. This could take the form of a bonus for having an old appliance removed.

Fiscal incentives for consumers

Tax incentives have been extremely successful for major household appliances in Italy. But in other countries, they are rarely applied for household appliances. This is probably due to the comparably low purchase price of these devices, and, as a result, of the high administrative costs. Also, the lack of an immediate connection between appliance acquisition and financial benefit reduces the psychological effect. Tax benefits therefore are primarily applied in the building sector, relating to equipment such as boilers, water heaters or air-conditioning systems. They can take the form of tax credits, deductions from income tax or enhanced capital allowances and may be financed by an energy tax which is "returned" to consumers in the form of appropriate incentives. Depending on operational features (limited in time or not), tax incentives can be appropriate means for both better replacement and early replacement.

Another variant is to reduce the VAT rate and thus the selling price for highly efficient appliances. However, due to EU VAT rules, reduced VAT rates may only apply to building-related measures, such as water heaters [16]. Furthermore, appliance manufacturers are sceptical of this measure, as the subsidy is not transparent to the consumer. Seeing only the final price, consumers might believe that highly efficient appliances are cheaper to produce than ordinary equipment, and their willingness to pay will (further) decline. All in all, these reasons suggest that this tool is not recommendable.

Tax incentives can be both effective and cost-efficient but there are also other cases where they showed little effect and high windfall profits. A windfall occurs when individuals are funded by the State for an action that they would have made even without State support. The higher the windfall, the lower the effectiveness of the measure. For an example of high windfall profits of 70-80% from modernising insulation of buildings see [17].

Therefore, design details are crucial. Among the criteria of success are: reliability, good timing, stakeholder participation and accompanying information measures, regular updates, appropriate level of requirements, selection of appropriate appliances (in most countries, products whose purchase price proves to be a major hurdle).

Indirect subsidies

In the case of indirect subsidies, as practised in the "Eco-point" system in Japan or the Korean "Carbon Cashbag", consumers obtain credit "points" instead of money upon the purchase of a highly efficient product [1]. Then, these points can be traded for certain products or services (e.g. for discounts in public transport, for other environmentally friendly products, cultural events, etc.). Another variant is that consumers can acquire vouchers or bonus points when they buy other products, or as a bonus on their salary, which can then be used to purchase highly efficient appliances.

The advantage of such indirect subsidies as compared to the disbursement of money is that the type of products or services that can be bought to receive the subsidies can be influenced. This can at least reduce direct rebound effects (when subsidies / refunds are used to purchase flights or other products with high CO_2 intensity).

Bonus/malus programmes

Bonus / malus programmes aim at adjusting the price of energy-using products according to their efficiency. When buying a highly efficient appliance, an allowance (bonus) is granted to the consumer, while he or she must pay an additional amount (malus) on purchase of a particularly inefficient product. When buying an average appliance, neither a bonus nor a malus does accrue.

The advantage of this tool is that it can be set so that it will either generate net revenues, that it will be revenue-neutral, or that subsidies will be needed. In designing the instrument, it is important that the threshold value between bonus and malus (i.e. the average efficiency) will be regularly adjusted to the market development. Due to the malus element, this is a tool to promote better rather than early replacement, as consumers buying less efficient appliances will actually be penalized.

So far, there is only one example, namely for automobiles in France. Here, the tool was linked to the CO_2 emissions, which has proven to be very effective. The market share of cars of emission class B has risen from 20 to 33% while the share of class G cars has been halved. An extension of the scheme to other products is being discussed.

Micro-credit models

Micro-credit models aim at eliminating the hurdle of high upfront costs by granting advantageous loans for the total purchase price or a part thereof. They are currently mainly used in the building sector and less for household appliances. The advantage may either reside in subsidized loans (low / no interest rates) and/or in a specific repayment mode, i.e. the loan will be repaid through the savings resulting from the lower energy consumption during the use phase. The latter is also known as "contracting". Credits/loans may be offered by different actors, such as governments, independent agencies, energy providers or third parties (e.g. ESCOs, Energy Service Companies).

- Government loans are generally only relevant in the building sector. Due to high transaction cost, they are not yet granted for household appliances.
- Due to various barriers, loans by third parties are only granted to a small extent, so far. Government subsidies could, however, stimulate the granting of loans by third parties.
- When loans are granted by energy providers, the latter installs energy-efficient appliances, which are paid with the monthly energy bill. The savings in energy consumption costs at least partly offset the costs for the installation of the device. There are both the credit and the rate variant: While the credit is tied directly to the customer, who has to pay it back even if he moves house, the rate is bound to the consumption meter and thus to the real estate. The rate option has the advantage that even tenants can participate without taking a greater risk.

This measure is mainly suitable for better replacement. It can be used for early replacement, too, if it would be temporary limited so as to provide an incentive to immediately replace the old appliance, and connected with a return of the obsolete appliance.

One problem that is encountered with this tool is that it often fails to reach the neediest households as well as tenant households. Further issues are high costs associated with the programme, the low participation rate, and the difficulty to make realistic estimates of the savings in advance.

Financial incentives for producers (upstream incentives) or retailers and installers (midstream incentives)

Producers may receive financial incentives to produce and sell more highly efficient appliances or to reduce their prices. Lower consumer prices improve the conditions both for better and early replacement. Such incentives may, for example, take the form of tax credits per produced unit or of a grant if certain criteria are met. Such incentives are particularly effective when the market is dominated by a few large producers that are present in all countries.

Furthermore, as a tool for better replacement, sales personnel or installers receive (financial) incentives to sell particularly efficient appliances. Hence, they will preferentially offer these appliances highlighting them in their sales discussions.

As compared to incentives offered directly to consumers, benefits of upstream or mid-stream incentives may be:

- lower transaction costs, because the number of manufacturers or retail companies is significantly lower than the number of consumers. Also, instead of many different criteria influencing the private consumer’s buying decision, profit is basically the only decision criterion in companies;
- lower incentive needed, as trade margins and taxes are avoided;
- lower total costs for the state, as losses in the electricity tax and costs of the tax relief are compensated by increased VAT revenues and increased corporate in-come taxes.

On the other hand, these instruments contribute less to consumer awareness and sensitization. Also, compared to end user rebates, it is mostly retailers and manufacturers who profit financially. Distributional effects therefore have to be considered.

Outlook: Integrated strategies

Integrated strategies combine several of these tools. In Denmark, for example, there have been three campaigns aimed at promoting highly efficient refrigerating appliances, combining a subsidy with an aggressive marketing campaign and a website launched to enable consumers to search for products and to compare prices. Another Danish campaign, targeting highly efficient circulators, linked voluntary agreements with manufacturers, retailers and installers with a voluntary labelling and a proactive marketing. A programme to replace old refrigerators in Oregon combined information measures, measurement of the household’s energy consumption, personal contact, financial incentives and comprehensive services for households.

In addressing different phases of the market launch process as well as different barriers, sophisticated combinations have proven to be more powerful than individual measures. Therefore it is suggested to consider an adequate bundle of single measures, addressing e.g. manufacturers, retailers and consumers and using different ways of addressing and involving people (e.g. personal contact, websites, interactive communities) when developing a new incentive scheme.

An Investigation of China's Subsidy Program for Energy-saving Products

ZHENG Tan, HU Bo, LI Jiayang, ZENG Lei

TOP10 CHINA & CLASP

Abstract

Subsidy is used in many countries as an important instrument to promote energy-saving products. China started subsidizing energy-saving products, including light bulbs and automobiles, in 2009. The subsidized product groups quickly expanded to major home appliances such as air conditioners, flat-panel TVs, refrigerators, washing machines and water heaters. The latest subsidies for purchasing the five types of energy-saving products reached 26.5 billion RMB since June 2012. It is expected that even larger financial budgets from the Chinese government will be allocated to support the wide deployment of high energy efficient products according to the national 12th Five-Year-Plan, which adopted the "energy conservation and emission reduction" as the national long-term development strategy.

In this paper, the policy framework of China's Subsidy Program for Energy-saving Products is reviewed. The recent subsidy schemes for air conditioners, flat-panel TVs, refrigerators, washing machines and water heaters are introduced. Based on retail market data, an investigation of the market status for the five types of products is conducted. The subsidy schemes are analyzed in terms of products' properties such as type, size, energy efficiency tiers, price, functional capacities etc. This paper concludes with suggested options to improve the subsidy program.

Introduction

In order to mitigate climate change and sustain human development, changing the way in which we use energy is more economically efficient than simply increasing the energy supplies. Energy efficiency was addressed by the Mckinsey & Company [1] as a cost-effective tool to fulfill this goal. In the last three decades, much effort has been made on promoting energy efficient appliances and equipment including technologies, regulation measures (e.g. MEPS - Minimum Energy Performance Standards - and mandatory labeling schemes such as Energy Label in China and Europe), financial incentives (e.g. tax, electricity price etc.), voluntary actions (e.g. endorsement labels such as "Energy Star" in USA) and more. Among financial incentives, subsidies are widely used in various ways to increase market penetration of energy-saving products in developed economies such as Europe [2] and USA [3].

China is now the world's largest carbon emitter [4]. With China's fast urbanization and increasing deployment of electrical appliances, the share of residential electricity consumption over total electricity consumption went up from 3.5% in 1980 to 12.5%[1] in 2012. Given the continuing trend in middle class growth, the residential electricity consumption in China will remain high in the coming years. Additionally, China has become a dominant player globally, which produces the majority of the world's home appliances. A report[2] showed that the nation's production capacity of color televisions accounted for 80% of the world's total. The production capacity of air-conditioners, refrigerators and washing machines also accounted for 70%, 50% and 40%, respectively. In August 2012, the State Council issued the 12th Five-Year-Plan on Energy Conservation and Emission Reduction in which China announced a goal of 16% cuts in energy consumption per unit of GDP by 2015 along with carbon dioxide emissions set to be cut by 17% from 2010 levels. This strong political commitment has led to a series of policy initiatives in which the so-called "Jienenghuimin" project [5] (a project to promote energy-efficient products for the benefit of the people) is a key subsidy program during this

five-year period to stimulate demand for products and drive market transformation towards higher energy efficiency.

China had subsidized efficient lighting products since 2008. Based on a series of important decisions (Guofa [2006] No.28 and Guofa [2008] No.23, see Table 1) made by the State Council, the "Jienenghuimin" project was initiated in June 2009. Together with the lighting products, air conditioners and cars were included into this program. The subsidies are given to manufactures by the central government. The participating manufactures must register to the program according to implementing rules for a specific product category. Additional cost between an energy-efficient model and an inefficient one is determined and taken as the subsidized amount to remove the purchase barrier for expensive efficient products. In general, the manufactures/retailers pay customers cash first (except cars) and they can only get the subsidy back from the government when they fulfill mandatory requirements such as a certain amount of registered models were sold, all procedures are proper and they pass the monitoring inspection etc. The energy efficient appliances are defined in national energy efficiency standards by "evaluating values of energy conservation" which is the minimum requirement for energy-efficient products certification (a voluntary endorsement label). The evaluating values of energy conservation also determine tier 2 products in the mandatory China Energy Label. Under this context, energy efficient appliances are known as those products which have the energy-efficient products certification, and those which are ranked tier 2 and tier 1 in China Energy Label. By the end of the 2010, 16 billion RMB were spent and 34 million efficient air conditioners, 1 million efficient cars and 360 million efficient lighting bulbs were sold and subsidized. The market share of energy efficient products has been highly increased, e.g. the market share of energy-efficient air conditioners increased from 5% to 70%. It was estimated that through this round of subsidies, 120 billion RMB of domestic demand was stimulated, 22.5 billion kWh of electricity was saved annually and 14 million tons of CO_2 emissions were reduced[3].

Note: Analysis is based on the highlighted policy documents in this paper.

From June 2012, a new round subsidy program with a larger scale of budget (26.5 billion RMB) has started and it covers five major household appliances including flat-panel TVs, air conditioners, household refrigerators, washing machines and household water heaters. Under such context, questions are raised, for example, how will this new policy shift the market? Can the regulation measures such as MEPS and labeling schemes effectively support this policy? How can you make this policy an opportunity to save more energy? To answer these questions, we reviewed this new

---

[3] Data published by National Development and Reform Commission. http://www.sdpc.gov.cn/xwfb/t20111009_437354.htm (in Chinese and read in February 2013)

policy and investigated the Chinese retail market for these five kinds of products. Based on our analysis, we introduced our findings and provided recommendations to improve the effectiveness of this policy.

China's MEPS, Labeling and Certification System

As the technical basis of implementing financial incentives for energy-saving products such as government procurement and subsidy programs, China has built an energy efficiency standards, labeling and certification system (see Figure 1).

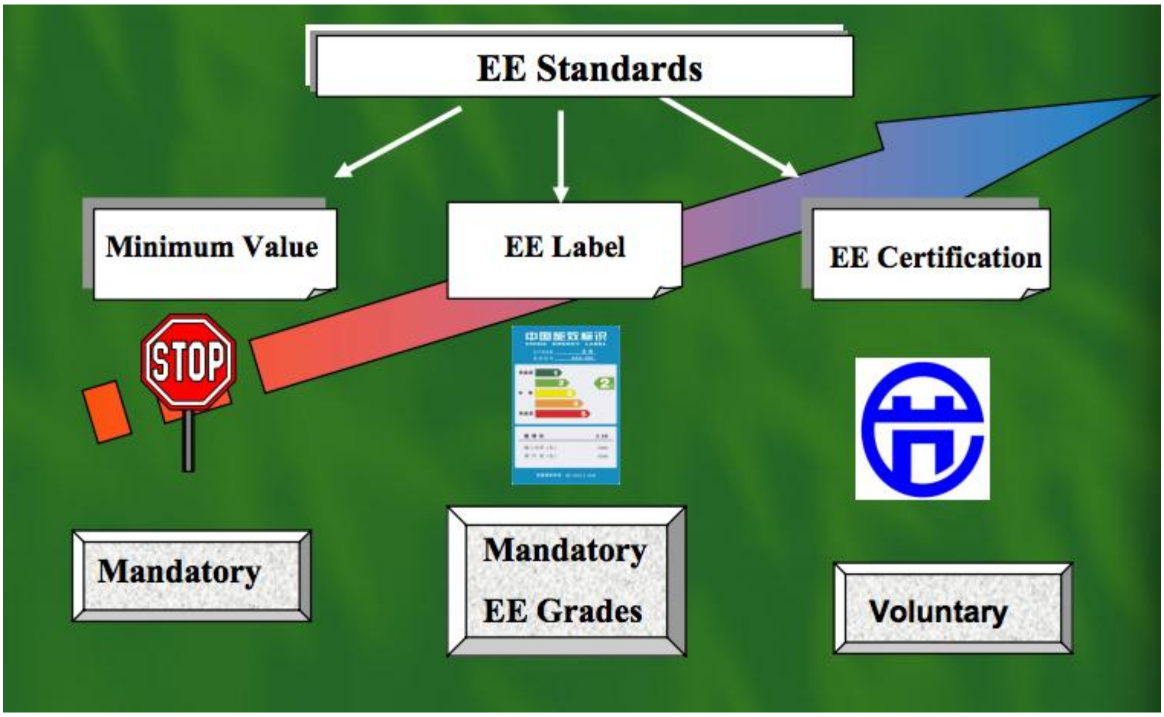

Figure 1: China's Energy Efficiency Standards, Labeling and Certification System (source: Cheng Jianhong, China National Institute of Standardization (CNIS), March 2009).

Figure 1 helps explain that the Minimum Energy Performance Standards (MEPS) eliminate inefficient products from the market. Comparative labeling and grading schemes (the mandatory China Energy Label) create market transparency that is particularly helpful for consumers to select energy efficient products, while the voluntary endorsement certifications (with energy efficient products labels) encourage manufactures to produce more high energy efficient products and to keep innovating energy-saving technologies.

From 1989 to 2012, China has established 48 MEPS covering household appliances, lighting equipment, commercial equipment, industrial equipment, vehicles and office equipment. Adapted from the EU energy label, China launched the mandatory "China Energy Label" [6] in 2005. As a comparable information label, three or five tiers are defined in the product MEPS. Tier 1 has the highest energy efficiency; tier 2 specifies the evaluating values of energy conservation for the product, which are the minimum requirements for energy-saving product certification; and the last grade (3 or 5) sets the minimum allowable values of energy efficiency, which are the threshold of market access. The principles of setting standards and grading the products are based on market statistics. To ensure a reachable value and enough product availability, top 15%-20% products in the market are identified as energy efficient products (tier 2 and tier 1). 10%-15% are to be eliminated as inefficient products from the market, and the rest in the middle are pushed to reach a higher level of energy efficiency. By the end of 2012, China Energy Label had covered 27 product categories. The MEPS and energy label information for the five subsidized products can be seen in Table 2.

Table 2: China's MEPS and energy label for the target five subsidized product categories.

Product	MEPS Reference	Standard Implementation Date	China Energy Label Implementation Date	Energy Efficiency Tiers
Flat-panel TVs	GB 24850-2010	2010-12-1	2011-3-1	3
Variable speed air conditioners	GB 21455-2008	2008-9-1	2009-3-1	5
Fixed speed air conditioners	GB 12021.3-2010	2010-6-1	2005-3-1	3
Refrigerators	GB 12021.2-2008	2009-5-1	2005-3-1	5
Washing Machines	GB 12021.4-2004	2005-5-1	2007-3-1	5
Gas water heaters	GB 20665-2006	2007-7-1	2008-6-1	3
Solar water heaters	GB 26969-2011	2012-8-1	2012-9-1	3

Based on these MEPS and the energy label implementing rules, the subsidy schemes were made and implemented for each product category. Since tier 2 specifies the minimum requirement for energy-saving product certification, the subsidies usually went to the models that fulfill energy efficiency requirements for tier 1 and tier 2. However, technologies innovate very quickly and the market transforms all the time, so the regulation measures, including MEPS, labeling and subsidy schemes, shall follow the market and change themselves accordingly.

We investigated market status of the target subsidized energy efficient products. The model-based distribution of energy efficiency tiers of each product is illustrated in Figure 2.

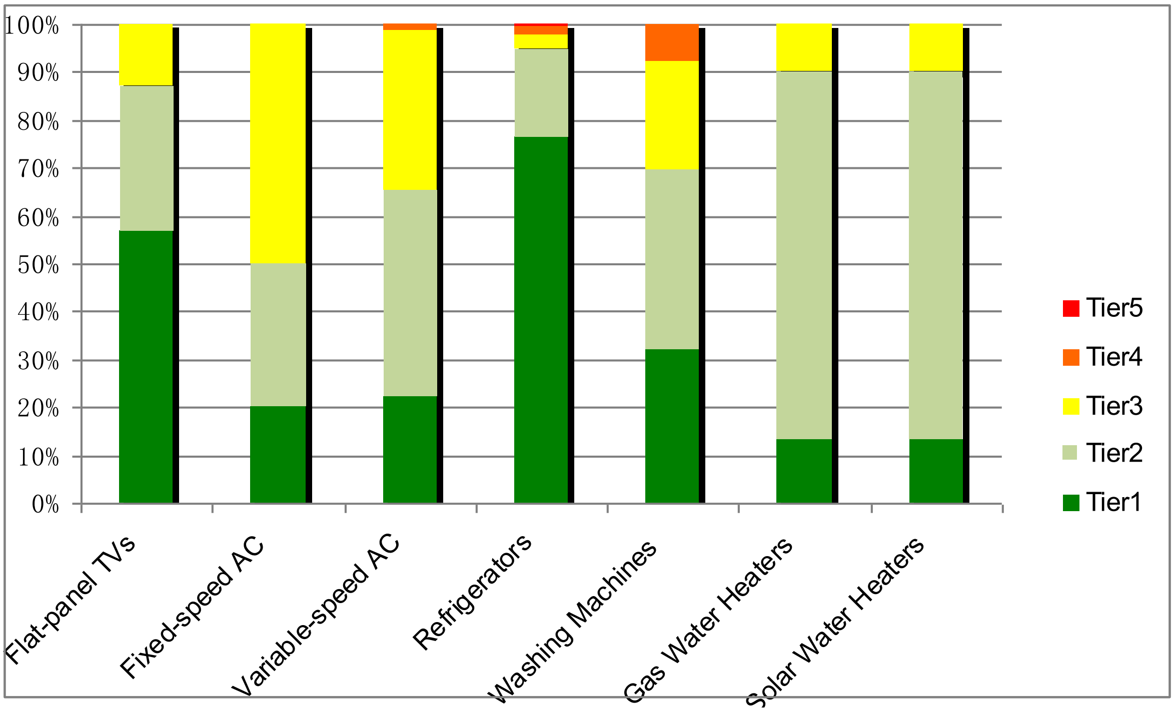

Figure 2: Distribution of energy efficiency tiers for target subsidized energy using products on Chinese retailer market by May 2012 (model based without sales data).

The share of tier 1 products for refrigerators, flat-panel TVs and washing machines are 76%, 57% and 32% respectively, which is too high to determine the actual energy efficient products. About 77% models of gas water heaters and solar water heaters are tier 2 products, so this is too hard to tell they are actual energy-saving products although all of them may have the energy efficient products certification. The share of tier 1 together with tier 2 products for the five products is all more than half of the models, so that subsidies shall not simply go to tier 1 and tier 2 products, but be used for those actual top efficient products.

Subsidy Schemes & Analysis

Our analysis was conducted on an available product model (*not sales*) basis. Several data sources including retailers, independent market research companies and labeling programs were integrated into one database for the analysis. It examines product type, size, energy efficiency tiers, energy consumption and efficiency index, price, functional capacity etc, and the correlation between these factors. In the following we review the policy, present our main findings and introduce what our analysis means to the subsidy schemes and how the policy can systematically be improved. The detailed subsidy schemes and analysis for each product are introduced as follows.

Flat-panel TVs[4]

MEPS for flat-panel TVs (GB 24850-2010) regulate two basic types of flat panel technologies that dominate the television market, Plasma Display Panels (PDPs) and Liquid Crystal Displays (LCDs). LCD televisions break down further into two types differentiated by the backlighting source, either Cold Cathode Fluorescent Lamps (CCFLs) or Light Emitting Diodes (LEDs). During 2008 and 2009, backlighting technologies have been rapidly innovated and in particular, the high efficiency LED has replaced traditional CCFL and become the dominant backlight in China's market. In June 2012, we analyzed 2337 models of which 66% were LED, 28% were CCFL and only 6% were PDP. Because of this fast technology upgrading, the market shifts to higher efficiency rapidly and 80.9% (see Figure 3) of LCD TVs based on LED backlight technology can reach the energy efficiency level Tier 1.

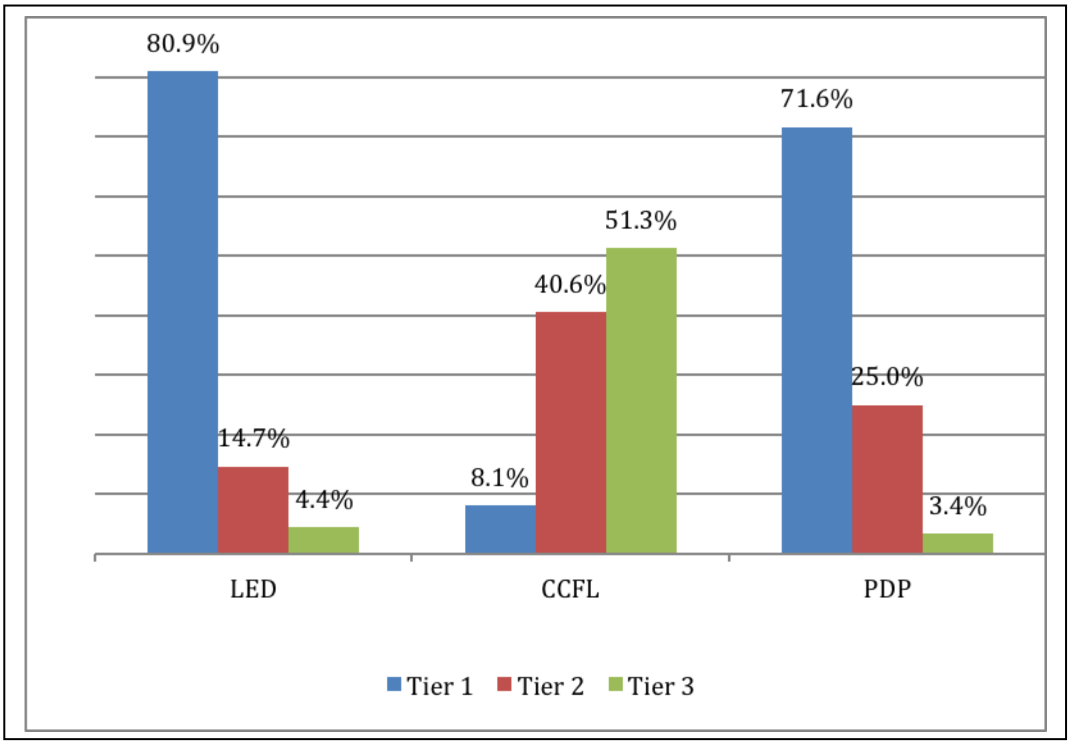

Figure 3: Distribution of televisions on the market in July 2012 across the 2010 energy efficiency standard tiers (note derivation of EEI's not comparable between LED/CCFL televisions and PDP televisions)

[4] http://www.sdpc.gov.cn/zcfb/zcfbqt/2012qt/t20120529_482367.htm

The latest subsidy program (see Table 3) only supports flat-panel TVs with EEIs higher than the current Tier 1 (GB 24850-2010) requirement. This illustrates policy makers are aware that the current Tier 1 requirements for LCD and PDP televisions are not sufficiently high to reflect the current levels of higher efficiency televisions. Further, the subsidy thresholds set suggest EEIs of 1.7 for LCD and 1.4 for PDP represent energy efficient products, and EEIs of 1.9 for LCD and 1.7 for PDP represent highly energy efficient products.

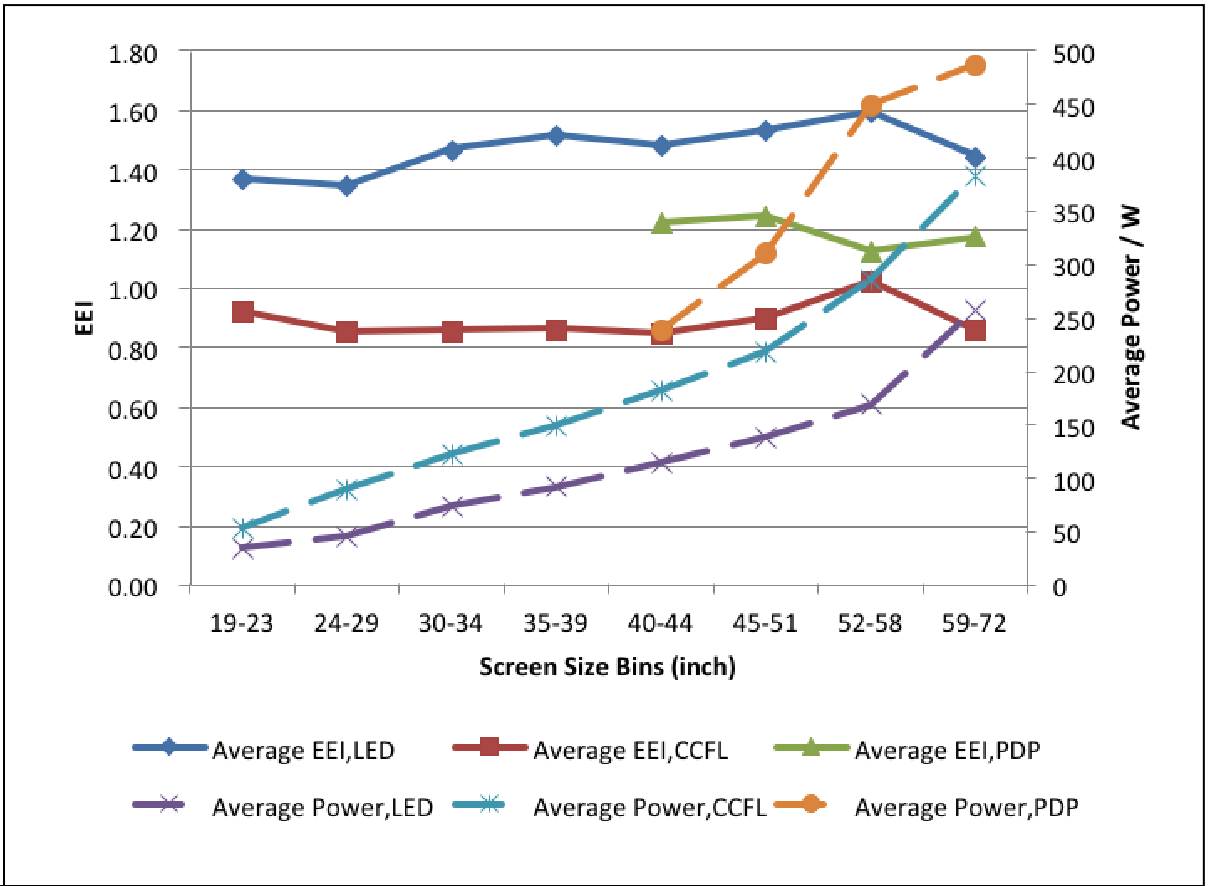
Table 3: Subsidy scheme for flat-panel TVs of varying efficiency and screen size (Energy Efficiency Index values calculated using GB 24850-2010).

Screen Size (inches)	**Liquid Crystal Display - LCD (RMB/Unit)**		**Plasma Display Panel - PDP (RMB/Unit)**	
	EEI>=1.7	**EEI>=1.9**	**EEI>=1.4**	**EEI>=1.7**
19-32	100	150	-	-
32-42	250	300	250	250
42 and above	350	400	350	350

However, in the coming MEPS revision draft, the proposed minimum energy performance requirement (MEPR) for LCD and PDP are 1.7 and 1.4, respectively. This means these values will be the requirement as an entry level. In this case, it reflects that the requirements for this subsidy policy are not stringent enough as declared to be only for efficient products, and most of the televisions on the market could benefit from it.

Secondly, there is only EEI and passive standby power information on the energy label so ordinary consumers are highly unlikely to understand the meaning of EEI. They don’t have any idea how much energy the TV consumes per day for a certain time of use. This gives the consumer no indication that that a PDP television is actually consuming significantly more energy than an equivalent LCD model, and thus removes the consumer’s ability to chose the fundamentally more efficient LCD television with the associated lower energy consumption. The reason is that the EEI thresholds defined in the MEPS for LCD and PDP televisions are not directly comparable. A compensation coefficient “$EFF_{PDP,ref}$” is defined to calculate EEIs for PDP televisions on an equivalent basis to LCD televisions. It means that both technologies can “fair play”, however without adoption of the “technology neutrality” approach as well as the information transparency for energy consumption, the energy label loses its nature of “saving energy by information”. We believe that the PDP TVs shall not be subsidized anymore and subsides shall only go to energy-saving technologies such as LED.

We also found that there is no energy consumption cap in the subsidy schemes, i.e. from the point of view of saving energy, subsidy program should exclude extremely big size TVs such as TVs over 60 inches because, based on the actual living condition in China, TVs bigger than 60 inches could be regarded as luxury products with very high energy efficiency but TVs consume more energy when they are bigger (See Figure 4) and should not be encouraged for purchase if a relatively smaller size product could meet the needs. TVs with bigger size get more subsidies. This will encourage



consumers to buy big sized TVs which consume more energy. Of course, the subsidy program has also goals to stimulate the domestic market and boom the economy. But without having a cap to control the total energy consumption, the "Jevons paradox" might happen.

Figure 4: Relationship between the energy efficiency index, power and screen size of televisions*

*Due to limited data availability, the data of power is not complete for all models. Power data was available for 1,547 models consisting of 925 LED models, 520 CCFL models and 102 PDP models.

Air conditioners

Fixed speed air conditioners were within the first batch of subsidized products in 2009. The subsidy scheme is listed in Table 4. Both the fixed and variable speed air conditioners are included in the latest subsidy program from June 2012 to May 2013. The subsidy scheme is shown in Table 5.

Table 4: Subsidy scheme for fixed-speed air conditioners (2009 ~ 2011).

Cooling	2009.6 ~ 2010.5[5] (RMB/Unit)	2010.6~2011.5[6] (RMB/Unit)

5 http://www.sdpc.gov.cn/zcfb/zcfbqt/2009qt/t20090525_281606.htm

Capacity (W)	Tier 1	Tier 2	Tier 1	Tier 2
CC≤2800	500	300	200	150
2800<CC≤4500	550	350	200	150
4500<CC≤7100	650	450	250	200
CC>7100	850	650	/	/

Table 5: Subsidy scheme for fixed-speed and variable-speed air conditioners (2012).

Cooling Capacity (W)	Fixed speed air conditioner (RMB/Unit)		Variable speed air conditioner (RMB/Unit)	
	Tier 1	Tier 2	Tier 1	Tier 2
CC≤4500	240	180	300	240
4500<CC≤7100	280	200	350	280
CC>7100	330	250	400	330

It was reported [7] that during the first subsidy period (2009-2010), the subsidized price (i.e. original price minus the subsidy) of an efficient air conditioner, with power consumption of around 1.5HP (horse power), was cheaper by 2000 RMB for tier 1 products, and by 1500 RMB for tier 2 products than its original price. It is clear that the latest subsidy scheme for air conditioners is not as generous as in the first phase. We found that taking the subsidy into consideration, it cannot sufficiently close or reduce the price gap between tier 1, tier 2 and tier 3 products (see Figure 5).

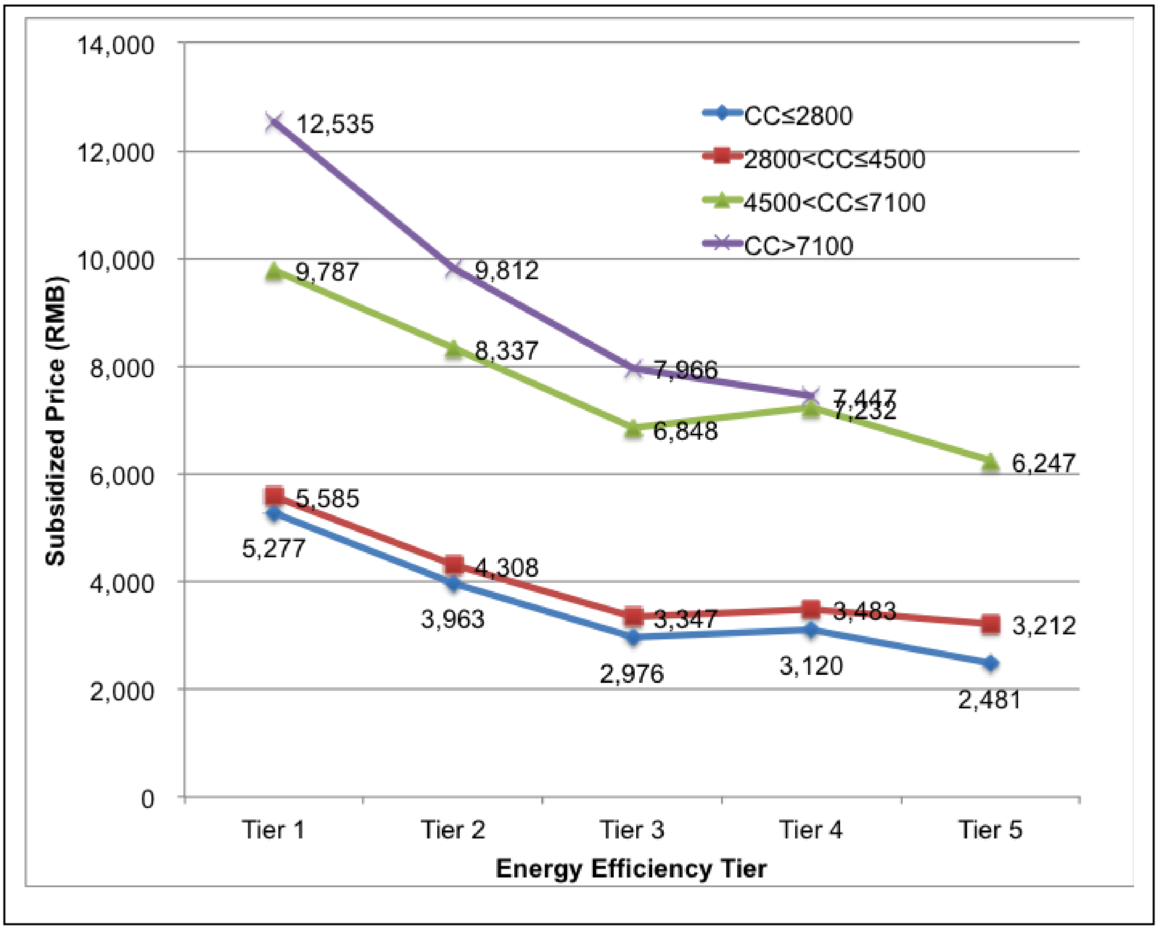


Figure 5: Subsidized average price of each efficiency tier in four cooling capacity groups

The price gaps and the increasing rate are shown in the Table 6.

[6] http://www.sdpc.gov.cn/zcfb/zcfbqt/2010qt/t20100511_346219.htm

Table 6: Price gaps and increasing rate among the tiers.

Tier	Price Gap (%)				Price increasing rate (%)			
	CC≤2800	**2800<CC≤ 4500**	**4500<CC ≤7100**	**CC>7100**	**CC≤2800**	**2800<CC ≤4500**	**4500<CC ≤7100**	**CC>7100**
1~ 2	1,399	1,345	1,519	4,287	33	30	18	37
1 ~ 3	2,584	2,550	3,289	7,814	86	76	48	98
1 ~ 4	2,457	2,402	2,905	8,332	79	69	40	112
1 ~ 5	3,097	2,673	3,890	6,880	125	83	62	77
2 ~ 3	1,184	1,205	1,769	3,526	40	36	26	44
2 ~ 4	1,058	1,057	1,385	4,045	34	30	19	54
3 ~ 5	1,697	1,328	2,371	2,593	68	41	38	29

The price difference between high efficiency products and lower efficiency products is so great that the higher tier models are at least 20% more expensive than those in lower tiers. Potentially, the price gap is large enough for the consumers to switch to the low efficiency products when they make their purchasing decision. It is speculated that the actual manufacturing costs of the high efficiency products are not as high as reflected by the price differences, as shown above. It is possible that the manufacturers and retailers are using the high efficiency tiers as a marketing tool to boost the retail price.

Refrigerators[7]

The implementing rules for subsidizing refrigerators took effect on June 4, 2012 with subsidies for energy-efficient refrigerators ranging from 70 RMB per unit to a maximum of 400 RMB per unit, depending on efficiency tiers and refrigerator type. The detailed subsidy scheme is shown in Table 7.

Table 7: Subsidy scheme for household refrigerators (2012).

Refrigerator type		**Subsidy Amount (RMB/Unit)**	**Energy Efficiency Requirement**
Freezer, Fridge/Freezer	Total Storage Volume (TSV) ≤120L	70	Energy Efficiency Index (η) ≤ 50% Tier 1
	120L< TAV ≤ 300L	130	
	TSV > 300L	180	
Fridge Freezer, frost-free fridge freezer	TSV ≤ 240L	260	η ≤ 32%
	240L < TSV ≤ 300L	330	
	TSV > 300L	400	η < 40% Tier 1

China Energy Label for refrigerators does have energy consumption information (kWh/24h), but there is no Energy Consumption Cap included in this subsidy scheme. It is still designed according to the EEI that is calculated as the ratio of the measured energy consumption of the unit during the test to the baseline value (maximum allowable value was proportionally set to the baseline value) of energy consumption. Since 90% of the available models in the retailer market are fridge freezers, we investigated 1143 of them in terms of EEI. 73.8% are tier 1 products and 248 models' EEI are lower than 32%. This indicates the subsidy scheme could be more stringent and the MEPS needs to be revised as well.

By the end of November 2012, 4197 refrigerator models had been registered and will be covered by the national subsidy programs. While it is possible that the subsidy has fulfilled its primary focus of stimulating demand for products, it appears the secondary goal of driving higher product efficiency

[7] http://www.sdpc.gov.cn/zcfb/zcfbqt/2012qt/t20120608_484887.htm

has not been fulfilled. It appears the subsidy program for refrigerators was designed based on outdated product information and thus a very high proportion of refrigerators were eligible for the subsidy rather than restricted to the higher efficiency products.

Currently 14.3% of the 4197 models that have been registered to receive a subsidy have a storage volume over 300L and will be given 400RMB per unit, of those, 9.1% have a volume over 350L. While sales figures for these models are unknown, the data from GOME[8] suggests that larger units are taking an increasing proportion of the market. If such big amounts of money can be used to subsidize the small and middle-sized refrigerators, the concept of both sufficiency and efficiency can be covered in this program.

Since the manufactures and retailers get more profit from the high-end market of refrigerators and the people who buy these expensive products are less likely to be sensitive to price, the impact of the subsidy is likely to be marginal even when at the maximum subsidy level of 400RMB. Figure 6 illustrates how the bigger the subsidized refrigerator is, the lesser percentage the subsidies account for from the average prices for the initial purchase. China's new subsidies average less than 10% of the appliance cost. Therefore, it is potentially helpful to stop subsidizing money-and-energy-consuming products and instead, add this budget to increase subsidies to attract the customers to buy ultra-energy-efficient refrigerators with the best energy-saving technologies.

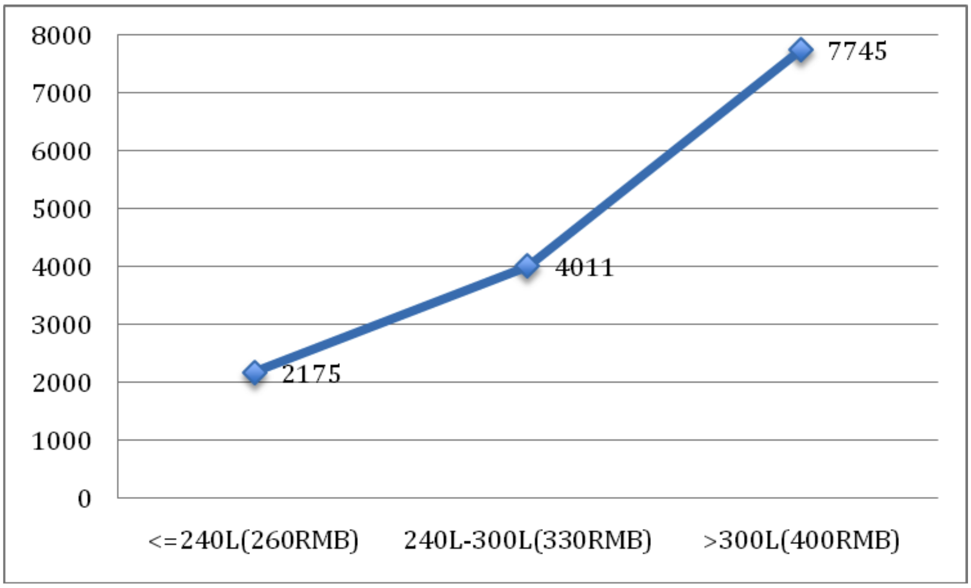

Figure 6: Average prices (RMB) for refrigerators with different subsidized volume groups.

Furthermore, it is found that some manufactures registered their refrigerator models for the subsidy with exactly the minimum value of the required energy efficiency index[9]. This raises risk for the monitors of the policy. To effectively examine and verify such kind of values, it is useful to define the tolerances that the tested parameters shall be subject to, namely each measured value shall be within the allowed tolerance from the value as required or declared.

Washing machines[10]

There are two main technologies of washing machine on the Chinese market: drum (front load) and impeller (top load). GB 12021.4-2004 regulates these two technologies with the same indicators

---

[8] It is estimated by GOME, one of the biggest electrical appliances retailers in China, that the market share of three-door and side-by-side door refrigerators (both of which typically use more energy than their two door top vertical equivalent units) will increase from 50% to 65% in 2012.

[9] http://www.sdpc.gov.cn/zcfb/zcfbgg/2012gg/W020120914638886942311.xls (read in October 2012)

[10] http://www.sdpc.gov.cn/zcfb/zcfbqt/2012qt/t20120608_484897.htm

including energy consumption (kWh/cycle/kg), water consumption (L/cycle/kg) and washing ability. Both types of product are included in this subsidy program and the scheme is shown in Table 8.

Table 8: Subsidy scheme for washing machines (2012).

Product type	EET and Energy efficiency requirements	Subsidy amount (RMB/Unit)
Full-automatic impeller	Washing capacity≤3.5 kg, tier 2 and tier 1	100
	Washing capacity>3.5 kg, tier 1	200
Double barrel impeller	Tier 2 and tier 1	70
Drum	Tier 1, Washing ability≥1.03, Water consumption≤10 L/cycle/kg, Energy consumption≤0.17 kWh/cycle/kg	260

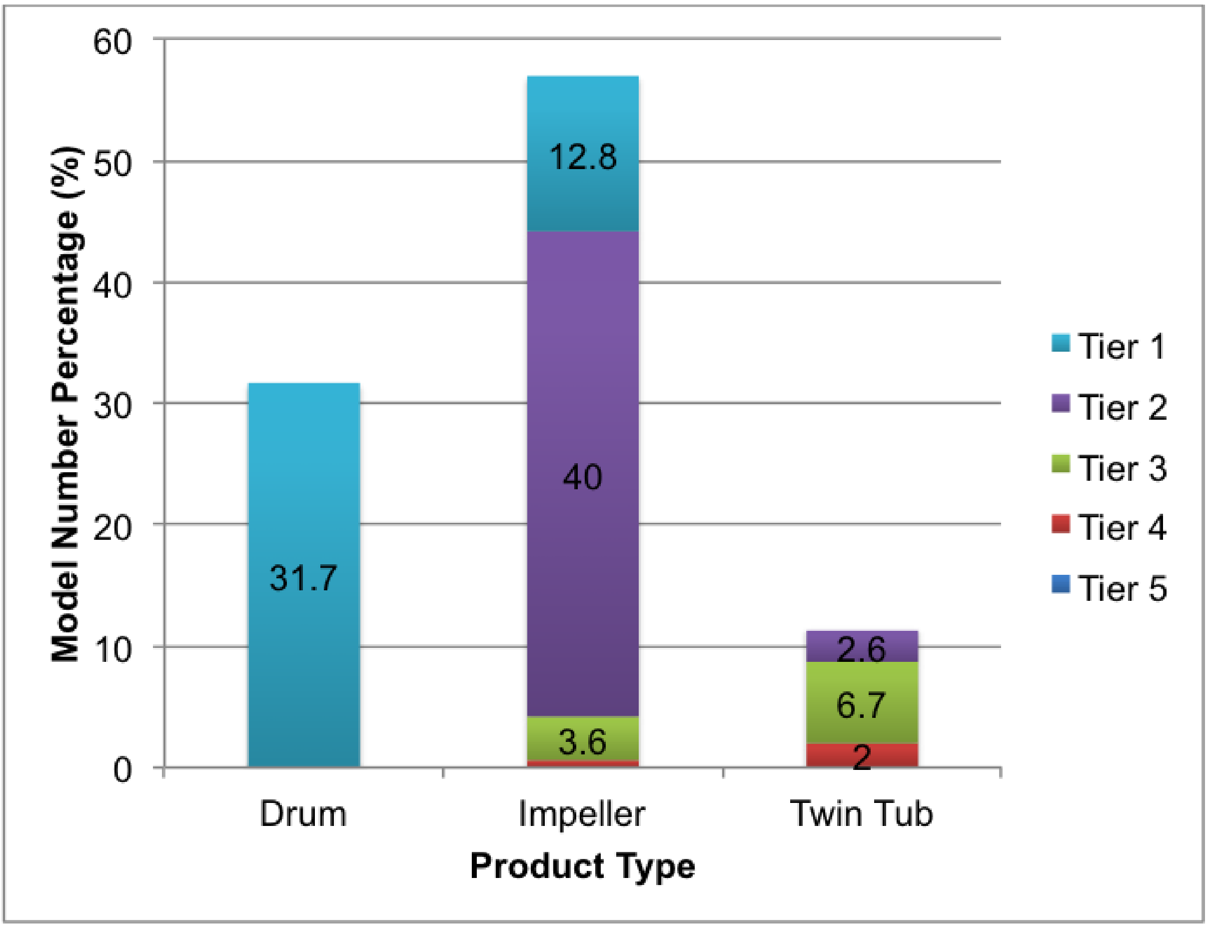

Figure 7: Energy efficiency tier share in different product types

Figure 7 shows all the drum washing machines are tier 1 products, while 25% of the impeller washing machines are tier 1 products. Taking tier 1 and 2 as the energy-saving products which is defined in the standard, there are more than 85% of washing machines that are energy-saving products. Resetting of the MEPS and energy efficiency classification of the washing machine is urgently needed.

Water heaters[11]

The latest subsidy program includes three kinds of water heaters: 1) Gas water heaters, 2) Solar water heaters, and 3) Air-source heat pump water heaters. It was encouraging that the electrical water heater was excluded from the subsidy because such kinds of products waste energy by multiple transformations (coal to electricity, electricity to heat). We found that the subsidy scheme was established before the minimum energy performance standard for air-source heat pump water heaters was available. This implies that the standardization work is sometimes behind the policy and the process time needs to be improved. Due to the current limited data and page, more detailed discussion about this product can be seen in our specific report.

Conclusions

This paper reviewed the latest subsidy program for energy-saving products in China, and analyzed the subsidy schemes for the five target product categories based on a market analysis. Due to the data limitation, we cannot see the full spectrum of the truth, but based on our existing analysis we still arrived at the following conclusions:

1. MEPS need to be revised soon. On one hand, the market share of tire1 models is too high to determine the high energy efficient products, on the other hand, the recent subsidy program needs a more stringent standard to regulate the energy-efficient appliances market. Technology-neutralism is needed to have lowest energy consumption when we receive the same services. In addition, the energy consumption information shall be visible on the energy label to ensure customers have options to select energy-saving products.

2. It is recommended that the new MEPS replace the last tier with a meaningful value according to the models distribution of energy efficiency tiers, and reclassify tier 1 accordingly. We also proposed possible plans, for example reclassification for refrigerators is given based on EEI distribution and the subsidy scheme.

3. The effectiveness of the subsidy program can be improved given the following advices: from the energy saving perspective, subsidies shall only go to top-efficient necessary products (follow the rules of both efficiency and sufficiency), i.e. no wrong signals shall be given to consumers to get the maximum subsidy and buy a big-sized product which is unnecessary, otherwise “Jevons paradox” might happen. Therefore high absolute energy consumption modes (even if it is very efficient) shall not be subsidized; High-end models and luxury products shall not be subsidized, instead, to promote energy-saving technologies for mainstream models, subsidies shall intensively go to those models that have small and medium size. (this statements is from our point of view of saving energy, not considering the economic effect)

4. Many products in Tier 1 and Top10 are made artificially expensive to profit from affluent customers. This needs to be stopped. Subsidy should only go to end-consumer, not manufacturers.

5. To ensure an effective implementation of the energy policies, more enforcement and monitoring measures need to be taken. Tolerance is strongly recommended for the evaluation of the difference between the tested parameter values and the required or declared values, especially during subsidy registration.

Acknowledgement

We thank Mr. Conrad U. Brunner for his insights and guidance, we thank Mr. Zhao Zhonghua for his guidance and support, and we also show appreciation to Mr. Stuart Jeffcott for his comments.

A Review of the Concept of Energy Service Efficiency as a Metric for Assessing the Provision of Energy Services in Residential Buildings

Authors: E. Marshall, J. Steinberger, T. Foxon and V. Dupont

University of Leeds

Abstract

Energy is used in buildings to provide multiple services such as illumination, comfortable temperature, sustenance, hygiene, communication and entertainment. This paper considers the potential methods and metrics for developing a framework to quantify the efficiency of delivered residential energy. If it were possible to provide these same services at the desired levels in more energy-efficient ways, the result would be lower emissions of greenhouse gases without a reduction in welfare of the building occupants. This paper develops the ideas of energy service efficiency as a more rigorous metric by which to choose appropriate low carbon technologies and energy efficiency measures.

The generally accepted engineering definition of energy efficiency as the ratio between useful output to energy input has been studied. The chain through which energy is transformed from primary energy to final and useful energy has been scrutinised under 'energy input', while the metrics for measuring the output have been examined in detail. This will lead to a better understanding and higher level of rigor in the analysis of the concept of service efficiency. Although the concept of energy services has long been considered, there is a dearth of literature focussing on methodologies for measuring the delivered service and on metrics for comparing efficiency.

This paper works towards establishing a tool for future assessment of the performance of low carbon technologies and practices such that the most appropriate options can be applied to individual buildings. The focus is on residentialenergy services, but the approach could subsequently be extended to other services.

1. Introduction

It is increasingly being recognised that the traditional focus for energy planning solely on the energy supply systems has resulted in a limited view of the potential for energy reductions [1], [2]. Expectation that supply can continue to meet an increasing demand lacks the reality that the majority of energy supply worldwide continues to be reliant on fossil fuels, supply of which is not unlimited and results in more intensive and controversial methods of extraction such as tar sands and arctic drilling. With better consideration of the demand side, greater potential for a drastic change to energy systems may be possible.

Energy demand is not a demand for fuels or electricity, it is driven by a demand for the services which energy can provide – comfortable rooms, illuminated spaces, sustenance, hygiene, mobility, entertainment [3–5]. Daly [6] described the 'ultimate end' of these services as 'want satisfaction' and Nørgård [7] extended the full energy chain beyond energy services through 'lifestyle' ('the system in which people organise society and daily behaviour in an attempt to satisfy their needs…constrained by the frames provided by the natural environment and society') and 'welfare' ('well-being, quality of life…the ultimate end of satisfying people's real needs and wants').

The concept of energy services is not novel, and it has formed a part of the business model of energy service companies (ESCos) and energy performance contracts (EPCs) since the early 1990s [8–10]. However, the method of measuring the efficiency of the delivery of energy services has still not been fully developed.

This paper provides the justification behind a new type of metric for assessing the performance of technologies and energy efficiency measures (design and control can also improve energy performance but are not specifically technologies). It is a framework through which different technical, design and operational configurations could be assessed, with the intention of developing the concept of energy efficiency to a more meaningful consideration of the energy required to deliver what people want and need to satisfy their welfare.

In order to identify the potential for this area of development, the concept of service efficiency requires more thorough analysis. This paper provides a review of the work done surrounding this area of research and combines the ideas to present a new methodology for assessing the efficient delivery of energy services. The concept of energy services are introduced in section 2 and the chain of the energy system which goes to delivering these services is discussed in section 3. In section 4, efficiency is explored, commonly defined as a ratio of output to input or the proximity that a system is operating relative to maximum potential. This leads into section 5 which starts with a literature review of the concept of energy service efficiency before going deeper into the discussion of how the development of these ideas could improve upon current metrics for assessing technology and building energy performance. A framework for development towards a systematic methodology for the measurement of service efficiency is presented. Section 6 develops this broader discussion and finally section 7 is a conclusion including outline of further areas of work which would move this area of study towards achieving its goals.

2. Energy Services

Energy demand is not driven by a demand for commercial energy itself, but rather by a demand for energy services [3–5], [11]. The term energy services is well used in literature as 'the benefits that energy carriers produce for human wellbeing' [12]. By making energy service delivery the focus of energy use, there is greater scope for consideration of the reduction of energy use without an implicit reduction in welfare. When aiming for a more detailed way of defining energy services, a balance is required between qualitative and quantitative metrics such that the service demand can be most accurately defined but comparable between different methods of delivery. Energy services include mobility, thermally conditioned spaces, cold beverages, warm meals, food storage, hygiene, illumination, communication, entertainment and security.

As a society we have come to rely heavily on an unabated supply of energy to deliver these services. It is not only energy which goes to their delivery; water, materials, infrastructure and data are examples of other flows which are required and for this reason, Jonsson *et al*. [13] explicitly used the term services as opposed to energy services. However, energy is required in the delivery of all of these flows also, and therefore a consideration of the energy system is useful within this discussion as is given in the following section.

Of course, energy is not only used in society to deliver these 'direct' energy services. Some authors included physical structure - consumer goods, buildings, machines, steel making, tables [3], [4], [13], [14] – Haas [11] and Jonsson *et al*. [13] described these as 'indirect energy services' through which the embodied energy in all of the technologies, materials, structures and other objects we use and own can be accounted for. The field of Life-Cycle Assessment (LCA) has developed methods for including embodied energy and all lifecycle aspects of energy use and waste into analysis of energy impact. These can be extended to analysis of indirect energy services. Haas *et al*. [11] also discussed the idea that short term and long term components of service demand exist; choice of temperature setting, km driven and stand-by operation of a TV or computer are examples of short term service demand, whilst area of an apartment, size of car and number of light bulbs form the long term service demand.

3. Energy Chain

The energy that we use for the delivery of services comes from a long chain of transformations through different forms. The flow of energy is not a simple linear chain and there are feedback loops

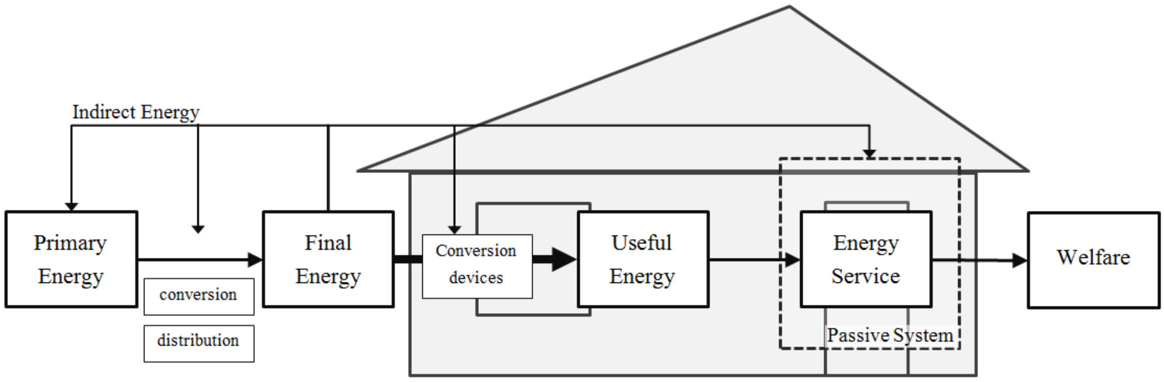

Figure 1: Energy system chain adapted from various sources [4], [7], [13], [14], [17], [18]**. The image of the house shows the split between on and off site stages, in this case suggesting the example of residential energy services.**

which need to be considered. **Error! Reference source not found.** depicts the energy chain and the parts along the chain are discussed below.

3.1. Supply Side Energy Carriers

Primary Energy

Primary energy is the term commonly used for the energy input to the whole energy system[15][15][15][15][15], most commonly from natural sources [4], [5], [7], [13], [15–20]. Conventional examples are fossil fuels (coal, petroleum, natural gas), other non-renewable fuels (uranium) and renewables (wind, sunlight, geothermal, hydropower, biomass). Waste may or may not be included as a type of primary energy carrier [21] and this definition will need to be agreed upon as waste to energy schemes becomes more common.

Final Energy

Final energy is the form of energy which is delivered to the end user or point of consumption [5], [17] such as electricity, natural gas, fuel oil, district heat, charcoal, petrol or diesel [4], [5], [7], [17], [18]. In the context of building energy use, final energy may either be centrally provided, such as grid electricity, mains gas and district heat, or it may be self-generated by an onsite technology such as a micro wind turbine or solar panel which converts primary natural energy (wind or sun) into final energy (electricity or hot water).

The term secondary energy is also commonly used in the literature, but the difference between secondary energy and final energy is not always clear. Some distinctions hold secondary energy as an intermediate energy carrier, where primary energy carriers are transformed, refined or converted into secondary energy carriers [7], [17], [22] which in many cases are *also* final energy carriers. Nakićenović *et al*.'s [23] distinction gave a more rigid distinction; that primary energy is transformed into secondary energy (eg coal to electricity) and secondary energy becomes final energy through distribution to point of use.

Within the building industry, the concept of 'Zero Energy Buildings' is gaining attention, for which on-site energy generation is equal to or exceeds the energy taken from the grid, over a year period. The 'net delivered energy', (energy delivered to site by energy companies less the exported energy from on-site generation) should not be confused with final energy as there will ordinarily still be significant energy consumption within a zero energy building and embodied energy in the construction [1], [24].

Useful Energy

Useful energy is heat, light or motion. Final energy is converted into useful energy in appliances [5], end-use devices [4], [17] or conversion devices and it is this form of energy carrier which goes towards delivering an energy service. Care must be taken in analyses as the term useful energy is also used synonymously with secondary or final energy, exergy or energy services [7], [20], [21], [25–27].

Indirect Energy

Currently, attention to energy efficiency tends to focus on operating energy, and although this is important, it must not occur at the expense of a greater increase in energy use at other stages of the life cycle. Jonsson *et al*. [13] proposed that the 'ultimate energy efficiency measure is to be able to provide the same [service] output without any input from the energy supply system', but this fails to take account of the input of indirect energy. As the energy used in operation decreases, the relative importance of embodied energy in all aspects of the production phase of technologies and energy efficiency measures increases and optimisation of design should be aimed at minimising the energy use over the whole life cycle [20], [28], [29]. Inclusion of these factors of indirect energy consumption is important for consideration of the full energy input to energy services.

3.2. Delivery of Energy Services

Most commonly, the focus of delivering energy services is on the conversion devices, defined as 'devices which transform or upgrade energy into more useful forms' [30]. However, it is the combination of delivering useful energy at the right time, in the right space that produces the required service. The idea that this space is important was a focus of the work by Cullen and Allwood in their analysis of the global efficiency of the flow from fuel to service [14] and they introduced the term 'passive system'. They described the delivery of energy services as being a two stage process whereby final energy was transformed or upgraded into useful energy in a conversion device and this useful energy is degraded and consequentially lost as low-grade heat within a passive system, in exchange for the provision of final energy services. Most literature has no inclusion of such a concept, but considerable improvements in the delivery of energy services can be made through improvements to the passive system; the requirement on room heating can be significantly reduced by improved insulation, as well as improvements to the heaters.

With regards to welfare, Daly [6] described the 'ultimate end' of these services as 'want satisfaction', and Nørgård [7] used the term 'welfare' as the 'ultimate end' after the intermediary 'lifestyle'. Welfare in this case means 'well-being, quality of life, or whatever terms have been applied to express the ultimate end of satisfying people's *real needs and wants*' [7 italics in original]. The inclusion of this step in the energy system represents the notion that the perceived need for energy services and the quality or quantity of service provided can also be a step for attention and optimisation. Optimisation in this case is not about maximisation but about sufficing people's needs.

3.3. Discussion

The breakdown of the energy system into the stages discussed in this section is useful when considering the energy input used in the equation for service efficiency considered later in this paper. Nakićenović *et al*.'s [23] analysis of the energy and exergy efficiencies at the different stages of the energy chain found that the main losses of energy and exergy occur at different points in the energy chain for different fuel types and although the data used would now be obsolete, the salient point is that comparison between different fuel inputs must reflect their relative efficiency of conversion through the whole energy chain.

For comparing the energy efficiency of whole systems - individual houses or single pieces of equipment - defining the boundaries is important for meaningful assessments. Considering different boundaries may highlight different opportunities for efficiency improvements. These boundaries should include the loops in the energy system whereby final energy is also required at every point along the chain and embodied energy is incumbent in all infrastructure of the chain.

This focus on energy input is important for thorough analysis of energy efficiency which is discussed in the next section.

4. Concepts of Efficiency

The term "energy efficiency" is 'widely used but not always well understood' [31]. It is used to represent how well a system is performing; the manner or quality of functioning or the extent to which a desired effect is achieved [1]. Quantitatively, it gives the ratio between input and output energy (or other measurable quantity), or the ratio of actual result to the best theoretically achievable result. These different approaches to a measurement of the performance of a system will be discussed in this section

Efficiency can be considered and assessed at different levels from the micro scale across a single piece of technology or energy efficiency measure, at a meso level across a whole house or community, or at a macro level at a national or global scale.

4.1. Efficiency as the ratio of output to input

In the field of engineering, energy efficiency is generally defined as the ratio of useful output to the energy input as shown in Eq 1.

$$\text{Energy efficiency} = \frac{\text{Useful output of a process}}{\text{Energy input into a process}} \qquad \text{Eq 1}$$

A similar metric is energy intensity, or specific energy consumption (SEC), which is the inverse of efficiency and represents the input of energy required to achieve a useful output as shown in equation**Error! Reference source not found.**.

$$\text{Energy intensity or SEC} = \frac{\text{Energy input into a process}}{\text{Useful output of a process}} \qquad \text{Eq 2}$$

These metrics are related to the first law of thermodynamics, that within a closed system, energy is conserved. Energy efficiency in this form shows the proportion of energy input which is converted to the desired output. Thermodynamic energy efficiency would have an output measured as energy, although other useful metrics involve a different output metric such as those indicative of a service delivered (mass of product, square metres of floor area or passenger-km), or an economic variable such as GDP; Patterson [32] termed these physical-thermodynamic and economic-thermodynamic indicators respectively.

The input measured can have an effect on the value of efficiency calculated depending on where the boundary of the system is defined. The energy may be measured at different points in the supply chain as discussed above; final (site) energy, delivered energy, primary energy, and may or may not include indirect (or embodied) energy [1], [18].

The type of metric measured can alter the insight gained from the efficiency term. Consideration of exergy as well as energy can give more meaningful analysis of the appropriate energy quality being used. Exergy is a thermodynamic quantity which represents the 'quality of energy' and includes the concept of the change in entropy from the second law of thermodynamics. Exergy is defined as the maximum amount of work which can be produced by a system as a consequence of it not being at stable equilibrium with some reference environment [33]. Unlike energy, which according to the first law of thermodynamics is conserved across a system's boundary, exergy is not conserved. When considering efficiencies of energy systems, exergy takes into account the quality of the energy carrier and accounts for the fact that electricity has more potential for doing work than low temperature hot water which can only be used for heating purposes [15]. The second law indicates that although it is possible to achieve full conversion of work into heat and internal energy (through dissipation), exergy losses in combustion and heat transfer contribute to poor thermodynamic performance [34]. In many cases, exergy efficiency is lower than energy efficiency, indicating that improvements could be made in terms of matching energy input to energy output. [35], [36].

4.2. Efficiency as the proximity to best theoretically achievable result

An alternative efficiency metric provides a measure of the actual input compared to the minimum input that would be required in the ideal case and therefore providing an indication of the proximity to the ideal system. This is referred to as second law efficiency when exergy is considered and incorporates the idea that exergy is not conserved and the quality of energy is degraded through conversion processes. When addressing the performance of a system, a baseline is useful for comparison to an ideal value to give an idea of potential for improvement. **Error! Reference source not found.** shows the generalised case (where input may be energy or exergy or some other input).

$$\text{Efficiency} = \frac{\text{Minimum theoretical input required}}{\text{Actual input}} \qquad \text{Eq 3}$$

Examples of the use of second law efficiency are found by Ayres [37] and Nakićenović [38] and Perez Lombard et al. approached the energy efficiency of heating system as the 'thermal energy virtually needed (ideal demand) to the final energy actually consumed', showing the use of a similar approach for efficiency as ideal energy demand to actual energy use.

Cullen and Allwood [14] calculated an estimate for the potential for energy savings in the global energy system by calculating the difference between current and target efficiency as shown in equation Eq **4**.

$$\begin{matrix}\text{Potential for}\\ \text{saving energy}\end{matrix} = \begin{matrix}\text{Scale of}\\ \text{energy flow}\end{matrix} \times \left[\begin{matrix}\text{Target}\\ \text{efficiency}\end{matrix} - \begin{matrix}\text{Current}\\ \text{efficiency}\end{matrix}\right] \qquad \text{Eq 4}$$

The target and current efficiency terms were measured as a 'utilisation ratio', calculated as the ratio of energy input to service output, and this shows an approach for using efficiency terms which combine the two alternatives above. This difference between target efficiency and current efficiency as an indication of the performance of the system allows identification of areas where current performance is sub-optimal and for energy efficiency improvements to be focused.

Other definitions of improved efficiency are achieving the same level of output at a reduced energy consumption, or an increased level of output for the same energy consumption [32], [39], [40]. The latter definition may signify an improvement in energy efficiency but not in energy consumption [1] and is related to the Jevons Paradox, or the rebound effect [41–44].

4.3. Considerations for measurement of efficiency

The '*where*, *when* and *how* … input and output [should] be measured and valued?' [13 italics in original] needs to be considered when accurately trying to define energy efficiency, and encompasses several important factors as listed below [1], [13], [45] and any assumptions should be clearly stated;

- the system boundaries,
- quality judgment of delivered output
- types of energy, quality of energy and units of measurement,
- method of determination (measured or estimated),
- temporal characteristics (static or dynamic)
- baseline (best theoretical, best practise or the performance of similar systems in other locations or at other times in history)

The evaluation of the efficiency of an energy system has been attempted on micro, meso and macro scales, for each of which a different methodology is suitable. The efficiency term is only as useful as the data available for its evaluation and often economic or supply side efficiency measures are favoured, particularly on macro national or global scale as this data is more widely available and comparisons can be made across regions. However, the temporal variation of monetary value means this is less useful at a micro scale [32], [40], [46] and limited insight can be gained into the current performance or potential for improvement and therefore new metrics for energy service would be valuable for the improvement of technology or building assessment.

4.4. Discussion

Of the approaches to energy efficiency discussed above, both present valuable information on the performance of a system. It is helpful to include explicit information of what the input and output of the system are, but this needs to be supported by details of what boundary is being used and what type of input and output are being measured. It is also useful to include an indication of how close a system is performing compared to its optimum as this gives the calculated value context. Ideally, a combination of the two types of indicators included above would provide context and clearer identification of where priorities for energy efficiency improvements should be concentrated.

5. Energy Service Efficiency

Energy efficiency has been extended to "service efficiency" in a number of publications. Daly [6] used the term "service efficiency" in his equation to describe 'ultimate efficiency' as 'getting more service per unit of time from the same stock[1]'. Patterson's [32] 'physical-thermodynamic indicators', and Haas *et al.*'s [11] term 'technical efficiency' both gave a measurement of a specific energy service per energy input. In other cases, the inverse is used; Pérez-Lombard *et al.*'s [47] definition of energy intensity, and Cullen and Allwood's term 'utilisation ratio' calculates the ratio of energy input to service output. Other publications have given equivalent definitions of using less useful energy without a loss of service quality [7], [13], [17]. The most common metric of energy service efficiency is the energy service energy intensity (the inverse of efficiency) as shown in equation 5.

$$\text{Energy Service Energy Intensity} = \frac{\text{Energy Input}}{\text{Service Output}} \qquad \text{Eq 5}$$

Ayres [37] uses the terms second law efficiency and service delivery efficiency synonymously in his analysis of the UK energy system as the difference between current and ideal maximum efficiencies. This was a similar approach to that used by Cullen and Allwood [48] for the estimation of the practical limits of energy reduction in the global energy system as discussed above. These show the approach of efficiency as a measure of proximity to the ideal system.

For use as the output term in a service efficiency metric, the quantification of energy services is necessary. Quantification requires the measurement of a suitable magnitude of demand indicator which involves the definition, assessment and analysis of a set of energy efficiency indicators (as discussed in the following section). In previous literature, measures of service efficiency similar to Patterson's [32] physical-thermodynamic efficiency indicators have been used where the service demand is measured in terms of capita, households or people. Cullen and Allwood [14] go beyond this and use units of final service of cubic metre-Kelvin of air for thermal comfort, or hot water and Newton-metres of work for hygiene, Joules of food for sustenance, lumen-seconds for illumination and bytes for communication. Other 'energy efficiency indicators' can be found in the literature, which appear to take the form of the above mentioned ratios and have been developed for the assessment of energy performance and for quantifying the success of energy efficiency improvement measures. **Error! Not a valid bookmark self-reference.** shows a broader range of such metrics found in literature and existing databases for describing energy efficiency by end use. The term 'energy efficiency indicator' is used in the literature, although the form of the indicators is the inverse of the efficiency and therefore technically a measure of energy intensity.

Table 1: Energy efficiency Indicators by End Use in Literature and Existing Databases

Service	Energy Efficiency Indicator	Measurement	Ref
Thermal Comfort	Unit Consumption (UC) per floor area for space heating	toe/m^2	[49]
	UC of useful energy per dwelling for space heating	toe/dw	[49]

[1] where 'stock' is the constant content of a steady state economy eg constant physical wealth and material artefacts

	UC of useful energy requirement per m^2 for space heating	toe/m^2	[49]
	UC of useful energy for space heating per degree-days	toe/dd	[49]
	UC consumption at constant structure of heating system	toe/dw	[49]
	UC per floor area per degree day for space heating	kJ / (m^2 . dd)	[50]
	UC per floor area per degree day for air conditioning	kJ / (m^2 . dd)	[50]
Illumination	Electricity per m^2 floor space for lighting	kWh / m^2	[51]
Sustenance	UC per capita for cooking UC per dwelling for cooking Specific Consumption (SC) for refrigerators, freezers, UC for refrigerator per litre	kWh or toe / cap kJ / dw (kWh/equi) kWh / litre	[49] [50] [49] [50]
Hygiene	SC for washing machines, dish-washers UC for washing machines, dish-washers UC per person	(kWh/equi) kJ / dw kJ / p	[49] [49] [50] [50]
Communication & entertainment	SC for TV, (other electrical appliances) UC for appliances	(kWh/equi) kJ / dw	[49] [50]

UC: Unit consumption, **SC:** Specific consumption, **kWh**: Kilowatt hour, **toe**: Tonne of oil equivalent, **dw**: Dwelling, **tCO_2**: Tonne of CO_2, **dd**: Degree-day, **cap**: Capita, **equi:** Piece of equipment **p**: Person

5.1. Measurement of Energy Services

When developing a metric by which technologies can be assessed for their service efficiency, the starting focus should be the desired service output. The above metrics go some way towards this, but they don't fully capture the extent of the required service and work in this area could be valuable for the development of the concept of energy service efficiency. This aspect must be considered, giving attention to the precise service required and the comparability of service delivery methods needs to be considered. For example, there is potential to further develop a metric for thermal comfort to occupied spaces not only being at a desired temperature, but more specifically that spaces in the building are at a specified temperature for the time that they are occupied. Overheating or overcooling any area, or heating or cooling unoccupied space, would be a waste of useful energy. Equally, a current measurement of chilled refrigeration space as litres of chilled storage doesn't address cases of a household having a large fridge when a smaller fridge would suffice for the service of 'chilled storage for the household's required food'.

A good example of how the definition of energy services can alter the approach was given by Haas *et al*. [11] in the contrast between the services of 'mobility' and 'transport'. They put that a common and more technical definition of 'transport' considers the energy service 'to reach the office' for which the aim would be to provide this 'distance travelled' with as low an energy input as possible, whereas 'mobility' considers the energy service 'to reach the shop where I can buy a certain product', which allows other possible approaches to reducing the energy input such as through alternative infrastructure (taking a bus or buying the product on the internet) or special planning (stopping at the shop as part of an existing journey). When comparing an inefficient bus in Delhi to an ultra-efficient sports utility vehicle, the Delhi bus is more efficient at delivering service quantity in terms of energy per passenger-km, but the quality of service is not equivalent [11]. Conversely, conservation measures for a car journey - improved use of the car, traffic conditions, walking, or replacing the journey with a phone call – could deliver the same desired service with less energy requirement, depending on the purpose of the journey [17].

This gives rise to the question of comparative services where by different means for service delivery can be compared. Jonsson *et al*. [13] discuss the potential for reducing the required energy input whilst maintaining the same 'experienced utility and quality of service'. They presented a rigorous qualitative framework for approaching service through four underlying of *volume*, *content*, *quality* and *motivation* to suggest an approach for 'complementary views' of the service delivery which would have a lower energy demand.

- **Volume**, as the underlying 'quantifiable amount of energy service delivered' such as passenger-km for transport and area of thermally conditioned rooms
- **Content**, as the 'experienced utility of service' such as thermal comfort or commuting to work
- **Quality**, as the 'experienced reliability, accessibility, safety and security, convenience and ease' such as acceptable journey time, ease of control panel for heating system or reliability of electricity delivered from the grid
- **Motivation**, as the reason for 'why a service is called upon in terms of practical (those which sustain comfortable everyday life), symbolic (those with symbolic value which support a certain lifestyle) or aesthetic (those which convey feelings of wellbeing to an individual) reasons

Due to the complexity of valuing the output of a service, tied into consideration of varying perceptions of 'quality of life', 'lifestyle' and 'welfare', they suggest that 'service should be considered quantifiable only in part'. They advocate for a broader interdisciplinary systemisation, focusing on why the service is called upon, but this qualitative aspect introduces complexities when trying to integrate service efficiency into a modelling context. Pérez-Lombard et al. [47] reinforced this point, highlighting the difficulty in quantifying the very diverse range of activities which services encompass, and they suggest the differentiation between quality and quantity. They suggest that energy efficiency indicators of any system or device are best sought in a case by case basis. The concept of analysing comparative methods of service delivery confers with Nakićenović's [17] argument that energy reduction requires not only 'the reduction in specific energy needs for performing a given task', but 'the reduction in energy needs due to changes in the nature or level of the required energy services' (which he defined as energy efficiency and energy conservation respectively). A reduction of level of energy service is unlikely to be popular with the general society unless it can be perceived that this level of service is chosen and therefore the focus on the change in delivery method is beneficial.

In order to compare service efficiencies, either to a maximum potential or when comparing the efficiencies of different technologies or measures, it is important to explicitly identify the service which is being compared. When comparing different systems to deliver a common output, it is beneficial to have a definition of a 'service unit'. As in the work by Cullen and Allwood discussed above, the service is defined in base SI units, but there is potential to develop these to match more closely the services people require, for a micro bottom up analysis or for use as efficiency indicators on a building level.

A ‘service unit’ could be defined for each service. This would be equivalent to a functional unit defined in life cycle assessment (LCA) as the 'quantification of the identified functions (performance characteristics) of the product basis for comparison for alternative goods or services' [52]. As with the functional unit in LCA [53], the service unit should relate as closely as possible to the function or service i.e. rather than a technology or energy efficiency measures being assessed on heating a square meter of floor area, it should be assessed on how well it can maintain an area of a certain type[2] for a given period at a desired temperature. This would enable comparison between different delivery methods, such as heaters, insulation or a given combination, based on this equivalent service requirement. Similarly, using a service unit for clothes washing as 'kg of clothing' does not account for

---

[2] Factors such as height of ceiling, or type of space (room, corridor, outside area) may lead to different options performing better in different situations

the variation in washing requirements of different types of clothing of different weight; a more appropriate service unit would be 'a cleanly clothed person for a given duration'.

5.2. Development of Energy Service Efficiency Metrics

In order to extend the concept of energy services to being commonly used in the performance of technologies and buildings, development of this work is required. If it is energy services we desire, then surely buildings should be designed to deliver energy services and assessments of buildings and technologies within them should be assessed directly related to these. Ideally, a metric of energy service efficiency, or as is shown here, the inverse of energy service efficiency (energy service energy intensity), could be developed relating to a more precise energy service required and this service unit could be a common point of comparison for different technologies or other energy efficiency measures; both conversion devices and passive systems. For the application to a building performance metric, the level of service unit demand for the different services could be multiplied by the energy service energy intensity to evaluate the energy input required by a building, as given in Eq 6.

$$\underbrace{\frac{\text{Energy Input}}{\text{Service Unit}}}_{\substack{\text{Energy Service}\\ \text{Energy Intensity}}} \times \text{Level of Service Unit Demand} \;=\; \text{Energy Requirement} \qquad \text{Eq 6}$$

As the ‘service unit’ metric in the efficiency equation gets more defined, characterisation of service demand becomes more difficult, but this approach is necessary in order to overcome the rebound effect such as that as energy per square meter of heated space or litre of chilled storage reduces, the demand for these aspects of service decrease.

However, with a miss-defined metric of service, this approach would be susceptible to a rebound in service demand with less energy leading to an ever increasing demand for house size and appliance size and therefore the right definition of services is important.

This methodology could lead to a new approach for energy service companies (ESCos) in which the customer pays for their demanded services. ESCos (or energy performance contracting as it is commonly sold as in the UK) has become more closely about selling energy efficiency measures rather than selling services, and the better quantification of energy services and associated efficiency metrics could allow this. The metric of total service demand could give freedom to an occupant to stipulate the service which they demand, i.e. the areas which they want thermally conditioned or illuminated, and at what temperature or light intensity, or the clothing regime which they prefer. This would allow greater flexibility that the current approach in which an 'adjustment factor' to accounts for changes in the service required, but in general it is assumed that the service demand will stay constant[3]. There are particular difficulties if the service demand changes or if historic data is not available, which is particularly prevalent in the residential sector, and this alternative methodology would allow for the consumer to specifically choose the level of service which they desire and pay for these services.

6. Discussion

The aim of this work is to produce a metric for the measurement and evaluation of the efficiency of delivering energy services; the energy service efficiency. This would be a valuable metric for assessing the performance of low carbon technologies and other energy efficiency measures acting as conversion devices and passive systems in delivering energy services.

Any measurement of energy service efficiency should be based around the energy service required. This would be most conveniently addressed by considering service units, equivalent to functional units used in LCA. Previous work in this area has used service definitions such as ‘squared metre of heated area’ , ‘litres of chilled storage’ or ‘kg of washing’, but there is potential to improve upon these

---

[3] The adjustment is also used to account for weather variation, particularly relevant to energy consumption in heating, using the concept of degree-days

metrics in order to most closely match the service measured to the service required and reduce the potential for rebound in the increasing demand for services. For example, a measure of sufficient clothing for a person for a week instead of kilograms of cleaned clothes for hygiene or sufficient food for a household instead of kilograms of cooked food for sustenance. The definition of these service units should consider the service being provided and the motivation for this service demand, the quality of service which is required and consideration of the time period over which the service is demanded may also be relevant. A meaningful quantification of the service required, including details of these aspects, would form the energy service demand metric. This metric would not be directly comparable for different services, but would provide the basis for comparison between different technologies and energy efficiency measures.

With the energy service defined and the requirement of useful energy input and schedule of operation determined, technologies or measures can be compared based on their energy, exergy or other inputs, or their related environmental impact such as CO_2 emissions. For meaningful comparison, the boundary over which the inputs are considered must be consistent; the use of final energy rather than primary energy would give different, potentially misleading, results over the whole energy system. The inclusion of indirect energy will help to build a more thorough comparison of the overall energy input to each technology or energy efficiency measure for delivery of the defined energy service.

Assessment of technologies and measures should include aspects of actual performance as used as opposed to only rated performance in laboratory tests, and the ease with which it can be installed and operated. Existing approaches to rating individual technologies exist, whereby technologies are assigned 'energy labels' based on the performance of the technology in a standardised test [54]. These test procedures measure the performance of the appliance under steady state in a controlled environment at the beginning of the product's life time [55], [56]. Meier [56] stated that 'every test procedure is a compromise' as the goals for an 'ideal test procedure which reflects annual usage conditions without compromising on reliability and cost effectiveness' are contradictory. However, in order for the concept of energy services to proliferate, an alternative assessment approach would be required which more accurately rates the technology based on the service which it is required to deliver. The methodology could also lead to a new approach for energy service companies (ESCos) whereby the customer pays not for the electricity and gas they consume but for the demanded services.

The work presented in the previous section provides a methodology through which the total energy demand of a building could be calculated based on the level of energy services desired by the occupants. This could provide an aggregated measure of the performance of delivering services for a whole house. This approach has the potential to be extended in order to provide a more rigorous method for assessing the energy performance of a building than the current approach using Standard Assessment Procedure (SAP) or Energy Performance Certificate (EPC). This micro scale approach could also be extrapolated to give an indication of the service efficiency on a national scale, but the inherent inaccuracies in these approximations should be recognised.

For a better metric of energy performance of a building to be developed, a more detailed reporting of what, where, when and why energy is being used would be highly valuable, and could provide a real-time indication of how well a building is performing compared to a modelled optimum. It would require heavier data collection than some metrics, but as the availability of smart metering and sub metering improves, and data processing becomes more effective, this will become less of a barrier the future.

Expected levels of service are a function of culture and lifestyle; by minimising energy service demand, significant levels of energy can be saved. The perception of this effect on welfare can be influenced by psychological means such as whether the change in energy service level is perceived as chosen or forced.

7. Conclusion

Faced with the challenge of shifting an existing well established energy system from supply focused to demand focused, this paper has considered some of the important issues related to the concept of energy service efficiency.

In the case of both energy efficiency and energy service efficiency, two types of metric were identified; a ratio of output over input, and a ratio of current demand compared to the minimum demand in the ideal case. This paper focussed mainly on the former case, exploring the stages of the energy chain from primary energy to welfare including the importance of considering indirect energy as well as direct energy and considering aspects for the quantification of energy services. In the latter case, the ideal maxima may be calculable for a given service, and a comparison to these would be useful to put into context how well the system is performing. However, when comparing services, it should be done on an equivalent basis regarding the quality as well as quantity and Jonsson *et al*'s [13] framework could be a useful guideline for this.

The existing quantified approach to demand side measurement in literature and national statistics, typically giving energy consumed per end use, is somewhat limited in its approach to actually addressing why energy is used. Conversely, the ideal approach to assessing energy service demand is qualitative and difficult to quantify. This work goes towards bridging this gap and developing a more rigorous quantitative approach.

Further work is required in the development of this area to turn the concept into a useful model such that data from upstream in the energy chain and metrics for the quantification of service delivery can be fed in and meaningful service efficiency results be calculated. The next steps are to bring together required energy input for point of use and embodied energy for all technical options for energy service delivery and link them to the service which they can provide. This could be integrated into new or existing building modelling packages to make them more explicitly apply the theory of energy services to building performance analysis. It could also give a better method for recommending the most appropriate technologies for delivering energy services.

This paper has not looked into the link between energy service and welfare however, but this link should not be overlooked as a reduction in demanded energy services would lead to a reduction in energy consumed overall. Determination of service can be taken from standards, but this average does not reflect the wide variety of people's needs and wants. As of yet, a method for using the concept of energy services has not been flexible enough to fully replace the traditional view of energy and this would be valuable work for the transition to a sustainable energy system in the future.

The benefits of creating a cross-country data framework for energy efficiency

Alex Katzman, VP of Business Development and Project Manager for SEAD Energy Efficiency Data Access Project, Enervee

Michael McNeil, Deputy Leader, International Energy Studies Group (Acting), Environmental Energy Technologies Division, Lawrence Berkeley National Laboratory

Stephen Pantano, Senior Director of Global Programs, CLASP (Collaborative Labeling and Appliance Standards Program)

Abstract

As manufacturers now sell a similar range of consumer electronics and home appliances to major markets around the world, the task of identifying a product's energy efficiency rating has usually been the responsibility of each country and its respective government agency. This has led to a multitude of energy efficiency testing procedures, ratings, and certifications, resulting in disparate data being captured on identical products. Furthermore, lack of consistent product identification criteria means product energy performance is not easily connected to relevant information about the product such as market availability, price or real world energy consumption.

This paper presents a new data standard for reporting energy performance and related product information that can be adopted internationally. To inform the development of this standard, we explore the existing energy efficiency market data for the two example products of TVs and Room Air Conditioners. This paper discusses current/future use cases of appliance level energy efficiency data across all stakeholders, including consumers, retailers/manufacturers, global standards organizations, third party service providers, and regulatory agencies. It also explains the key benefits of moving to a common international data framework for energy efficiency, such as: 1) a centralized product information repository for comparing energy use, ratings/certifications, and pricing data 2) improved access to relevant consumer electronics and appliance data to facilitate new policy development and harmonization across markets 3) enablement of retailers and other third parties to embed actionable energy efficiency information as part of the consumer experience.

1. Introducing a Cross-country Data Framework for Energy Efficiency

Among the most useful tools in the development of effective consumer electronics and home appliances efficiency programs and promoting consumer awareness of efficiency are data that allow for:

- Linking consumer retail information to efficiency parameters more effectively.
- Tracking efficiency trends over time (monitoring) and comparison of efficiency in different markets and jurisdictions (benchmarking).
- Tracking retail prices of appliances over time, and between countries.

Currently, broad access to consumer electronics and home appliances efficiency and price data and comparability between markets is imperfect. Product energy use labels, in countries that require them, are often not prominently displayed on sales websites; and in many cases it is difficult to access detailed product energy rating information. Policy makers must invest significant time and money in collecting data about the market status of the efficiency of available products when determining appropriate levels for energy efficiency policies. In addition, comparability of attributes across markets is often difficult, even for identical products, due to inconsistencies in model identifiers and efficiency metrics and protocols. A well-defined *data standard* for appliance attributes and efficiency characteristics could potentially solve this and many other product energy information access problems.

Key objectives of the data standard include: (1) development of internationally compatible data specifications for populating, retrieving, and cross-referencing data from web-based product databases and (2) definition of standardized methods for populating these product-specific databases. Data sources may include the use of product certification databases (such as those maintained by agencies that administer energy labeling and minimum performance standards programs); software tools (e.g., “webcrawlers” to gather and regularly update product-specific availability, efficiency and pricing data); and guidelines for the gathering and reporting of actual field (on-site) data on product energy use.

This paper outlines a proposed data framework for consumer electronics and home appliances energy performance and cost data being developed as part of the Super-efficient Equipment and Appliance Deployment (SEAD) Initiative of the Clean Energy Ministerial.[1] The goal of this project is to publish a data standard that can be implemented by relevant organizations that collect and store data about the energy performance, market availability and costs of energy-consuming equipment and appliances. This data standard can be used for sharing data among relevant organizations, and in the development of databases that store and analyze this information.

The data framework relies on two main data source types and anticipates a high degree of data collection automation. Product model lists are collected directly from retail websites, using online shopping application programmer interfaces (APIs). Connection to these online data feeds enables automated downloading of product model numbers, many product attributes and current retail prices. The second dataset type consists of efficiency certification databases, often maintained by regulating bodies responsible for minimum energy performance standards (MEPS) and labeling programs.

The combination of these two datasets provides a wealth of new information. The correlation of models found on retail websites with those in efficiency databases provides a time-dependent picture of the distribution of efficiencies on offer. These data could be updated frequently (perhaps daily), creating a high temporal resolution picture of the evolution of the market. Finally, datasets collected in this way can be used to compare the market for efficiency in different countries. By connecting real time prices with efficiency ratings and market share for the same product sold across markets, there is the potential to compare the cost consumers are willing to pay for efficiency across markets. This step may require robust algorithms for converting efficiency metrics between test procedures used in different countries.

.

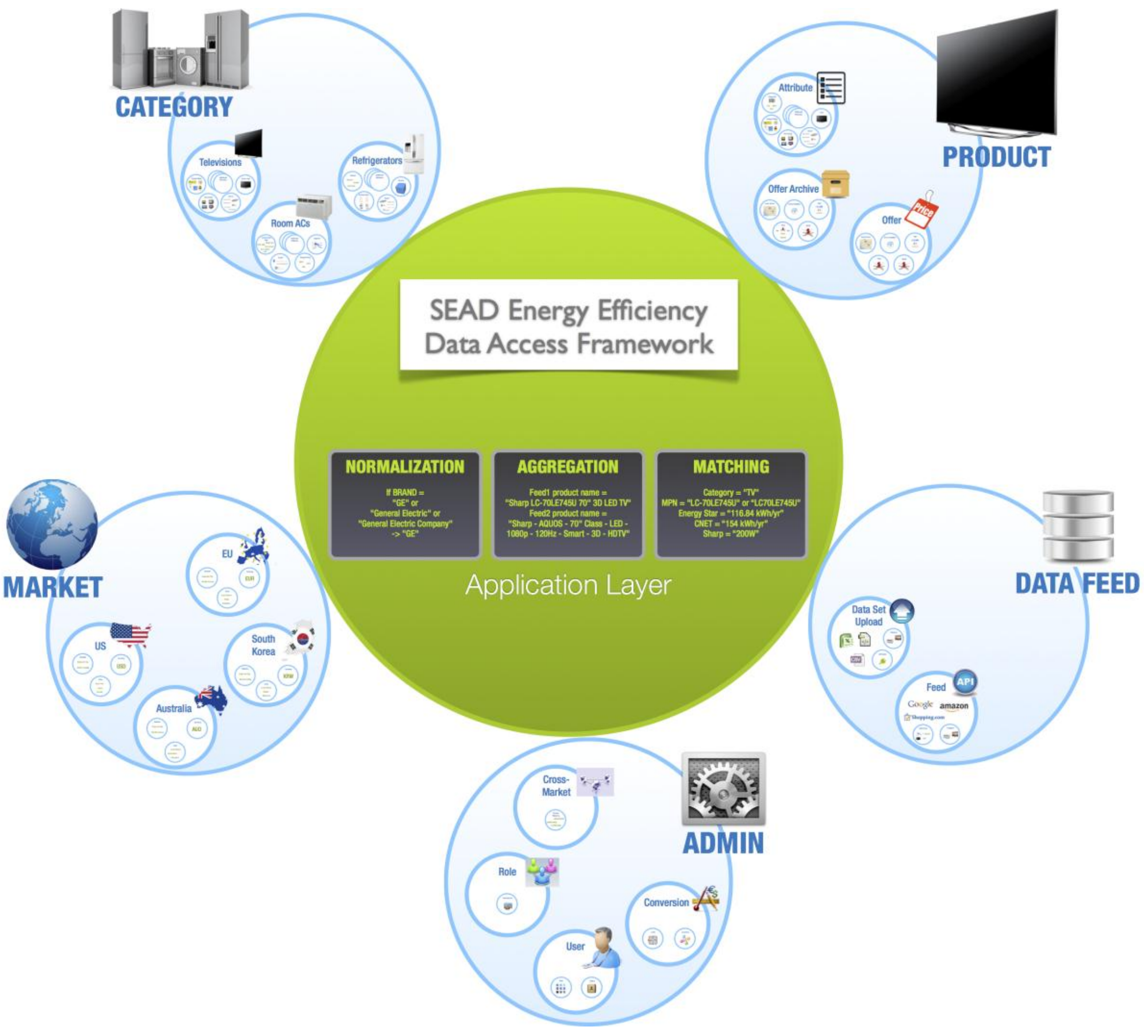
The following sections provide a detailed description of the framework developed as a pilot project supported by the U.S. Department of Energy as part of the SEAD initiative. We then consider two products – room air conditioners (Room ACs) and televisions (TVs) – as a test case to demonstrate the facility of the data standard. The paper concludes by considering applications of a fully implemented framework and discussion of implications.

2 Defining the Framework and Data Standard

2.1. Overview

The SEAD Energy Efficiency Data Access framework was designed to be able to capture and compare energy efficiency product data for the many types of consumer electronics and home appliances that are sold around the world. It uses a product-centric model with an extensible design to ensure that it can meet the requirements of any market or category. The core of the framework standardizes markets, brands, categories, product attributes, and units of measurement with common definitions. An intelligent application layer would connect with the framework to normalize, aggregate, and match data across the disparate energy efficiency certification and retailer data sources. The outcome is a new data standard that defines a methodology for capturing and sharing this data.

Figure 1 – Data Framework Conceptual Overview



2.2. Identifying Use Cases

To ensure that the new framework design could handle a wide range of potential use cases, feedback was gathered through surveys and interviews with the members of the SEAD Standards and Labeling Working Group, which consists primarily of policymakers from the 13 SEAD member economies. The outcome of the surveys and interviews was a prioritized list of use cases.

Table 1 – Prioritized Use Cases

#	Use Case	Need Type	Priority
1	Access to other countries' certifications and ratings for monitoring, verification, and policy design	Policy	High
2	Connect sales and efficiency trends	Policy	High
3	Ability to assess impact of marketing campaigns on consumer adoption	Policy	Medium
4	Enables comparison of product rating methods across countries	Policy	High
5	Facilitates procurement activities	Consumer	Medium
6	Enables development of consumer mobile apps/online comparison tools	Consumer	High
7	Facilitates product energy efficiency awards	Consumer	Medium
8	Facilitates utility incentive programs	Consumer	Medium
9	Enables comparison of testing procedures	Policy	Medium

Expressed needs broke down into two distinct categories: Policy and Consumer. 'Policy' refers to use cases that relate to analyzing, benchmarking, or creating appliance standards. 'Consumer' refers to use cases that enable consumers to have access to and leverage this data in their purchasing decisions. The overwhelming feedback was that this data standard should focus mostly on Policy development but also enable development of consumer mobile apps/online comparison tools.

2.3. Creating a Global Data Standard

An essential part of establishing a data standard is agreeing on a simple, consistent model that can be applied across diverse markets. To accomplish this task, the concept of a Global Category was developed which defines a universal set of product attributes that are gathered irrespective of the category. This is the mandatory information that will be captured for any category, covering the unique product identifiers, market, brand/manufacturer, pricing, energy, certification, and marketing related data.

Global Category Definition

To the greatest extent possible, the Global Category definitions have been based off of the IEA 4E Mapping and Benchmarking[2] and GS1 Global Product Classification (GPC)[3]. These existing definitions were chosen to facilitate harmonization of product category definitions across markets using international standards. Table 2 shows the proposed definition.

.

Table 2: Global Category Data Standard

Attribute	Type	Notes
Manufacturer Part Number (MPN)	String	Product Model Number stripped of extraneous characters
Brand	String	Normalized Across All Markets
Manufacturer	String	Parent Relationship to Brand
Market	Code	Defined region based on ISO 3166-1 country codes
Global Trade Item Number (GTIN)	String	Universal Product Code (UPC) or International Article Number (EAN)
QR Code	String	Quick-Response Code
Price	Numeric	Min, Max, Mean, Median, and Standard Deviation of Daily Prices
MSRP	Numeric	Manufacturers Suggested Retail Price
Product Energy	Numeric	Operating and Standby Watts, Annual Energy Consumption (from a single data source)
Product Certification	Code, Date	Certifying Authority, Current Test Procedure, Registration Date
Product Images	String	Links to Images of the Product (multiple)
Product Marketing	String	Product Title, Headline, and General Description

Product Category Definition

While the Global Category attributes capture the common data across all products, it is also necessary to capture attributes specific to each product category, since the data required for TVs will vary substantially from that of Room ACs or Refrigerators. These category-specific attributes are the descriptors that bridge regional differences across markets. Below are examples of the TV and Room AC category definitions.

Table 3: TV Data Standard

Attribute	Type	Notes
Screen Technology	String	LCD, LED, Plasma, Projection, CRT
Functions Available	String	Analog, Digital
Screen Size	Numeric	Size in inches, centimeters, meters, or other unit of measurement
Resolution	String	HD or Conventional
Aspect Ratio of Screen	String	4:3, 16:10, 16:9
3D Ready	String	Yes, No

Table 4: Room AC Data Standard

Attribute	Type	Notes
Cooling Capacity	Numeric	BTU, kW, W
Refrigeration Method	String	Electrically driven, Absorption units
Condenser	String	Air cooled, Water cooled

Cooling		
Heat Transfer Fluid	String	Air, Water
Type	String	Unitary, Split units, Multi-split
Cooling/heating	String	Cooling, Heating, Cooling/heating
Variable speed drive/multi-speed compressor	String	Present or Not
Refrigerant	String	Refrigerant Type

2.4. Customization by Market

While the standard sets guidelines for which attributes to capture, it still allows for flexibility when implementing for a specific market. Each market using the framework will have the capability to add new attributes to an existing category or define a new category for products that are not currently covered. These extensions cannot be compared across markets.

Modifying a Category Definition

For example, some countries may want to classify types of Room ACs in more granularity and therefore there may need a 'SubType' attribute added to their Room AC category definition. Additionally, there may be a need to set up an attribute to capture a numeric rating that is assigned by a country's certification program.

New Category Definitions

It is also possible to define an entirely new category that is not currently covered by the data standard. This new category would automatically inherit the base attributes (such as MPN, UPC, or Brand) and would only need to have defined the specific attributes unique to that product category and market.

As more and more countries begin to adopt the data standard, the result will be that the majority of categories will have been standardized across all markets.

2.5. Methodology for Populating the Database Framework

To make the adoption of the data standard as seamless as possible, a comprehensive approach for populating the framework from existing data sources is detailed below. An application layer is required to normalize the disparate data across markets into the new standard.

A system using the framework would create unique products from online shopping APIs such as Google, Amazon, and EBay by pulling in product IDs, marketing details, technical specifications, and prices. Access to Amazon, EBay, and other international online shopping APIs is provided for all organizations that agree to be part of that retailer's affiliate network.

It would then match energy efficiency data based on MPN or GTIN via CSV uploads of certification data sets. An unlimited number of feeds from retailer APIs and certification data sets can be utilized in the framework to ensure strong coverage of each market.

Online Shopping APIs

Online shopping feeds from the retailers with the broadest product coverage will be utilized for creating a list of all current products on the market. One or many APIs per market will be accessed on a daily basis to pull the most up to date products and pricing data. The methodology for doing this as follows:

- Data feed retrieval: establish a connection with the retailer API to select which products should be returned by the data feed.
- Normalization: map the raw data in the retailer data feed to the definitions of the data standard. Data rules will need to be applied to common factor MPN, Brand, and product attributes.
- Aggregation: combine product specifications and prices (Min, Max, Mean, Median, and Standard Deviation of daily offers) from multiple retailer feeds to create and maintain a single, unique product record in the framework.
- Matching: update offers and product specifications on already existing products based on MPN or GTIN. Matching MPNs requires logic to strip extraneous characters and process the many wildcards present in certification records.

Data rules

Rules can be defined per retailer API to control for the variation in data quality coming from online data sources. The power of this data framework is that rules can be configured to reject products based on category attributes, using logical operators such as any, in, not, >, <, >=, <=, and =.

Examples would be: TV Screen Technology in “LCD, LED” or Screen Size > “15 inches” or for Room AC Volume Capacity <= “14 kW”. This ensures only data of the highest quality is captured into the framework. Additionally, it will be necessary to rewrite attribute names and values to normalize them across data sources and markets.

Certification Data Sets

Government certification/rating data will be utilized to capture products’ energy efficiency information. This data will be imported into the framework as a Comma-separated Value (CSV) file. The framework will then match each record’s MPN to an existing product in the database following the methodology below:

- Data set parsing: Certification data sets are uploaded in CSV format to add energy efficiency related attributes to product records.
- Matching: Capture the associated energy efficiency data such as energy consumption, certification level, certifying authority, registration date, etc. on already existing products based on a matched MPN or GTIN code.

If an MPN match is not successful there is also the capability to capture the certification record directly into the database. This will cover the use case whereby certification data sets contain historical products which are not currently available on the market.

2.6. Mapping Products Across Markets

As many manufacturers sell the same products across many markets using different MPNs and GTINs, there is a need to be able to link comparable products. The data framework includes a reference that links an MPN and/or GTIN from one market to another. The power in capturing product attributes in a standard way is to enable automated cross-market mapping.

By using logical rules to compare MPNs and key product attributes such as a product’s size, capacity, or energy consumption, the framework could facilitate identification of potential matches. As testing procedures may differ across markets, the challenge will be to identify which conversion factors and thresholds to apply. With the framework linking the test method with each product’s energy certification record, it would be possible to compare differences in the actual test procedure conditions (such as AC room temperature or TV viewing mode) between comparable products. Further analysis by all countries planning to participate in the data standard would be required to identify appropriate conversion factors and thresholds.

A good example would be for Samsung TVs across the US, Europe, South Korea, and Australia. Samsung TVs: UN40EH5000F (US), UE40EH5000 (Europe), and UA40EH5006M (Australia). Notice that the first two letters of the MPN define the market: UN for the US or South Korea, UE for Europe, or UA for Australia. This is the most basic way of identifying comparable products but does not guarantee success.

The next step would be to look at attributes such as Screen Size and Annual Energy Consumption. Using logical rules to first convert these attributes to a common unit of measurement, it will be possible to apply thresholds based on the underlying testing procedures to have the framework automate the identification of potential matches across markets. By continually fine-tuning the attribute conversion and threshold algorithms, the framework can significantly cut down on the amount of manual work required to clearly establish a set of like products across markets in each category.

3. Benefits of a Data Standard

A data standard accomplishes the following primary goal – improving access to data about consumer electronics and home appliances products' availability, pricing, and performance.

3.1. Existing Data

Currently, much of the data to feed into the proposed standard is not provided in a consistent format. For example, currently 26 countries have some type of minimum performance standard or energy performance labeling program.[4] Several of these have multiple programs, and may have different government or non-governmental agencies responsible for administering the program.

Each agency maintains their own qualification system, verifying that products comply with the requirements of their program. Often, these agencies publish lists of qualified products. For instance, the US ENERGY STAR program publishes a list of qualified products on their website.[5] This list contains 37 attributes about each product, such as manufacturer, manufacturer's product number, energy rating, size, and ENERGY STAR model identification number. Meanwhile, the Australian government collects similar information for its categorical labeling program, including 17 fields. Aligning these data formats to make reasonable comparisons across economies requires working directly with the governments that collect this data, as IEA 4E does in its mapping and benchmarking studies.

However, this certification data is further limited in that it doesn't necessarily represent the range of products available in a market, and it is not connected to price information. For instance, data from an endorsement label naturally represents the higher performing products on the market; it would not be possible to use this data to illustrate trends in efficiency of products in that market. However, each day vendors of this equipment are offering this equipment for sale – with associated identifying information such as manufacturer part number/model number (MPN), global trade identification number (GTIN) and manufacturer. By collecting these offers, we can know what fraction of the market is represented by the high performing products and what fraction of products do not have energy information available. When these products are available for sale, these products also have price information. By matching the offers for products at a given price with the energy rating provided by the rating agency, we can estimate average incremental cost for increased efficiency.

3.2. Uses

While a snapshot summary of most of this information can be done with existing tools, it requires significant undertaking on the part of the government or organization doing the research. In many cases, governments must purchase data or do their own research; the high cost of this puts it out of the reach of many organizations and often means that potential uses of the data are not cost effective. A data standard lowers the incremental cost of implementing any particular use by reducing the amount of work needed to reformat and clean the data sources.

Importantly, a data standard also opens up the possibility for continuous, real-time monitoring. Under the conventional approaches, the manual effort involved in collecting and aligning data sources means that information may lag by months or years, and only be available publicly in aggregate summary reports. While with the standard it make take effort to build an initial platform for viewing information, summaries can be updated on demand when source data is updated.

By developing a data standard, this data could be used to feed any number of applications or resources, limited only by what people are willing to design and create. We propose some potential applications of this data that could be developed.

Informing policy

Currently, it is an expensive process to collect data on market status and the availability of products. Most energy performance standards and labeling programs use cost-effectiveness as a test for setting improved target levels. This data standard could enable real-time monitoring of efficiency distribution within a market or region and changes in price among products of different efficiencies. Lowered cost of this process by automating the data collection can put this type of data collection into the reach of some governments that currently can't afford to do thorough market evaluation, and can shorten the revision process for those that already do this.

Cross-market advocacy

Currently, mapping and benchmarking studies by organizations like IEA 4E provide a way for countries to compare the performance of products in their markets. However, these are limited in how frequently they can be updated and how many products can be done. Implementation of a data standard would allow richer data to inform studies such as these, as well as broader product coverage.

Comparison of test methods

In many cases, products are available across markets and are tested to different standards. However, because of variations in test methods, direct comparison of the results is not possible – it is comparing apples to oranges. By using the data standard to identify the same product sold in multiple markets, conversion factors can be estimated.

Consumer mobile applications

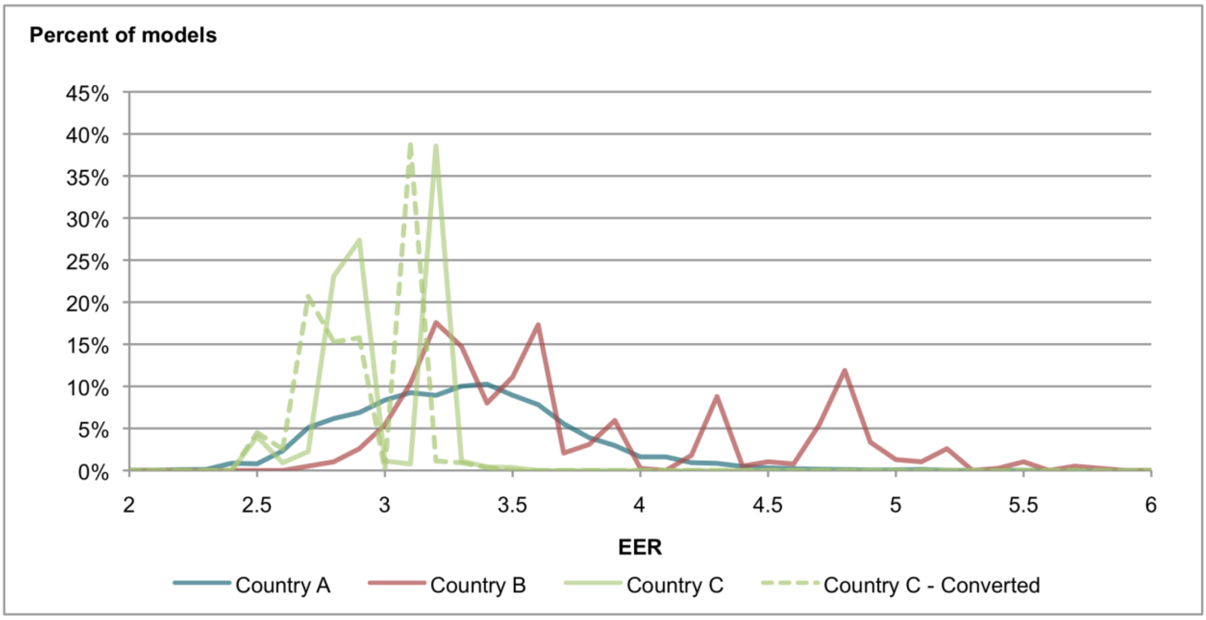
Currently, consumers must rely on energy efficiency information that is presented via various types of labeling schemes – usually showing the relative efficiency of a product and an estimated annual energy cost based on average utility rates and usage profiles (i.e. hours of TV watched per day). The data standard could enable developers to build a mobile application that allows consumers to scan a product's bar code to instantly compare personalized energy cost across all products of a specific class. The application could then recommend more efficient products within a specific price range that are available to purchase at local retailers within the consumer's local area. By also including the savings available from retailer incentives and utility rebates, it could incentivize consumers to purchase more energy efficient appliances.

4. Example Application

4.1. Efficiency Distribution Across Markets

As part of the development process, we collected sample data sets of room air conditioner performance from several countries. While this is the most basic comparison available, it does illustrate the first possible level of comparison. With the implementation of a data standard, this information could be made available via web portal that is up-to-date with current product information, along with data from additional countries.

Figure 2 – Distribution of Room AC EER



In this example, Country A and Country B follow the same methodology for calculating the energy efficiency ratio (EER). However, Country C uses a different methodology. Previous research assessed the differences in test procedures and demonstrated that the ISO 5151 test conditions could be estimated by dividing the NAFTA test condition EER used in Country C by 1.032. This conversion factor has been applied to the dotted green line in Figure 2. While this conversion approximation is available for EER, many other products do not have such conversions available. Applying analysis of the same products across markets, as described above, could be used to obtain additional conversions; building the test method and conversion factors into the data standards allows for improved comparison in product availability. [6] [7]

4.2. Price-Efficiency Trend Across Markets

A key additional benefit to the data framework is the ability to compare price to efficiency across markets. In the chart below, we show an illustrative example using real data to compare the average EER (in Watts Output/Watts Input), which has been normalized to W/W, and retail price level in US dollars for Room ACs across three different markets. This type of analysis could be automatically generated based on any interval (i.e. daily, weekly, monthly, quarterly) and using any price bucket (i.e. specific dollar amounts as shown below or more general divisions such as low, medium, or high). In addition, it could be filtered by size to look at the price-efficiency relationship for Room ACs of a specific cooling capacity.

Figure 3: Price-efficiency Comparison of Room ACs

5. Conclusion

This paper has presented the first steps of an attempt to develop the framework of an international consumer electronics and home appliances database and demonstrate some of its most important applications. The next stage of development will rely heavily on input from stakeholders within the SEAD initiative and elsewhere, to optimize and populate the database. Establishment of a full set of use cases will drive database design. In addition, the population of the database is in early stages. A major test of the data standard and algorithms will be its ability to associate products for offer in online shopping websites with models listed in certification database. The intended result of this project is a well-populated database that allows access to both efficiency and price data for a wide range of uses and end users.

An equally important outcome of the project will be the establishment of an international data standard for appliances. The natural follow-up to this outcome is to seek wide diffusion and stakeholder input, with the ultimate goal of seeking adherence to the standard from as many countries as possible. As argued above, the establishment and adoption of such a standard would yield rich benefits to policymakers, consumers and researchers concerned with consumer electronics and home appliances energy efficiency.

Abstract

The Global Efficiency Medal competition, a cornerstone activity of the Super-efficient Equipment and Appliance Deployment (SEAD) Initiative, is an awards program that encourages the production and sale of super-efficient products. SEAD is a voluntary multinational government collaboration of the Clean Energy Ministerial (CEM). This winner-takes-all competition recognizes products with the best energy efficiency, guides early adopter purchasers towards the most efficient product choices and demonstrates the levels of energy efficiency achievable by commercially available and emerging technologies. The first Global Efficiency Medals were awarded to the most energy-efficient flat panel televisions; an iconic consumer purchase.

SEAD Global Efficiency Medals were awarded to televisions that have proven to be substantially more energy efficient than comparable models available at the time of the competition (applications closed in the end of May 2012). The award-winning TVs consume between 33 to 44 percent less energy per

unit of screen area than comparable LED-backlit LCD televisions sold in each regional market and 50 to 60 percent less energy than CCFL-backlit LCD TVs.

Prior to the launch of this competition, SEAD conducted an unprecedented international round-robin test (RRT) to qualify TV test laboratories to support verification testing for SEAD awards. The RRT resulted in increased test laboratory capacity and expertise around the world and ensured that the test results from participating regional test laboratories could be compared in a fair and transparent fashion.

This paper highlights a range of benefits resulting from this first SEAD awards competition and encourages further investigation of the awards concept as a means to promote energy efficiency in other equipment types.

Competition Objectives

The SEAD awards program is part of a suite of policy interventions by governments designed to drive markets towards greater efficiency in electrical end-use equipment. The Super-efficient Equipment and Appliance Deployment (SEAD) Global Efficiency Medal competition recognizes products with the best energy efficiency performance, subject to certain quality constraints, in different regions as well as globally. This program complements existing standards and labeling programs in promoting energy efficiency.

The primary goal of the competition is to maximize energy savings by increasing the market share of efficient products. It also aims to spur innovation among manufacturers and foster international government collaboration to strengthen the technical foundation of efficiency policies for globally traded products. The competition process supports the harmonization of test procedures, the building of testing capabilities and the provision of internationally-comparable and transparent test results. The SEAD awards program is provides insights into market dynamics, stakeholder positions, potential market interventions, and gaps in the supporting policy environment for the product in question.

Competition Design and Features

The SEAD Global Efficiency Medal competition for flat-panel display televisions was launched at the International Consumer Electronics Show in Las Vegas, Nevada, USA in January 2012. Between August and October 2012, SEAD awarded Medals to Samsung and LG for producing the most energy efficient flat panel display televisions (FPD TVs) in the world. A global awards ceremony was held at the Clean Energy Ministerial in New Delhi on 17 April 2013. The awards are a pure recognition prize and do not involve a financial component.

TVs consume more than 3%-4% of global residential electricity consumption. Relative to a baseline prevalent in the market today, there is an energy efficiency improvement potential of up to 35% with more efficient technologies [11]. Based on technology market shares and specific technology efficiency forecasts, an average improvement of 10% is in energy efficiency expected over the business-as-usual forecasts as of 2012. The choice of TVs as the product category for the first round of the competition was driven by the significant energy savings potential and efficiency improvement potential indicated by the above analysis. Within the broader television category, the choice of flat-panel televisions was based on the trend of increasing global market share. In addition, the existence of a well-established, accepted international test method (IEC 62087) and the ability to differentiate TV models by their energy efficiency reinforced this selection. Finally, the relative homogeneity of the global market and market dominance by a few manufacturers contributed to the feasibility of launching a global competition and successfully promoting it to manufacturers.

The first SEAD Global Efficiency Medal competition aimed to encourage the production and sale of super-efficient TVs in three different size categories (small, medium and large as described in Table 1) and four geographical regions (Australia, Europe, India, and North America). Size categories were determined through a market analysis and are consistent with natural segmentations found in these markets. TV screen technologies sold in different regions of the world are very similar, as TV manufacturing is highly aggregated. The four award regions of the SEAD TV Awards account for more than 40 percent of the global TV market. An award ceremony to announce the European regional winners was held at the Internationale Funkausstellung (IFA) Fair on August 31, 2013 in Berlin. The global awards also recognized an overall winner for each size category, as well as the most efficient emerging technology product.

Table 1. Size Categories for Commercially Available Products

	Small	Medium	Large
Viewable Screen Area	Less than 2400 cm^2 (372 in^2)	2401 cm^2 (372 in^2) to 4800 cm^2 (744 in^2)	4801 cm^2 (744 in^2) to 6890 cm^2 (1068 in^2)
Nominal Diagonal Screen Size	Less than 29 in	29 in to less than 42 in	42 in to 50 in*

Note: TVs with screen larger than 6890 cm^2 (equivalent to 50 inches in diagonal) were eligible for this competition, but a value of 6890cm^2 was used as the screen area in the efficiency calculation (on-mode power/min{viewable screen area, 6890}) for these products.

Winning TVs were selected based on energy efficiency performance, which was evaluated as on-mode power consumption (expressed in Watts) normalized by screen area (expressed in square centimeters), using the IEC 62087: 2011 test procedure. Efficiency was evaluated based on product performance with "out-of-box" settings, and products were required to have a default luminance setting that was 65% of the maximum luminance (aligned with US EPA ENERGY STAR requirements). These requirements were aimed at ensuring that winning products delivered good picture quality and that test results were representative of real-world consumption, since most consumers use their TV's default settings. Additionally, products were required to have a maximum standby power consumption of 0.5W.

A note on the automatic brightness control (ABC) feature: According to the IEC 62087 test procedure, on-mode power consumption is measured with ABC disabled if the feature exists. If the ABC feature cannot be disabled, then measurements are performed with the light shone directly into the television's ambient light sensor at a level of 300 lux or greater, effectively disabling the ABC feature. The competition adopted the same approach to ABC.

The SEAD competition further established minimum sales requirements as a condition of entry to ensure market access of winning products. For the Commercially Available Technology product sub-category, applicants were required to have plans to sell at least a minimum number of units of a product model in the region of nomination as specified below.

Region	**Minimum Sales Threshold Units**
Australia	5,000
Europe	10,000 in one country or 50,000 units across all EU27 and EFTA-countries
India	5000
North America	50,000

The sales threshold was intended to ensure that award-winning TVs have a significant footprint in terms of market share, in order to maximize potential energy savings. For the Emerging Technology product sub-category, applicants were required to have plans for mass production of nominated products within two years of the end of the competition.

The competition identifies the most efficient products based on manufacturers' nominations, requiring active participation by the manufacturers, rather than awarding products based on publicly available data. The active approach was adopted, to expose interest from the manufacturers in producing more efficient products and spur innovation to compete and win the competition. Manufacturers entered the competition by submitting nominations forms with details about their products, including their on-mode energy usage. The Awards Administrator then identified presumptive wining products based on manufacturers' energy efficiency performance claims. Manufacturers were required to provide serial numbers for 50 products from different retail or warehouse locations from which the Awards Administrator randomly selected 2 products for verification testing. The tested products were required demonstrate an energy efficiency performance within a margin of 2 percent of the manufacturer's claims. Models that exceeded the 2 percent margin requirement during verification testing would be disqualified and the Awards Administrator would request test samples for the TV model with the next best energy efficiency performance claim for verification testing. Testing costs were borne by the SEAD governments of the respective Awards region while manufacturers were responsible for paying the shipping costs to send test samples to the laboratories.

A detailed description of the design of the competition can be found in a paper published in the conference proceedings of the 2013 European Council for an Energy Efficient Economy (ECEEE) Summer Study [10].

Competition Results

SEAD Global Efficiency Medals in the Commercially Available Technology category were awarded to the most energy efficient TVs in each of four award regions, as specified in Table 2. All award-winning models are light emitting diode (LED) backlit liquid crystal display (LCD) TVs.

Within each size category, winning products in each region were similar models from a single manufacturer, with minor technology differences to comply with regional regulations. This is reflective of the global homogeneity of the TV market and the market aggregation around a few manufacturers. The standby power of these models are well below the competition limit of 0.5W, following the global trends of sharply dropping standby power consumption driven by regulation.

Another interesting observation is that the large size winners consume less power and have lower luminance than the medium size winners. Since larger TVs typically consume more power, this demonstrates the commercial viability of technology that can significantly reduce the power consumption of TVs.

Table 2. Award-winning Models in Commercially Available Technology Category

	Size category	Australia	Europe	India	North America
Small	Model	Samsung UA26EH4000M	Samsung UE26EH4000W	Samsung UA26EH4000R	Samsung UN26EH4000F*
	On Mode Power (W)	24.4	24.9	24.9	22
	Viewable Screen Area (cm2)	1863.83	1863.83	1863.83	1863.83
	Standby Power (W)	0.15	0.13	0.13	0.13
	Max. Luminance (cd/m2)	220	260	240	240
Medium	Model	Samsung UA40EH5306M	Samsung UE40EH5000W*	Samsung UA40EH5330R	Samsung UN40EH5000F*
	On Mode Power (W)	47.4	44	47.4	44
	Viewable Screen Area (cm2)	4411.62	4411.62	4411.62	4411.62
	Standby Power (W)	0.15	0.17	0.15	0.17
	Max. Luminance	240	280	290	240

	(cd/m2)				
Large	Model	LG 47LM6700	LG 47LM670S*	LG 47LM6700	LG 47LM6700
	On Mode Power (W)	43.4	43,1	43.4	44.5
	Viewable Screen Area (cm2)	6080.6	6080.6	6080.6	6080.6
	Standby Power (W)	0.2	0.2	0.2	0.12
	Max. Luminance (cd/m2)	160	160	147	159

* International Winners
Note: More details are available at http://www.superefficient.org/TVawards

The SEAD Global Efficiency Medal in the Emerging Technology category was awarded to an LG 47-inch LED backlit LCD prototype TV that used an advanced optical film and back-light dimming technology. Per the competition rules and eligibility criteria, the Emerging Technology winning TV will be commercially available within 2 years of winning the SEAD Global Efficiency Medal.

Competition Outcomes

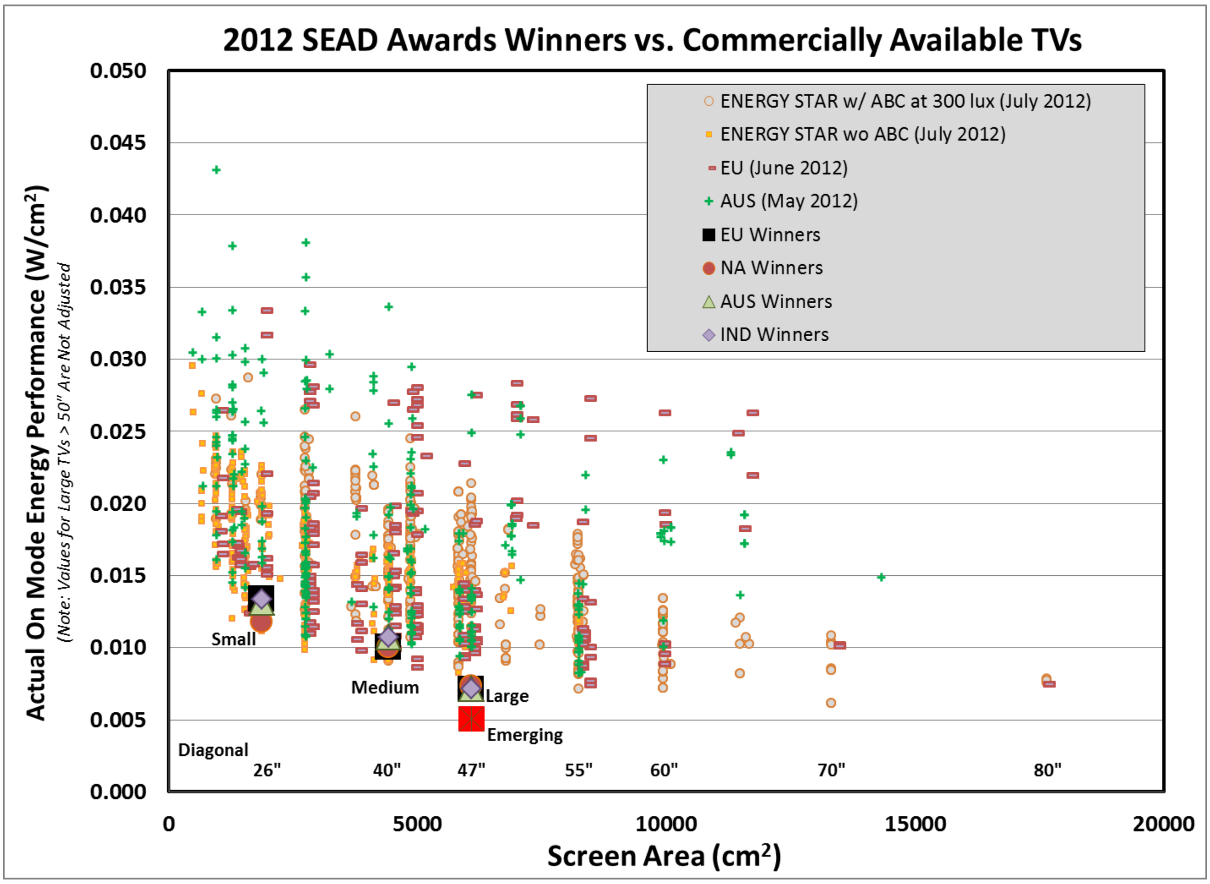
The first round of the SEAD Global Efficiency Medal competition provided many new insights into the global television market and demonstrated the potential for greater energy savings through increased product efficiency. This section provides an overview of the major findings that resulted from this competition.

1. Award-winning TVs are up to 71% more efficient than commercially available TVs, demonstrating significant efficiency improvement potential in flat-panel TVs

The energy efficiency performance of SEAD award-winning TVs was compared with TVs registered to regional databases in 2012. The dataset includes only TVs with standby power consumption less than 0.5 W and the luminance ratio between default home mode and brightest picture mode greater than 65 percent. [1], [4], [5] All TVs in the database were considered to be commercially available and weighted equally since sales weighted data was not available at the time. For North America, the dataset was taken from the U.S. EPA ENERGY STAR database and for Australia, the source of the dataset is the Australian Energy Rating. The majority of TV models compared with the European winning models are from the Intertek database, which can be regarded as representative of TVs sold in Europe. (Country-specific changes from basic models are made mostly in tuners.)

The performance of the award-winning TVs is shown in comparison to the other TVs in the different regional databases in Figure 1. The figure compares against two different U.S. EPA ENERGY STAR datasets. Since the U.S. EPA ENERGY STAR Version 5 on-mode power calculation is weighted by ABC for ABC-enabled TVs, award results are compared to on-mode power consumption of ABC-enabled U.S. EPA ENERGY STAR qualified TVs at high ambient lighting conditions (300 lux) and TVs without ABC. [1]

[1] It is also important to note that on-mode power with ABC at 300 lux is not necessarily the same as on-mode power with ABC deactivated.



Note: AUS (Australia), EU (European Union), IND (India), NA (North America), ABC (Automatic Brightness Control)

Figure 1. On-mode power performance (W/cm^2) –SEAD TV Awards Winners vs. Commercially Available TVs

Figure 1 shows that the award-winning models in the Commercially Available Technology category can be regarded as the most efficient products in the regional markets in most cases. However due to voluntary nature of participation, it is possible that the most efficient products were not nominated for this competition. It is also possible that the most efficient models do not meet the sales criteria stipulated by the competition. A more detailed comparison to the regional labels is available in [12].

The efficiency of award-winning models compared to the average efficiency among commercially available TVs in the different regions is summarized in Figure 2. “Conventional TVs” denote Cold Cathode Fluorescent Lamp (CCFL) backlit LCD TVs and “Comparable TVs” denote Light Emitting Diode (LED) backlit LCD TVs. The winners were at least 20% and as much as 71% more efficient than the average TV in the datasets. While the comparison was made to the average performance of the TVs in the database, the median performance was very close to the average.

The international award-winning model for the Emerging Technology category is approximately 30% more efficient than the winners of the large-size Commercially Available Technology category and approximately 59% more efficient than the most efficient models available in the market. This demonstrates that there is significant potential to improve the energy performance of TVs.

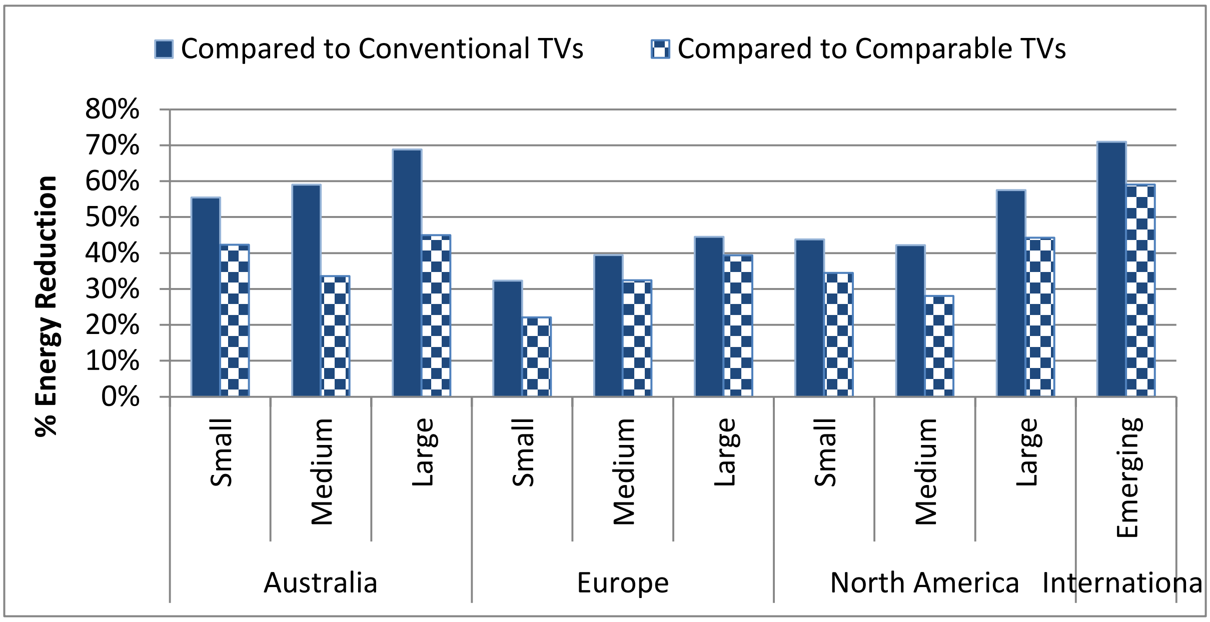


Figure 2. Comparison of Award-Winning Models vs. Commercially Available TVs

2. The SEAD Global Efficiency Medal spurs manufacturers to make ongoing changes in efficiency improvement

The regional award-winning models for the Commercially Available Technology category were already registered to the corresponding regional energy efficiency database, such as the U.S. EPA ENERGY STAR database. That is, these models were not new at the time of nomination; rather the models were a part of the manufacturers' existing product line. However, the on-mode power consumption values registered in early 2012 in the U.S. EPA ENERGY STAR database are higher than those claimed for the SEAD TV Awards.

Typically, manufacturers take into account a margin-of-error when reporting on-mode power consumption of their products to the regional databases. The volatile nature of television markets suggests that on-mode power consumption can be expected to decrease throughout the production year as manufacturers make running changes[2]. However, the 30 percent reduction in the energy use of the large size winner is well beyond the running changes typically achieved through the year. It is likely that the manufacturer made significant improvements to compete in and win this competition.

This improvement is an indication that the SEAD Global Efficiency Medal competition can spur innovation among manufacturers to improve the efficiency of their products. In fact, one of the winning manufacturers reported that they examined the product efficiency of their entire product line as a result of this competition.

3. Award-winning TVs demonstrate significant global energy savings potential

In our analysis, we estimate that if all the TVs sold were as efficient as the SEAD award-winning models, more than 84 billion kilowatt-hours (or 84 terawatt-hours [TWh]) of electricity would be saved worldwide in the year 2020 [12]. Table 3 provides the estimated savings by region.

If all new TVs (with the exception of OLED TVs) expected to be sold globally from 2013 to 2020 meet the efficiency levels that award-winning models for the Commercially Available Technology category have achieved, compared to the scenario of all new TVs with *no further efficiency improvement* within each screen technology from 2013 onward, it would provide annual savings in 2020 as follows:

- 2.9 TWh in Australia (equivalent to the national annual electricity use of Botswana [6])
- 17.2 TWh in Europe (equivalent to the national annual electricity use of Croatia [6])
- 5.4 TWh in India (equivalent to the national annual electricity use of Bolivia)

---

[2] A generally accepted industry term denoting "ongoing design changes made throughout the year"

- 18.6 TWh in North America (equivalent to the national annual electricity use of Nigeria [6])
- 84.6 TWh, equivalent to 28 medium size coal-fired power plants with 500 megawatts capacity, or taking nearly 12.3 million cars off the road for a full year [9], in all regions (more than the combined annual national electricity use of Denmark and New Zealand [6]).

Table 3. Regional and Global Savings Potential for Efficiency Improvement in SEAD TV Awards

	Annual Savings (TWh)		Cumulative Savings (TWh)	
	in 2015	in 2020	2013-2015	2013-2020
Australia	1.2	2.9	2.5	13.7
India	2.3	5.4	4.6	25.9
Europe	7.0	17.2	14.0	81.1
North America	8.0	18.8	15.6	88.7
Global	34.8	84.6	69.8	399.6

If all new large TVs (screen size equal to or larger than 42 inches) expected to be sold globally from 2013 to 2020 meet the efficiency level that the award-winning model for the Emerging Technology category has achieved, it would provide additional annual savings in 2020 of approximately 12 TWh for all regions. This is the equivalent to 28 medium size coal-fired power plants with 500 megawatts capacity[3], or taking nearly 12.3 million U.S. cars off the road for a full year [9].

4. SEAD Award-winning TVs demonstrate that energy efficient products can be cost effective

For the U.S. market, Commercially Available Technology winners in the small and medium size categories are entry-level models and that are less expensive than comparable TVs (see Table 4), which suggests that consumers can reap electricity cost savings without incurring an additional first cost for efficient technology. This demonstrates that energy efficiency can come at cost effective prices. A type of LED-direct[4] backlit LCD TVs, often referred to in industry parlance as “low-cost LED-direct backlighting” or “emerging market TVs”, employ about half of the LEDs used in typical LED backlights, and use lower-cost optical components in the backlight system [13], [14], resulting in overall lower cost TVs for the same picture quality.

It is also possible to intelligently decrease the maximum luminance level and color-reproduction capability with material-based and algorithmic improvement and without sacrificing picture quality. Lower luminance allows manufacturers to use fewer LED lamps as well as low-voltage driven electronic parts in the circuitry [11].

Table 4. Market Prices and On-mode Power of the Regional Winners in North America and Typical TVs with Similar Technology

Regional Winners in North America			Typical TVs in the U.S. Market		
Model	Price[a]	On-mode Power Consumption	Model	Price[b]	Average On-mode Power Consumption[c]
Samsung UN26EH4000F	$260	22.0 W	26" LED-LCD 1366×768	$278	29.2 W
Samsung UN40EH5000F	$548	44.1 W	40" LED-LCD 1920×1080	$566	64.9 W
LG 47LM6700 (3D enabled)	$919	44.5 W	47" LED-LCD 1920×1080	$845 (3D)	92.2 W

[a] www.amazon.com, www.alltimetvs.com (lowest price, as of Sep 2012)
[b] Average market price as of Q3 2012 projected by DisplaySearch in Q4 2011 [2]
[c] Average on-mode power consumption of U.S. EPA ENERGY STAR qualified TVs in the given category. This data is measured in the same manner as specified by the competition.

---

[3] In rough back-of-the-envelope calculations, if an efficiency technology or policy would save 3 TWh per year, it saves one 500 MW coal plant operating at 70 percent capacity factor in that year, this unit of energy savings is called one Rosenfeld [7].

[4] “LED-direct” or “LED full-array” configuration means that the LEDs are uniformly arranged behind the entire LCD panel. Unlike LED-direct models, “LED-edge” or “Edge-lit” configuration means that all of the LEDs are mounted on sides (or edges) of the display.

On the other hand, the large size winner (LG 47LM6700) does not appear to be cheaper than a typical model of its size. Another way to look at cost effectiveness is the cost of conserved electricity (CCE)[5]. CCE is estimated by dividing the annualized incremental cost (IC) (i.e., incremental price) of the energy efficient model by annual energy savings due to that option. For this calculation, the comparable product category is defined by screen size, backlight type and 3D capability (i.e., 47-inch 3D-capable LED-LCD TV). The CCE for the product category is calculated using annualized IC for the product category and energy savings for the product category, as follows:

$$CCE = \frac{annualized\ IC}{energy\ savings} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

where

$$annualized\ IC = IC\left[\frac{discount\ rate}{1-(1+discount\ rate)^{-lifetime}}\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

$$Energy\ Savings_i\left(\frac{kWh}{year}\right) = Power\ reduced\left(\frac{watts}{unit}\right) \times daily\ usage\left(\frac{hours}{day}\right) \times \frac{365\ days}{year} \times \frac{1\ kilowatts}{1000\ watts} \ldots\ldots (3)$$

, *lifetime*$_i$ is the TV economic lifetime[6], i.e. and *discount rate*[7] is the discount rate of the end user.

Given that on-mode power saved is 47.7 W and the incremental price is $74, compared to a typical model, the winner in the large size category (LG 47LM6700) has CCE with a range of $0.105/kWh and $0.178/kWh as described in Table 5.

Table 5. Cost of Conserved Electricity (CCE) for the Large Winner (LG 47LM6700)

USD/kWh		Economic Lifetime				
		6 years	7 years	8 years	9 years	10 years
Discount Rate	4%	0.162	0.142	0.126	0.114	0.105
	5%	0.167	0.147	0.132	0.120	0.110
	6%	0.173	0.152	0.139	0.125	0.115
	7%	0.178	0.158	0.142	0.130	0.121

The average electricity price of the U.S is $0.115/kWh. Thus, the CCE of the LG 47LM6700 model, with 3D capability and wireless network functions, is currently similar to or higher than the average residential electricity prices of many states in the U.S. (in some regions, average residential prices (tariffs) are lower than the marginal residential tariffs---the tariff for the last unit consumed which is equivalent to the reduction in consumer bill if one unit of electricity is saved.) The market price of 3D capable 47-inch LED-LCD TVs was projected to come down to about $560 by the end of 2015 [2]. Therefore, while the winning model in the large size category may not be cost effective today, it is likely to become cost effective in the future.

5. Several energy efficiency organizations support the competition and the SEAD award-winning TVs through promotional campaigns and financial incentives

---

[5] CCE is a metric used to compare the cost of saving electricity to the cost of providing electricity to assess the desirability of energy efficiency measures. CCE is estimated by dividing the annualized incremental cost of the energy efficient model by annual energy savings.

[6] In the U.S., the average age of recently replaced TVs was about 8 years [3]. This analysis provides the CCE results in range of 6 to 10 years.

[7] Residential and commercial sectors may use various methods to finance the purchase of TVs. The U.S. Department of Energy (DOE), in a technical support document for the energy efficiency program for consumer products analyzed that the average discount rates are 4.8 percent for residential consumers and 6.2 percent for commercial sectors [8]. This analysis provides the CCE results in range of 4 to 7 percent.

SEAD promoted the winning televisions through media campaigns and partnerships with key organizations with synergistic goals for promoting energy efficiency. Partner organizations include the Alliance to Save Energy, Consortium for Energy Efficiency, Consumer Electronics Association, Efficiency Vermont, Enervee, EPEAT, New York State Energy Research and Development Authority (NYSERDA), and TopTen USA. These organizations supported SEAD by promoting the Global Efficiency Medal competition and the award-winning televisions to their consumer base.

SEAD promotional efforts resulted in:

- Features in prominent media outlets across the globe, including Reuters and the Wall Street Journal. The competition was also promoted through popular consumer blogs such as CNET, ClimateWire, Gizmag, and Sustainable Brands. Winner announcements also appeared on digital displays in Times Square in New York City.
- SEAD award-winning TVs being placed in the top tier incentive of Efficiency Vermont's three-tier incentive program directed at retailers. Efficiency Vermont is a non-profit organization that provides technical assistance and financial incentives to reduce energy costs.
- A social media campaign to give away 10 SEAD award-wining TVs. Mass Save, an energy efficiency program in the U.S. state of Massachusetts, partnered with Samsung to organize the give-away.The sweepstakes was promoted through radio and social media campaigns and increased awareness of Mass Save's energy efficiency programs.

6. The SEAD Global Efficiency Medal competition supports testing capacity building and test method harmonization

Reliable and comparable test results are essential to a global awards program's credibility. To this end, it is critical to ensure that laboratories responsible for performing verification tests have the necessary qualifications and capabilities, and that common test protocols are available for use.

This competition employed the IEC 62087:2011 test procedure, an internationally accepted test procedure for TVs and other video equipment, to verify manufacturers' energy efficiency claims. An international round-robin test (RRT) was conducted across the designated verification test laboratories in the different participating regions by shipping the same set of 6 TVs to each laboratory and testing them in an out-of-box condition as per IEC 62087. An expert witness was dispatched to each laboratory and charged with ensuring the consistency of testing across all test laboratories. The expert witness assessed test laboratory equipment and provided training to lab technicians to ensure that all test labs were qualified to conduct TV efficiency testing according to the IEC 62087:2011 procedure. As a result, two test laboratories in India have improved testing capabilities, which are now the only test labs in India capable of testing television efficiency using IEC test methods.

At the request of the Philippines Department of Energy, SEAD extended the RRT to include a recently built government TV test laboratory. SEAD identified necessary improvements to laboratory equipment and trained several staff technicians. As a result, the Philippines Department of Energy TV test laboratory is now comparable to other leading international TV test laboratories.

Lastly, SEAD collaborated with the China National Institute of Standardization (CNIS) to incorporate the international SEAD television RRT in CNIS's ongoing national television round robin testing. This allowed SEAD to further validate the international test procedure used for verification testing.

It also allowed Awards Administrator to identify international winners without having to test all of the regional winners in the same test laboratory.

7. Data from the SEAD TV awards competition informs standards and labeling processes

The competition influenced energy efficiency standards and labeling in three different countries/regions as described below.

- *Korea:* Based on the test results from the SEAD competition, the Republic of Korea revised its television efficiency standards. These new standards are expected to save 2.2 billion kWh annually in 2020. That's enough to offset the CO_2 emissions of over 320,000 U.S. cars for a year [9].

- *India:* As a result of participating in the SEAD competition, India's Bureau of Energy Efficiency:
    - Added LED-backlit LCD televisions to the top category of their 5-star energy label
    - Is adopting the latest version of the IEC 62087 international test procedure as a basis for their efficiency labeling program. This was supported by the improved test laboratories described above.
    - Is improving the 5-star energy label rating criteria for color televisions.

- *Europe:* The SEAD competition informed the European Commission's revision of the EcoDesign regulation for televisions.

8. The competition's success necessitates further analysis of awards program as a concept

Outcomes of this first competition will help policy makers:

- Determine if an awards program can be an effective market transformation mechanism to promote energy efficient products in other markets,
- Inform subsequent rounds of the competition for other award category productsm, and
- See how efficiency improvement of globally manufactured products can be effectively accelerated.

This first round of the SEAD Global Efficiency Medal competitions merits further analysis to carefully establish its impacts in the aspects described below.

- An increase in the sales of internationally or regionally recognized award-winning products is expected to reduce electricity consumption in newly sold TVs that would otherwise have been less efficient. To determine the impact of the sales of the award winning TVs, SEAD proposes to purchase sales data for these TVs and perform further analysis to determine the net impacts of this competition.
- All award-winning Commercially Available Technology models within each size category are very similar in product design across all 4 regions. Consequently, it would be interesting to determine whether the cost effectiveness results for the U.S. market are applicable to other countries.[8]

Game Consoles: Comparing International Policy Actions

Paul Ryan[1], Jonathan Wood [2]

[1] EnergyConsult, Australia, [2]Tenvic, UK

Abstract

Video game consoles have been identified for policy action in the European Union (EU), USA, Australia and New Zealand. Game consoles, such as the PS3, Xbox 360 and the Nintendo Wii U are increasingly being used for non-gaming functions, including media play and motion control of entertainment systems. In Europe, the Ecodesign Directive on Energy Related Products (ErP) Lot 3 Sound and Imaging Equipment Impact study report identified game consoles as using over 6,000 GWh pa of electricity in 2013. In Australia, game consoles are estimated to use 395 GWh pa in 2010, representing over 15% of the total energy consumption by devices associated with household home entertainment (other than TVs).

Game console energy efficiency has been the focus of several international policy initiatives, including the EU Ecodesign Directive, US Environmental Protection Agency (EPA) ENERGY STAR, E3 program in Australia and New Zealand and the Appliance Standards for California. The EU is currently conducting an impact study on policy options for game consoles, while the Australian government has been exploring voluntary agreements with the game console suppliers to improve the efficiency of their products. The USA EPA has also established an ENERGY STAR recognition scheme for video game consoles, and the California Energy Commission (CEC) requested proposals for consideration of new appliance energy efficiency standards in California in October 2012. These policy initiatives are under development, but most propose maximum power demand limits for game consoles in various modes. Game play modes have been specifically excluded from some policies/programs, but media play/streaming and navigation modes are included. Standby power and auto power-down requirements are also specified.

These policy initiatives aim to improve the energy efficiency of video game consoles using a variety of approaches, voluntary agreements, Minimum Energy Performance Standards (MEPS) or endorsement labeling. There have been some early moves by policy makers to harmonize the various policy requirements, and this paper explores, compares and contrasts the different policy frameworks. It may be possible to leverage the existing policy initiatives and create an internationally harmonized requirement, or at least partial overlap, as the game consoles are traded internationally, with little variation in product design between markets. There are however challenges to address, including the different video and game-play specifications between console suppliers, and models.

Introduction

Game consoles are consumer electronic devices that are optimized to play video games and deliver media entertainment in the home. There are currently three main suppliers of video game consoles internationally; Nintendo, Sony and Microsoft (although it is recognised that more manufacturers are entering the market). They sell current generation consoles (Xbox360, PS3 and until recently the Wii) and are transitioning to future generations of game consoles (the Wii-U was released in late 2012), the PS4 (planned for release late 2013) and Microsoft's next generation console the Xbox One (also planned for release late 2013). There is usually a period of 4 to 8 years between releases of different generations of game console. During this period iterations of the same game console model may be released, with the manufacturers generally modifying the circuitry components with the aim of decreasing the power demand and size (or both). During these iterations there is often no significant change to the basic architecture of the platform. The game console market is changing however, with new types of game consoles coming to market which threaten to disrupt the current status quo of the three main players. These new types of game consoles are likely to be either lower powered devices or higher powered devices which are more closely related to traditional gaming personal computers.

Over the last four years, game consoles have been promoted as devices which offer more than just game playing functionality. Additional features include multimedia capabilities, such as HD video play back (streaming, video on demand, DVD, BluRay), entertainment (news, chat, web access), on-line gaming, TV tuners (add-on to PS3), and motion user interfaces (Xbox Kinect, Sony Move, etc.). The range of services provided by the three major manufacturers is increasing and the future of gaming is certainly changing to the motion user interface, very high definition video (e.g. 4K) and probably 3D capabilities.

In Europe, the recently published Energy Related Products (ErP) Lot 3 Sound and Imaging Equipment *Impact Assessment Study For Sustainable Product Measures* report estimated that game consoles used 6000 GWh pa of electricity in 2013 [1]. In Australia game consoles were estimated to use 395 GWh pa in 2010, representing over 15% of the total energy consumption by devices associated with household home entertainment (other than TVs) [2].

Several international policy initiatives have begun to focus on the energy efficiency of game consoles. These initiatives include the EU Ecodesign Directive, US EPA ENERGY STAR, E3 program in Australia and New Zealand and the Appliance Standards for California. The EU has undertaken a comprehensive preparatory study on game consoles which sought to detail the current and future environmental impacts arising from these products as well as identify policy options that could help to reduce the future impacts [3]. Following the preparatory study, the EU launched an Impact Assessment which sought to quantify the energy savings that could be achieved through the introduction of different policy measures aimed at game consoles and updated some of the background technical data found in the earlier preparatory study. The Australian government has also been exploring policy measure options which tackle the energy efficiency of game consoles. The US EPA has developed an ENERGY STAR specification for game consoles in anticipation that manufacturers will strive for ENERGY STAR recognition. ENERGY STAR is not the only US based initiative aiming to improve the energy efficiency of game consoles as the CEC is also investigating the development of mandatory energy efficiency requirements for game consoles. Most of the policy measures appear to focus on maximum power demand requirements in non-game playing modes such as media playback, navigation and low power modes. Attention has not focused on game play modes due to the close correlation between game play functionality and power demand. These developments are described in the following sections.

Game console power demand and energy use

Comparison of power demand and modes of operation

The energy use of game consoles is a function of the power demand and usage time by mode. There are several different modes of operation found in game consoles but these may not be standard across all consoles. The main power modes found in game consoles can be seen in Table 1 (based on ENERGY STAR requirements [4]).

Table 1: Modes of operation

Mode	Description
Game Play	A game is actively loaded and running either with or without user input.
Game Play pause	A game otherwise being played is paused after receiving user input or an automatic signal
Media Play	The game console is providing video or audio playback
Video Stream Play	playing a video via a network connection
Optical Disk Play	playing a video via an optical disk
HDD Video Play	playing a video direct from an internal or external storage device
Audio Stream Play	playing audio via a network connection
Optical Disk Play	playing audio via an optical disk
HDD Audio Play	playing audio direct from an internal or external storage device
Navigation	Includes the screen(s) initially displayed for user navigation through the game console operating system (e.g. the home menu)
Network standby	A lower power mode where the game console maintains connectivity to at least one external network.
Standby/Off	The mode where the game console is plugged into a power source but is not providing any primary or secondary function and has no saved hardware state. The game console has no active network link although may be capable of charging devices in this mode

The current High Definition (HD) generation consoles have managed to reduced their overall power demand from over 180 W when first released in 2008 to around 60W to 90W now in game play mode. However, power scaling of internal components during media play back or navigation mode is minimal and so power demand remains relatively high. Microsoft and Sony have both engaged with policy makers and advocates to develop an Auto Power Down (APD) functionality that is progressively being applied to their current generation game consoles via a firmware update. The APD is planned to be set to 1 hour or less from the time of the last user interaction and after 4 hours or less of audio or video media playback (or 1 hour after video play has finished). These measures have improved the energy efficiency of game consoles however there are concerns that with increased media play and no power scaling, energy use will trend higher. Table 2 shows the power demand by mode of use, for the various game consoles in the market during 2012.

Table 2: Video Game Console Power Demand by Mode (Watts) 2012

Mode	MS Xbox 360 (W)	Sony PS3 (W)	Nintendo Wii (W)	Nintendo Wii U (W)
Off or Standby	0.67	0.05	10/0.8*	11.0/0.5*
Idle (UCI Home Screen)	76.9	67.6	13.0	32.0
Gameplay	81.3	76.6	14.4	35.0
Video Streaming	73.8	61.9	13.3	29.0
Video - DVD	58.9	73.5	n/a	Unknown

Energy Consumption

The energy consumption of game consoles has been estimated in Australia to be 395 GWh pa in 2010, representing over 15% of the total energy consumption by devices associated with household home entertainment (other than TVs) [2]. The EU has estimated that game consoles used 6,000 GWh pa of electricity in 2013 [1]. Forecasts of energy consumption by game consoles are difficult to undertake, as assumptions need to be made regarding the sales, power and usage of future games console products, and these details are not released by the manufacturers before the launch of a product. However, in Australia, the EnergyConsult study has assumed that next generation game consoles will have power demand by mode and incremental reductions similar to current generation products as hardware is modified. APD was assumed to be implemented. Another key assumption of this study was that usage would remain at current levels (approximately 1 hour game play, 1 hour media play and navigation mode and 22 hours standby mode per day). The study forecast that energy use of game consoles will increase by 19% to 470 GWh pa in 2020.

Using this forecast model, updated scenarios have been provided with different usage and the power demand of the latest next generation game consoles. If usage increases along the trends shown in the Nielsen survey for 2012 [6], the average time spent playing games on consoles will decrease while the time spent streaming video, watching movies or other functions (music, internet browsing) will increase. Assuming that the game console manufacturers continue to improve the media capability and content of the next generation and current game consoles, a scenario was modelled with slowly increased usage (~ 3 mins per day per year increase in game play time and 9 mins per day per year increase in media play till 2020. Total game play = 1 hr 24 mins, total media play = 2 hrs 10 mins in 2020). This results in an increase of energy use by game consoles by 60% to 640 GWh pa in 2020 as shown in Figure 1 and demonstrates that the assumptions relating to usage are critical to estimating the overall impact of game consoles and energy use.

Similar proportional increases in total energy consumption have also been estimated in the EC Impact Assessment study [1]. Under the BAU scenario, energy consumption by Games Consoles is estimated to increase from 6,000 GWh pa in 2013 to 11,000 GWh pa in 2020, an increase of over 80%.

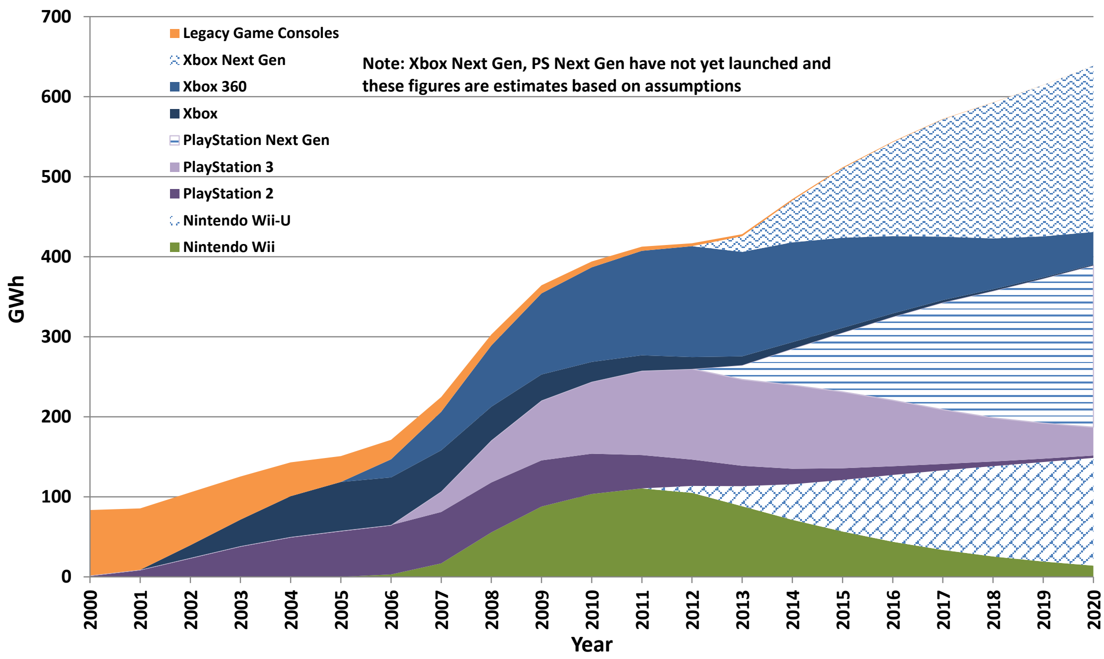

Figure 1: Forecast energy consumption of game consoles in Australia with increased usage.

Game console policy initiatives

Europe

The European Commission – as part of the Ecodesign Directive 2009/125/EC on Energy Related Products (ErP), is investigating possible policy approaches for 'sound and imaging equipment', of which game consoles are included. A preparatory study identified game consoles for action in December 2010, and the commission is undertaking an Impact Assessment Study [1] in 2013. This study, of which a draft consultants' report has already been published, investigates several policy approaches, including voluntary agreements and mandatory regulations. The main options considered, which offer greater potential energy savings that under the BAU scenario; are:

1. **Industry proposal for self-regulation/self-commitment**: with draft energy efficiency criteria. The feasibility of this proposal would depend on sufficiently stringent requirements that result in an improvement over the business-as- usual scenario and a clear commitment to future revisions as products evolve. Also, the effectiveness would require the participation of all 3 manufacturers (there is a risk that if just one manufacturer was to default then the failure rate would be 33.33%). An appropriate legal framework would be required for administrative aspects of the agreement (there is currently no clear legal commitment by the three manufacturers in the draft document).

2. **Mandatory Ecodesign requirements (regulation):** This option would involve setting mandatory maximum levels for the power demand of game consoles. The aim is to: (i) set limit values at a level providing the highest energy savings while ensuring no negative impact on product functionality and affordability, and (ii) specify implementation timing so that the cost-effective potential is realized as early as possible while ensuring that the industry has sufficient time to redesign the effected products.

3. **Mandatory energy labeling**: Energy labeling has advantages in terms of transparency, consumer information and consistency with approaches for other products. However this approach has significant issues that decrease effectiveness. There are only three main product types/models and product architectures vary widely between the three different products. This means considerable differences in functionality and power demand between each manufacturer's product may make application of an across-the-board categorization

unrepresentative. In addition, the level of energy efficiency exhibited by a game console is unlikely to be the most important purchasing criteria for most consumers. Despite these drawbacks, the EC considers that impacts may be estimated and are included in the Impact Assessment.

The potential for an international agreement on game console energy efficiency, (brokered by the Australian Department of Climate Change and Energy Efficiency (DCCEE) under the IEA banner within the 4E implementing Agreement) is under exploration. As an example, an international agreement could involve as a minimum the EC, the Australian DCCEE and the CEC. The chosen requirements could be the most robust of the requirements from the EC and Australian industry initiatives. There are advantages in this approach for manufacturers, as there will be less variation in requirements placed upon them among countries. There would need to be active input from the EC and other collaborating countries to ensure that the end agreement complied with the principles of effectiveness, efficiency and consistency. An Internationally recognized agreement was considered by the EC, but as discussions are at an early stage, the effectiveness of the proposal could not be evaluated. The EC Impact Assessment assumes the outcomes would be broadly comparable to either the industry proposal approach or the Mandatory Eco design option, depending on the requirements put forward.

Australia and New Zealand

The DCCEE have been investigating the potential for a voluntary agreement with the game consoles manufacturers since 2011. They received the industry proposal in August 2012 (which is the same as the European Commission received from industry [7]). A study by EnergyConsult recently reviewed the impact of game consoles energy use and efficiency opportunities and was prepared with input and suggestions from game console manufacturers (however they do not endorse the study). A voluntary agreement must demonstrate energy savings above the Business as Usual (BAU) for it to be considered acceptable by the Australian and New Zealand governments. The industry proposal does not appear to provide significant benefits compared to the BAU, and hence the DCCEE is now investigating other options, especially harmonization with similar regulatory approaches internationally.

USA

EPA Energy Star

The US EPA ENERGY STAR program has released their "Recognition Criteria for Game Consoles", which recognizes game consoles that meet the energy efficiency criteria, measured by the ENERGY STAR test method [4]. The EPA has proposed maximum power limits for three modes: Active Navigation Menu (40.0 W), Active Streaming Media (50.0 W), and Standby (0.5 W). Auto Power Down (APD) is also specified and activated by default. The game console must auto-power down to a Standby Mode within the period of user inactivity specified (1 hour for Active Game Play/Game Pause, Video Stream Pause or navigation Menu and 4 hours for Active Video Stream Play)

The EPA recognizes that consoles are increasingly providing non-gaming services, such as media play and could demand similar amounts of power as devices providing these same services (standard IP set-top boxes typically consume 10-20 W). These voluntary requirements are reflective of current and well-tested approaches used in related products and are intended to incentivize greater efficiencies in game consoles. The EPA will recognize manufacturers that take the steps to make energy efficiency a top priority for the design of their game consoles. Leadership is demonstrated by the companies who achieve these levels of performance. However, it is less clear if ENERGY STAR recognition will encourage purchasers to consider energy efficiency above other features of game consoles such as gaming functionality.

California Energy Commission (CEC)

The CEC requested proposals for consideration of new appliance energy efficiency standards in California in October 2012, and has prioritized game consoles for investigation in Phase 1 (2nd Qtr. 2012 to 2nd Qtr. 2013). The modes and levels proposed by the CEC are not yet published.

The CEC has received a proposal from the state Investor Owned Utilities (including Pacific Gas and Electric Company, Southern California Edison, Southern California Gas, San Diego Gas & Electric) for

Video Game Consoles. The proposal was prepared by the Natural Resources Defense Council (NRDC) [8] and proposes that California adopt a two-tier standard (2014 and 2016) for video game consoles, including auto-power down requirements and power limits in significant modes other than active gameplay. The proposed limits are shown in Table 3.

Table 3: Proposed Tier 1 and Tier 2 Measures by the NRDC for the CEC New Appliance Regulations

Function	**Tier 1 – Jan 2014**	**Tier 2 – Jan 2016**	**Rationale**
Auto Power Down (APD)	Enabled by default	Enabled by default	Savings estimate: 50% reduction in idle time.
Active Gameplay	N/A	N/A	No limit on active gaming for fairness with gaming PCs and in order not to impact performance.
Inactive - Gaming (Pause)	70 W	60 W	Console needs to scale power-down when not fully utilizing the capabilities of the device.
Navigation	70 W	60 W	Modest reductions from current levels, recognizing that this is a transitory mode with a limited impact on annual energy use.
Media (movies, music, internet)	50 W	25 W	Benchmarks: - Most efficient stand-alone Blu-Ray player: 9.9W - Wii movie streaming: 14 W
Other modes (internet browsing, photos, music, set-top etc.)	70 W	60 W	Same as Navigation. If any of the other modes emerge as one of the primary uses of consoles, specific limits would need to be set.
Standby/Off	0.5 W	0.5 W	Same as EU Ecodesign 1275/2008
Networked Standby	4.0 W	2.0 W	Same as proposed EU Ecodesign Lot 26, which have recently changed to 6W and 3W

In June 2013, the CEC issued a request for proposals from stakeholders in relation to the potential efficiency opportunities from Game Consoles. These stakeholder proposals will be considered by the CEC staff in formulating a staff report with draft proposed regulations. The staff report and draft regulations (if applicable) are likely to be published in the late 2013.

Comparison of policy initiatives

To contrast the approaches by these different regions/programs each of the following key factors has been compared:

- Policy Approach - mandatory, voluntary, endorsement,
- Metric for performance measure – power demand by mode or Typical Energy Consumption (TEC) or similar
- Modes of operation - game play, media play, standby, etc.
- Testing method
- Timeline
- Scope

Policy Approach

The policy approach to be used by each of the programs is yet to be determined; however a comparison is made in Table 4.

Table 4: Policy Approaches

Region/Program	Approach
Europe – Ecodesign Directive	**Not Decided**, voluntary agreement, mandatory labelling mandatory measures to be fully investigated
USA – ENERGY STAR	**Recognition** of those manufacturers that pledge to meet ENERGY STAR requirements
USA – CEC	**Not Decided**, but mandatory appears to be favored based on historical rules
Australia New Zealand	**Not Decided,** joining an international agreement is preferred

The USA ENERGY STAR program is currently the only formally announced policy measure on game consoles, and has opted for recognition of those game consoles that meet the published ENERGY STAR requirements. If a substantial economic region (such as the EU or California in the USA) implements a mandatory approach, this may become the de facto international standard as manufacturers will be unwilling to forgo such a market. The implementation of mandatory limits (such as MEPS) aims to prevent poorly performing products from entering the market. However as there are only three main consoles from the manufacturers currently being sold, a MEPS may prevent one or more manufacturers from offering their product. If this occurs, the overall efficiency may increase, however the reduction in product availability may have a detrimental effect on consumer choice. This may not occur, if all the suppliers meet the MEPS levels, but the risk is that manufacturers may choose not to enter a particular market if the product changes required to meet the MEPS are too costly or difficult to achieve over a short time frame. However, this potential negative aspect for MEPS can be offset by developing suitable mandatory levels which ensure energy efficiency without being too stringent as to remove products from the market place.

Metric for performance measure

The measurement metric that will be employed by most of the policy measures discussed above is yet to be defined. However the application of Maximum Power Limits (MPL) by mode appears to be the favoured choice rather than other approaches such as energy efficiency metrics. A comparison is made in Table 5.

Table 5: Metric for performance measure by Region

Region/Program	Approach
Europe – Ecodesign Directive	**Most likely approach**, Maximum Power Limit (MPL) by mode
USA – ENERGY STAR	**Decided,** Maximum Power by mode
USA – CEC	**Not Decided**, but Maximum Power Limit (MPL) by mode appears to be favored based on submissions to the 2012 Rulemaking
Australia New Zealand	**Not Decided,** joining an international agreement is preferred

A Maximum Power Limit would provide certainty to the manufacturers that the absolute maximum power demand in a certain mode is not to exceed a specific value. The verification is relatively simple and straightforward, with power measurements taken during each predefined mode of operation. A Typical/Total Energy/Electricity Consumption (TEC) metric for performance measurement takes the power demand of the devices in various modes and multiplies this by an assumed period of time to produce an energy consumption figure over a given period of time. A maximum TEC value is then set and the manufacturers are free to meet the TEC value by reducing the power demand in different modes in a flexible manner. While this approach provides some flexibility, the assumed time spent in each mode is often difficult to establish and varies by region and potentially by game console model. The TEC approach provides an incentive to manufacturers to minimize the energy consumption of products in all power modes while providing some flexibility on how much power may be used in each mode.

A major issue with any TEC approach is the need to define and consistently measure all the major power modes of game consoles and to identify suitable periods of time for each power mode. For example, one of the major modes that could potentially be included in any TEC approach is "game play". The game play mode is difficult to measure as there can be variation in user behavior, the performance specifications vary between game consoles and there are few games released for all three of the game consoles currently on the market. It has only been since late 2012 that all three game console suppliers have a HD console on the market and the features of future generation game consoles are not known until they are released. This makes direct comparisons of game play performance difficult to measure.

Modes of Operation and Maximum Power Limits (MPL)

Perhaps the most contentious issue for harmonization approaches for game console policy is the selection and definition of various modes that are included in the metric for measuring performance. Table 6 shows the various modes chosen or potentially proposed for the regional programs.

Table 6: Modes of Operation Considered and MPL where relevant

Mode/Feature	Europe – Ecodesign Directive(1)	USA – ENERGY STAR (2)	USA – CEC (3)	Industry Proposal (4)	Australia/ New Zealand
Timing (Tier 1/2)	2014/2017	2013	2014/2016	2013/2017	Joining an international agreement is the preferred option
Game Play	✗	✗	Not Decided	✗	
Game Play pause	✗	✗	70W/60W	✗	
Media Play MPL	70W/50W	50W	50W/25W	90W/70W	
Video Stream Play	✓	✓	✓	✓	
Optical Disk Play	✓	✓	✓	✓	
HDD Video Play	✓	✗	✓	✓	
Audio Stream Play	✓	✗	✓	✓	
Optical Disk Play	✓	✗	70W/60W	✓	
HDD Audio Play	✓	✗	70W/60W	✓	
Navigation	70W/50W	40W	70W/60W	90W/70W	
Standby	1W	0.5W	0.5W or 1W	0.5W or 1W	
Network standby	6W/3W	In future	4W/2W	4W/4W TBC	
Auto Power Down	✓ (1 hour)	✓ (1 hr, 4 hr media play	✓ (1 hr, 4 hr media play	✓ (1 hr, 4 hr media play	
Natural User Interface Additional Allowance	7W/5W	✗	Not yet considered	20W/15W	
Power Supply Efficiency	✓	✗	Not yet considered	✗	

Sources: (1) Europe – *Impact Assessment Study For Sustainable Product Measures – Lot 3 Sound And Imaging Equipment, 2013* see [1]. **Not Decided**
(2) USA – **ENERGY STAR** – Final Version 1.0 EPA Voluntary Criteria for Energy Efficient Game Consoles see [4]. **Decided**
(3) USA – CEC, Based on the submission by utilities PG&E, SCE, SoCalGas, SDG&E to the CEC see [8]. **Not Decided**
(4) *Energy Efficiency of Games Consoles* , by Sony, Microsoft and Nintendo, submission to Australia and Europe Commission see [7]. **Draft outline Proposal**

The coverage and MPLs described in Table 6 are not yet confirmed in the majority of regions, however early indications show that regional differences may exist if the preliminary proposals are adopted. Also, the ENERGY STAR requirements are not comparable to the MPLs for a regulatory program, as the ENERGY STAR requirements recognize the most efficient products in a category and are revised regularly to ensure they maintain this bias. There appears to be consistent consideration of the Standby Mode with all regional programs requiring that the European Commission Ecodesign regulations 1275/2008 [9] are met. Similarly, the proposed Network Standby limits are mostly similar to the Lot 26 draft amendment (27/07/2011) to the ErP standby regulation (EC) No 1275/2008. ENERGY STAR has noted they will adopt the outcome of this regulatory proposal in their future game console requirements.

The proposed MPLs for Media Play and Navigation mode range from 90W to 25W across the regions/programs. There are also substantial differences in the coverage of modes, with ENERGY

STAR not considering audio play and the other proposals including this mode. Other programs are also considering the addition of allowances for gesture and speech recognition Natural User Interface (NUI) functionality. The game console industry proposal has proposed the highest limits for most modes. Again, many of the programs have not yet officially proposed modes and MPLs and hence the final proposals may differ or converge.

Auto power-down is another area where all programs agree with the implementation of this feature, but differences may exist in the implementation. There are various discussions underway between program officers and the industry to determine the best way to implement APD without impacting on the user's operation of the game console or encouraging users to bypass the APD. These discussions center on the ways users can change the default settings (or accept the defaults on setting up the games console) and how accessories bundled with the console and using the console as a direct power source shall also power-down.

Scope

The scope of coverage of the various programs can also vary; with the ENERGY STAR program not applying to game consoles incapable of rendering HD (720p) video output via HDMI. The EU scheme will likely apply to '*Mains powered standalone devices providing video game playing as the primary function through an external screen'*, which includes all current generation consoles as well as future generation game consoles. There are no indications on the scope of coverage for the CEC appliance regulations at this time.

The definitions of Media Play are possibly another area where the scope of coverage could be important. In the industry proposal, Media play is playing of anything up to high definition (1080p), whereas the future generations of game consoles are likely to support 4K content or even higher definition content.

International Harmonization

These policy initiatives discussed earlier aim to improve the energy efficiency of video game consoles using a variety of approaches, voluntary agreements, MEPS or endorsement labeling. There have been some early moves by policy makers to harmonize the various policy requirements; however there are potentially major differences in the modes, scope and MPLs proposed in the various policy frameworks.

The most effective framework for international harmonization is still to be explored, with some proposals to the IEA 4E implementing agreement [10] considering game consoles as a separate work area. If the regional programs can cooperate to create an international framework for harmonization, there will be significant advantages, including:

- Supplier certainty – regardless of the nature of the policy initiative, suppliers will be able to produce and sell game consoles across regions without modification to their products.
- Greater negotiation power – the regional policy officials may be able to negotiate more effectively and enhance the efficiency outcomes when all regions agree on the same MPLs and modes.
- Lower policy development costs – if the policy initiatives are sharing common technical/market resources.

It may be possible to leverage the existing policy initiatives and create an internationally harmonized requirement, or at least partial overlap, as the game consoles are traded internationally with little variation in product design between markets. There are however challenges to address, including the different video and game play specifications between console suppliers and models. At the very least there seems to be potential for the harmonization of energy efficiency programs targeting game consoles in the following areas:

Standby and Network Standby Levels – all programs have initially proposed to harmonize with the European regulatory requirements of ErP.

Modes for MPLs – the majority of programs target media play and navigation. These are fairly easy to define and measure. The remaining issues to be harmonized are the media playback modes included and the MPLs specified. The largest area of contention will likely be the target values for MPLs. It should be possible for all regions to specify the same MPLs, taking into account the differences between programs targeting recognition and those regulating minimum performance standards.

Auto Power-Down – the requirements for APD are very similar between regions and the industry proposal (auto power-down after last user interaction of 4 hours for media play and 1 hour for all other modes). There are few potential small variations to finalize, including the default settings for disabling and setting up APD and including peripheral controllers/interfaces.

Timing – the programs have focused on two tiers – with levels for the Tier 1 in 2013 or 2014, and Tier 2 from 2016 to 2017. The timing appears to be very close to common dates for all initiatives, however these are not yet decided.

The major areas of difference will require further research and negotiation. These are likely to include:

- MPLs for Media Play and Navigation – agreement on the appropriate levels for regulatory programs will require significant cooperation between regions/programs.
- Game Play Pause – the inclusion of this mode is not supported by the manufacturers. The ENERGY STAR program focused on using APD to save energy when the user pauses the game rather than a MPL for this mode.
- Power Supply efficiency – it is argued by ENERGY STAR that a manufacturer should have the design freedom to meet the MPLs via whatever cost effective method is applicable to their console, rather than a prescriptive requirement on the power supply componentry.
- Allowances for NUI – the inclusion of various Gesture and Speech Recognition Natural User Interface (NUI) functionality will increase the power demand of game consoles, however further research is required to determine the appropriate levels/allowances.
- Charging peripherals – there is likely to be greater power use by consoles as controllers incorporate secondary screens (e.g., Wii U) and require these devices to be charged from the primary console. How APD is implemented without impeding the user experience will be essential to ensure that consoles power-down after the peripheral is charged.
- Network Standby Modes – the availability of network connected consoles will increase the importance of this mode and the impact of standby power in the overall console energy use. As network connections are prevalent now, the efficiency of how they are implemented will be highly important to the overall potential energy savings. If a product uses 8W when in a network connected mode, its overall energy use in this mode will be significantly higher than most current generations of game consoles. However, game consoles which provide more functionality in network standby mode, such as support for software updates, may allow for game consoles to spend more time in this mode than in on mode and therefore save energy overall.

These challenges are potentially addressable when local policy makers and technical experts engage with the manufacturers in a coordinated and resourced manner. Examples of other product groups that have led to generally agreed outcomes in recent times include MEPS for external power supplies and televisions. These two product groups include products that are generally manufactured in a single location but traded internationally. The coordinated test development and policy action led to the creation of international test methods and agreed performance levels across many jurisdictions. This same approach could be used for game consoles, especially as very few manufacturers need to be engaged.

Technical Challenges

There are a number of technical challenges to the development of policies that aim to reduce the energy use of game consoles. The key issue for game consoles is that power and functionality in some power modes is closely correlated (meaning reducing power may reduce functionality, especially in game play mode). Also, the functionality in one mode (e.g. game play) can influence power demand in another mode (e.g., media play back) because the commands are run through the same components. Some proponents suggest that separate components may be a way to reduce the power use (such as separate DVD player integrated into the game console), however separate components can't be easily used or their functionality updated via software updates. Perhaps a better approach is to use power scaling, where the power use is scaled down and up according the use/function of the device. The amount of power used by the current generation of consoles only decreases by 10% to 20% when playing a video or streaming media. Other media devices and PCs can reduce power demand significantly when lower levels of processing power are engaged.

Finally, the exact functionality of future products is often not known. This creates a situation where policy makers are unable to assess the impact on functionality from power demand limits placed on individual power modes and rely on the manufacturers to indicate what is possible. For example, the suppliers provided statements to the EPA Energy Star process [11] that *"neither the navigation nor the media streaming power caps suggested in Draft 3 are achievable, either by the present generation of game consoles or by employing the best scalable technology appropriate for any next generation console platform*". Nintendo released the Wii U a month later which easily achieved these requirements.

There are also difficulties in comparing game consoles with other products, such as gaming notebook PCs, which offer higher functionalities than current generation game consoles but use significantly less energy. To compare game console with gaming desktops, which may use more energy but provide a higher graphic functionality, is also difficult. Comparisons to gaming computers are difficult because these products provide significantly more functionality than most game consoles but may have very different energy use profiles such as significantly higher active mode power demands but lower idle mode power demands. Game consoles, on first release, may also offer significantly more functionality than an average gaming computer and so initially have higher power demands which are reduced overtime as more efficient components become available. However, the game console manufacturers have more control over the manufacturing and the software that is used on the devices compared to computers, which should enable greater system optimization. Other comparisons can involve comparing game consoles with stand-alone media/optical disc player/streaming devices, which use between 10W and 25W, compared to the Nintendo Wii U (32W) and current generation HD consoles (60W to 70W). These media playing devices have less functionality than game consoles.

Policy Challenges

There a number of policy challenges to the development of internationally harmonized energy performance goals for game consoles. These include:

- **Different timing** – various regional policy approaches are progressing at different rates, with some (e.g., ENERGY STAR) already announced. The EU is likely to announce their policy approach during 2013, while the CEC has just begun their appliance standards rulemaking. These different timings inhibit the development of coherent approaches because when government policy developments are progressing at different rates this creates multiple timings for implementation.
- **Different policy drivers** – some regional policy approaches are targeting voluntary or mandatory minimum energy performance standards while others are setting aspirational targets. These varied objectives create differences in the targeted levels for game console energy performance.
- **Different levels of ambition and political support** – the targeted power levels envisage an improvement over the BAU scenario. However, various regional jurisdictions have diverse levels of ambition in this regard and likewise different levels of support by the political leaders. Greater levels of ambition usually require high level support from leaders in political institutions as industry may lobby against implementing significant changes to the energy efficiency of products, especially if any changes lead to increased product costs.

Conclusions

The energy consumption of game consoles is likely to rise over the next decade. The escalation in usage of media streaming could be one of the major drivers of an increase in the overall energy consumption of game consoles. A user may not need to purchase a separate device for these media playing functions, however the power consumption of the current generation HD game console when playing media is at least three times higher than a dedicated media playing device (of around 20 W or less).

There are significant opportunities for international cooperation on the various policy and technical approaches that governments can apply to improve the energy efficiency of game consoles. Although there is often different timing, policy drivers and levels of ambition in various regions, the fundamental elements of policy approach (modes of use, standby/network power levels, testing approach, APD, etc.) are similar. These policy parameters are potentially close to harmonisation internationally and will benefit from coordinated action. The major issues faced by policy officers will be the maximum power demand levels that can be established to encourage efficiency improvements. International cooperation by various regions/programs will assist in developing suitable mandatory levels which will encourage energy efficiency in game consoles without being too stringent as to remove products from the market place. It will also provide certainty for game console manufacturers who will be deploying their next generation of game console during 2013 to 2014.

An Evaluation of the Energy Efficiency Level of Households Appliances and Lighting in Bauchi Town, Nigeria

Ibrahim Udale ***Hussaini*** *(PhD)*

Architecture Programme, Abubakar Tafawa Balewa University, Bauchi- Nigeria

Abstract

Nigeria as a nation is endowed with abundance of natural resources, yet undergoing energy crisis. It is currently experiencing rampant energy poverty due to the inefficiency of the energy industry to meet the energy demands of its customers. This situation adversely affects all sectors of the economy, and particularly the housing sector with great impact on the welfare of the residents. In fact, the household energy consumption constitutes a substantial amount of societal energy demand resulting from rapid growing population, increase in living standards and the rising number of apartments in all parts of Nigeria including Bauchi. An immediate complementary measure suitable for the current Nigerian situation is to reduce energy demand which can be achieved through use of energy efficient designs, appliances and practices. On this premise, a study was undertaken on some selected households in Bauchi town to determine the energy efficiency level of appliances/lighting in use through an inventory study (case study). The result reveals a very low level of energy efficiency in appliances and lighting; therefore prompting the need to direct attention towards improving the energy efficiency level of household appliances and lighting.

Keywords: Energy resources, Energy efficiency, Appliances, Inventory study, Households, Bauchi-Nigeria.

Introduction

The issue of energy efficiency has recently become a critical one in all aspects of national development, particularly housing. This is because energy represents not only a high percentage of the running cost of a building but it also has a major effect on the thermal and optical comfort of the occupants. In Nigeria, the residential building sector is the highest energy/power consumption sector of the economy [1], and is associated with energy efficiency problems. Most household appliances and lighting are electrical and constitute a major part of the energy consumption bill [2]. To adequately address this issue, the energy performance of households needs to be improved upon, which according to Baker [3] is dependent largely on three factors of building, systems and occupants; i.e.,

i. that which is inherent in the building design,
ii. that which relates to services systems design and efficiency, and
iii. that which is due to the effect of occupant behaviour.

This shows the importance of services system /appliances design efficiency in household energy use. Unfortunately, most households' lighting installations/appliances today are inefficient due to inadequate briefing at the design stage, too much emphasis on capital cost, lack of thought during design and installation, and poor maintenance procedures. Therefore, to design or accomplish a house which has low energy running and maintenance costs, energy efficient considerations must be taken into consideration at every stage of the design process [4, 5]. The implication of this (i.e. attaining energy efficiency) is that developers can build cheaper and simpler buildings, landlords can increase rents due to added benefits of lower running and maintenance costs, tenants pay lower running and maintenance costs, and building users are more productive and healthier in the better indoor environments which can accompany energy efficiency in buildings [6].

The Need for Energy-Efficient Appliances and Lighting

A careful selection of building materials/services systems can have a dramatic effect on energy consumption and the operational costs of a building. Though, increasing number of households tends to raise energy consumption, but improving efficiencies of appliances and lighting will tend to reduce consumption. According to Zold [7], the energy consumption of household appliances is more uncertain because variations in their type and power cannot be predicted, nor can changes in the use of the building itself; and also the variation in the schedule of use of the different household appliances, and the consumption of hot water. But recent developments in energy technology has made it possible to decrease significantly the energy consumption of buildings, to create housing that is more comfortable and to implement a major decrease in emissions to the environment [2]. The housing designers can therefore do much to cut energy costs of electric lighting and other appliances by specifying and installing low energy lighting and appliances. However, the continuing shortfall between electricity demand and supply, the escalating cost of building new power plants and the competing needs for investment capital are some of the few obvious reasons why Nigeria should have improved energy-efficient households. Moreover, the prevailing rampart power shortages are attributable in part to peak demands caused majorly by lighting, air conditioning, and use of other higher energy consuming appliances (water heaters, deep freezers, washing machines, etc.) in major cities.

Continued effort by the government in establishing a lasting sustainable financial structure and incentives for energy-efficient products backed up with formidable policies and public awareness programme in this direction can help abate the efficiency problem.

In fact, appliances and lighting represent the bulk of residential energy use growth area, and has been witnessing increasing consumption levels (about 2% per year) since the 1970s [8]. In Nigeria, the residential energy is about 50% of the total electricity consumption [1]. This value compared to the global residential energy consumption as in figure 1 is due largely to the gross inadequacy of the Nigerian energy industry to provide the needed energy drive for industrial growth (leading to the almost collapsed industrial sector).

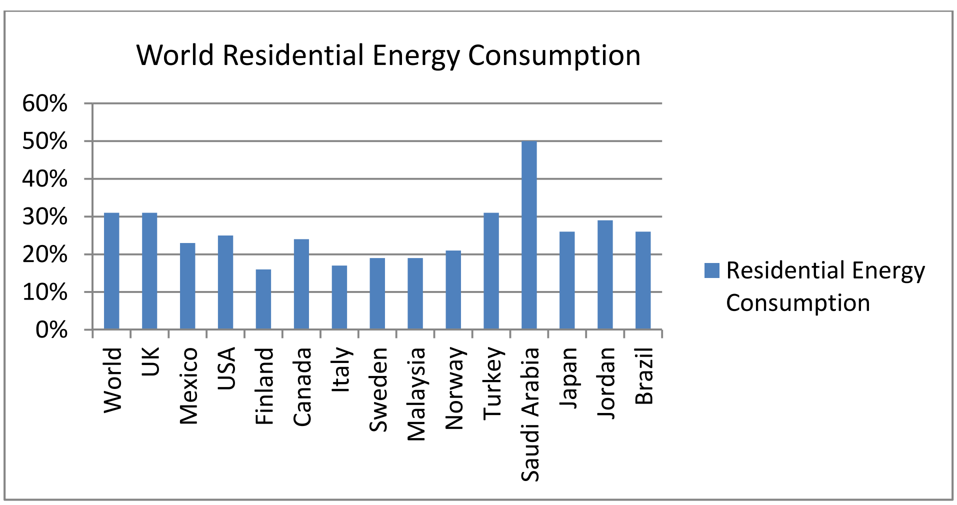

Figure 1: Worldwide residential energy consumption

Source: (Meyers et al., 2003; Nicola, 2001; Boardman, 2004; Ueno et al., 2006; Araujo et al., 2001; Kamal, 1997; Lenzena et al., 2006) in Saidur, Masjuki, Jamaluddin [9].

Household energy use occurs in the form of space conditioning, lighting, water heating, food refrigeration/freezing; and other miscellaneous energy services like clothes washing and drying, cooking and cleaning, home entertainment, etc. [10].

Space Conditioning

Space conditioning occurs in the form of heating, cooling, ventilation and humidity control. This requires more energy than any other service in both commercial and residential buildings. It accounts for more than half of total residential/commercial energy use. In residential buildings, space heating accounts for about 46% and space cooling for about 9% of energy use [10]. Because of the tropical climatic conditions of Nigeria, space heating is almost negligible except for a few mountainous regions of north central and north eastern part of the country.

There has been serious advancement in the technologies for room air conditioners in recent years. There is the new trend in household air conditioning toward central air conditioning systems in new single-family homes and multifamily buildings in developed worlds, particularly in the United States where over two-third of households are constructed with central systems. This development show a trend of increased efficiency resulting from continual free-tuning and adjustment: larger condenser and evaporator coils, better motors, improved insulation, reduced airflow-path resistance, and better fan blade design.

The energy efficiency of room air conditioners has improved due to higher efficiency compressors, improved fan designs, and larger heat exchangers. The average new unit bought today needs about 30% less electricity to deliver the same cooling as the average unit bought in early seventies [10]. Yet, many households in Bauchi, Nigeria with space conditioning facilities still maintain the old energy-inefficient types.

Lighting

In fact, a good lighting system design enhances the energy performance of buildings by offering extraordinary opportunities for energy and cost saving. Using the technologies currently available in the market, electricity use for residential lighting could be cut by about one-third [10].

The quest for increased light levels for good performance coupled with the growth in population and building construction will cause lighting demand to grow quickly, probably faster than overall electricity demand. During the last five years, the average annual increase in lamp production was about 15% compared to an 8-9% increase in electricity production [11].

However, the lighting needs of a household need to be identified, both quantitatively and qualitatively as part of the environmental programming conducted early in the project. This is because, some spaces require more of daylighting like lobbies and circulation areas with low lighting levels. But spaces used for high demanding tasks require high light levels and a glare-free environment. Such spaces may shift the designer’s attention from daylighting system to a very efficient electrical lighting system with integrated occupancy sensors and other controls [12].

In Nigeria at the moment, the illumination levels for households and other functions like classrooms, hospital examination rooms, general office, falls grossly below 100 lux as compared to other advanced nations (see table 1), except in exclusive private dwellings of the high class people with sufficient and independent power plant.

Incandescent lamps provide most lighting in the residential sector. Although, there are several improved (advanced) incandescent lamps (presently not available in Nigerian markets), they are still far less efficient than fluorescent lamps.

Fluorescent lamps are about four times more efficient than incandescent lamps, but their use in residences has been limited by their higher frost cost, unattractive light, and inability to fit in incandescent fixtures.

Table 1: Comparison of illumination standards in different countries (lux)

	U.K.	Germany	Japan	Russia	USA	China
General office	500	500	300–750	300	300	100–200
Drafting	750	750	750–1500	500	750	200–500
Classroom		300	200–750	300	300	75–150
Hospital examination room	500	500–1000	200–500		540	75–100

Source: Min, Mills and Zhang [11].

Production of CFL provides reasonably attractive light and fitting regular incandescent fixtures yet using the efficient fluorescent technology. The CFL achieves an efficiency of 61 lumens per watt, or 3.8 times the efficiency of a comparable incandescent, though they are not suitable for all residential applications. Therefore, lighting efficiency can be improved by improved lighting operation and design. That is;

i. turning off lights when not needed,
ii. using automatic (dusk-to-dawn) switches on outdoor lights, and
iii. designing fixtures that reflect rather than absorb light.

These opportunities are difficult to quantify, and their savings potential will depend on the specific situation [10]. However, the bulk of the lighting facilities in the households in Bauchi according to this study, are incandescent lamps (over 50%). This provides the opportunity to achieve great reduction in lighting energy consumption if they are replaced by CFLs.

Water Heating

Water heating accounts for about 15% of residential and 4% of commercial energy use. In residential buildings, hot water is used for personal washing (in showers and baths), clothes washing, dishing washing and other miscellaneous uses.

The efficiency of residential-size water heaters has improved in recent years due largely to increased tank insulation, smaller pilot lights, and improved heat transfer from combustion gases to the water in the tank. Other methods of improving water heating efficiency include demand reduction, retrofits to existing units, and technical improvement in new units [10]. But, due to the hot climatic region of N. E. Nigeria where Bauchi is located (except a few mountainous regions), the water heating energy demand is not much emphasized.

Food Refrigeration/Freezing

About 10% of residential energy use goes into keeping food cold. The energy efficiency of food refrigeration equipment has improved greatly in the last 10-20 years. Among these improvements are the use of polyurethane foam rather than fiberglass insulation, more efficient motors and compressors, improved door seals, and improved air flow between cold coils and food compartments.

Many other technologies such as improving compressor design, installing separate compressors for the freezer and the refrigerator (dual compressors), and moving the compressor from the bottom to the top of the refrigerator to reduce heat flow from the compressor into the refrigerator could be considered to improve energy efficiency [10]. In fact, there is a gradual ‘phase-out’ of inefficient refrigeration appliances in the Nigerian households as the old ones (no longer in the market) are being replaced by the new energy-efficient types.

Other Energy Services

There is a wide range of energy services provided in residential buildings other than space conditioning, lighting, water heating, food refrigeration and freezing. These include clothes washing and drying, cooking and cleaning, home entertainment, etc. These miscellaneous energy services account for about 13% of residential energy use [10]. Except for cooking, majority of these 'other energy services' in Bauchi town are energy-efficient types as available in the market.

Approaches and Methods

The objective of this study is to evaluate the energy efficiency level of households' appliances and lighting in Bauchi town, Nigeria as a prelude to proffering ways to improving household energy efficiency. To accomplish this effort, an inventory (case study) of households' appliances and lighting was undertaken in twelve (12) selected houses from the three (3) geographical districts of Bauchi town between October and December, 2010. That is, two (2) housing units from each housing estate; and two (2) housing estates from each of the three (3) geographical districts (Bauchi, Galanbi & Zungur) of Bauchi (metropolis) LGA.

In the process, the items were categorized as lighting, cooling, heating, refrigeration, cooking, computers, electronics; and 'others' which comprise of pressing iron, blender, toaster, deep fryer and washing machine as identified in all houses understudied.

These items were further classified as 'ordinary' (i.e. not efficient), 'efficient-type,' and 'undetermined' for ease of analysis (see table 2).

The result obtained was further subjected to appliances description categorization *scale of 1-5* (% range) to measure energy efficiency from 'Very unsatisfactory' to 'Very satisfactory' for the subsequent inventory analysis:

Table 2: Classification of Appliances/Lighting

Appliances Classification	Definition
1. Ordinary	Appliances with higher energy consumption ratings. Usually of old technology, either labeled or determined by deduction based on none performance at low voltage levels.
2. Efficient	Appliances with lower energy consumption ratings compared with existing types with higher ratings. Usually of modern technology, either labeled or determined by deduction based on very low voltage performance.
3. Undetermined	Appliances that the energy consumption rating is not labeled and could not be determined by deduction.

Categorization scale: 1- 5 (% range)

	Unsatisfactory		**Satisfactory**	
(0-20%)	(21-40%)	(41-60%)	(61-80%)	(81-100%)
Very unsatisfactory		**Neutral**		**Very satisfactory**

Source: Hussaini [13]

Result and Discussions

The lighting appliances were categorized into incandescent and fluorescent lightings respectively as recorded in table 3. Meanwhile, the incandescent lamps are generally described as 'ordinary' (i.e. not efficient) since there are no efficient incandescent bulbs in Bauchi market for now. On the other hand, the fluorescent lighting can either be 'ordinary' or 'efficient-type'. The 'efficient-type' refers to the compact fluorescent lights (CFL).

From table 3, it is observed that there were one-hundred (100) incandescent lamps and ninety-nine (99) fluorescent lamps in the twelve (12) households. Out of the ninety-nine (99) fluorescent lights, twenty-six (26) (i.e. 26.3%) were the ordinary type while seventy-three (73) (i.e. 73.7%) were the CFLs. That is, in a total of one hundred and ninety-nine (199) lighting points, only seventy-three (73) points are fixed with energy saving bulbs. This accounts for only 36.7% lighting efficiency. This level of energy efficiency in lighting which is a fundamental aspect of energy consumption in Nigeria and based on the above scale is *unsatisfactory.*

The cooling appliances are categorized as fans and air-conditioners respectively. From table 3, it is clear that there were sixty-eight (68) fans and five (5) air-conditioners (ACs) in the twelve (12) households surveyed. Fifty-nine (59) (i.e.86.8%) of the fans are 'ordinary' while only nine (9) (i.e. 13.2%) are the 'efficient-type.' Meanwhile, all the five (5) ACs (i.e. 100%) were observed to be energy efficient-type. That is, in a total of seventy-three (73) cooling appliances, only fourteen (14) (i.e. 19.2%) are energy efficient. This level of energy efficiency is *very unsatisfactory* considering the importance of cooling appliances which is next to lighting in terms of consumption level in Nigeria.

Table 3 indicates that there are seven (7) room heaters and all are 'ordinary' type; ten (10) water heaters and all are 'ordinary' type; and fifteen (15) water boiler/kettles, out of which two (2) are efficient-type (13.3%) and thirteen (13) are 'ordinary' type (86.7%). This implies that only two (2) (i.e. 6.3%) of the thirty-two (32) heating appliances are energy efficient. This is a *very unsatisfactory* level of energy efficiency.

The refrigeration group of appliances includes the fridge and the deep freezer. There were fourteen (14) fridges in all; out of which nine (9) are 'ordinary' type and five (5) are efficient-type. The deep freezers are thirteen (13) in all, and only four (4) are 'ordinary' type while nine (9) are 'efficient-type'. That is, in a total of twenty-seven (27) refrigeration appliances, only fourteen (14) (i.e. 51.9%) are energy efficient. The energy efficiency in this scenario is on the *neutral* level (i.e. neither satisfactory nor unsatisfactory).

As indicated in table 4, four (4) different modes of cooking were identified in the households surveyed. Among them are three (3) electricity-type cooking appliances, one (1) gas-type cooking appliance, one (1) kerosene-type cooking appliance and wood fuel (one-type) for cooking. Except for the electrical appliances, all others were classified as undetermined.

The three (3) electricity-type appliances are; electric cooker, electric stove and micro-wave oven. There were three (3) electric cookers and all classified as 'ordinary'; six (6) electric stoves, all classified as 'ordinary'; and one (1) micro-wave oven which is classified as 'efficient-type'. That is, among all the ten (10) electricity-type cooking appliances, only one (1) (i.e. 10%) is energy efficient. This is a *very unsatisfactory* level of energy efficiency.

Table 3: Inventory of Appliances in Use in 12 Selected Housing Units

Factors	Parameters	Description	Frequency	Percentage (%)
1. Lighting	Incandescent	Ordinary	100	100
		Efficient type	-	-
		Undetermined	-	-
	Fluorescent	Ordinary	26	26.3
		Efficient type	73	73.7
		Undetermined	-	-
2. Cooling	Fans	Ordinary	59	86.8
		Efficient type	09	13.2
		Undetermined	-	-
	Air Conditioners	Ordinary	-	-
		Efficient type	05	100
		Undetermined	-	-
3. Heating	Room Heater	Ordinary	07	100
		Efficient type	-	-
		Undetermined	-	-
	Water Heater	Ordinary	10	100
		Efficient type	-	-
		Undetermined	-	-
	Water Boiler/Kettle	Ordinary	13	86.7
		Efficient type	02	13.3
		Undetermined	-	-
4. Refrigeration	Fridge	Ordinary	09	64.3
		Efficient type	05	35.7
		Undetermined	-	-
	Deep Freezer	Ordinary	04	30.8
		Efficient type	09	69.2
		Undetermined	-	-

There were sixteen (16) computer appliances identified in the twelve (12) households under study classified as PC/accessories and Laptops (see table 4). There were eight (8) PCs out of which three (3) are 'ordinary', three (3) 'efficient-type', and two (2) 'undetermined'. All the identified eight (8) laptops are classified as 'efficient-type'. That is, eleven (11) (i.e. 68.8%) of the sixteen (16) computer appliances are energy efficient. This score is a *satisfactory* level of energy efficiency according to the scale of measurement.

There were fifty-two (52) electronic appliances as shown in table 4, classified as television sets, satellite decoders, and DVDs/Video/Radio players. There were twenty-seven (27) television sets, out of which twenty-three (23) are 'ordinary' and four (4) 'efficient-type'. The satellite decoders are ten (10), out of which are two (2) 'ordinary', seven (7) 'efficient-type', and one (1) 'undetermined'. The DVD/video/radio players are fifteen (15), out which six (6) are 'ordinary' and nine (9) 'efficient-type'. That is, in a total of fifty-two (52) electronic appliances, only twenty (20) (i.e. 38.5%) are energy efficient. This level of energy efficiency score is *unsatisfactory*.

Table 4: Inventory of Other Miscellaneous Energy Services

Factors	Parameters	Description	Frequency	Percentage (%)
5. Cooking	Electric Cooker	Ordinary	03	100
		Efficient type	-	-
		Undetermined	-	-
	Electric Stove	Ordinary	06	100
		Efficient type	-	-
		Undetermined	-	-
	Gas Cooker	Ordinary	05	100
		Efficient type	-	-
		Undetermined	-	-
	Micro-wave Oven	Ordinary	-	-
		Efficient type	01	100
		Undetermined	-	-
	Kerosene Stove	Ordinary	-	-
		Efficient type	-	-
		Undetermined	17	100
	Wood Fuel	Ordinary	-	-
		Efficient type	-	-
		Undetermined	11	100
6. Computers	PC and Accessories	Ordinary	03	37.5
		Efficient type	03	37.5
		Undetermined	02	25
	Laptops	Ordinary	-	-
		Efficient type	08	100
		Undetermined	-	-
7. Electronics	Television Sets	Ordinary	23	85.2
		Efficient type	04	14.8
		Undetermined	-	-
	Satellite Decoders	Ordinary	02	20
		Efficient type	07	70
		Undetermined	01	10
	DVDs/Video/Radio Players	Ordinary	06	40
		Efficient type	09	60
		Undetermined	-	-
8. Others	Pressing iron, Blender. Toaster, Deep fryer.	Ordinary	04	18.2
		Efficient type	18	81.8
		Undetermined	-	-

In the category of 'other' appliances as in table 4, we have the pressing iron, blender, toaster, deep fryer and washing machine; all together twenty-two (22) in number. Among these, four (4) are 'ordinary' while the remaining eighteen (18) are 'efficient-type'. That is 81.8% energy efficiency score which is *very satisfactory*. The effect of this result is negligible as most of the houses do not possess these appliances.

The cumulative result reveals a very low level of energy efficiency in household appliances in Bauchi. Invariably, lighting and all appliances of cooling, heating, cooking, refrigeration and electronics are in the category scores of very unsatisfactory, unsatisfactory or neutral. These scores fall below the desirable satisfactory level necessary for the accomplishment of good energy efficiency practice in the households.

The finding has also indicated that cooking in Bauchi, typical of Nigeria and other underdeveloped countries (Africa) has both the modern and traditional methods incorporated in a majority of the households. The modern ways include the use of electric cooker, electric stove, gas cooker, micro-wave oven etc., while the traditional method includes the use of kerosene stove and wood as fuel. The latter is a substitute and an alternative to the former in most cases because of the scarcity and high price of the electric energy and cooking gas required to utilize these appliances. Meanwhile, kerosene and wood are relatively cheap and readily available. As a result, almost all households subscribe to this substitute. However, it is discovered that among the electricity-type appliances only ten percent (10%) are energy efficient. Improving the reliability of power supply along with the use of energy efficient appliances would assist to remedy this situation.

Conclusion

Concisely, it is apparent that the lighting appliance is the dominating appliance in use in all the households; an indication that lighting is a very important part of our energy need. Therefore, promoting efficiency in lighting alone can lead to immediate enormous gains. In general, the government must ensure the promulgation of policies/measures that would lead to the replacement of the existing inefficient appliances either by retrofitting, halting the production/importation of inefficient appliances, and/or adopting the following improvement strategies (according to literatures) to remedy the appalling situation of households appliances and lighting energy efficiency;

- Reduce energy consumption by substitution of electric heating by other energy sources.
- Reduction of energy consumption of air conditioning systems and lighting.
- Reduction of energy consumption of electronic equipment in stand-by mode.
- Development of windows with heat transfer coefficient less than $2W/m^2k$ and the development of special glass with increased reflection and selective absorption and emission abilities.
- Consideration of the passive energy design strategies for natural lighting (daylight) and natural ventilation; and the development of measurement techniques for evaluating the energy efficiency of buildings.
- Setting energy efficiency standards by the controlling authority by imposing minimum level of efficiency though manufacturers are not usually disposed to it because of administrative and adaptation costs.
- Stimulating the supply of efficient products by technology procurement, i.e. offering incentives to manufacturers to take part in development and diffusion of highly energy efficient products.

PROMOTING ENERGY EFFICIENCY REFRIGERATORS IN GHANA

Eric Kumi Antwi-Agyei

UNDP-GEF-Energy Commission

ABSTRACT

Ghana launched a Refrigerator Rebate and Exchange Scheme in September 2012 as a tool to reduce energy consumption and address the environmental impacts of old refrigerators. The West African nation has taken significant strides in promoting energy efficiency in recent times by instituting regulations and other innovative market tools to curb the rising demand for energy.

This paper discusses the implementation of a refrigerating appliance transformation project, which intends to promote more energy efficient appliances on the Ghanaian Market. This project, which is at its mid-term, is already making significant impact and proves that market transformation schemes in developed countries could equally work in a developing country such as Ghana when modified to suit local conditions.

Introduction

In most developing countries, the demand for electrical energy is fast on the heels of installed generation capacity. Ghana is experiencing a similar situation in view of its growing population and attendant economic growth. As the standard of living in any country improves, residential electricity demand is expected to grow rapidly as more people purchase TVs, refrigerator, air conditioners and other appliances. This is the case of Ghana, which achieved a growth rate of 7.1% in 2012 against a global growth of 3.2% and Sub-Saharan Africa growth of 4.8% [1]

As expected, electricity demand in Ghana is also growing at an average rate of 11% annually. However, wastage in the end-use of electricity is estimated at about 30% [2]. The main electricity consuming sectors in the country are the industrial, commercial and the residential sectors. As shown in figure 1, the industrial sector continues to be the highest consumer of electricity followed by residential and the commercial sectors respectively.

The Government has therefore committed to increase the total electricity output to 5,000 MW by 2015 to meet the growing demand for electrical energy[3].

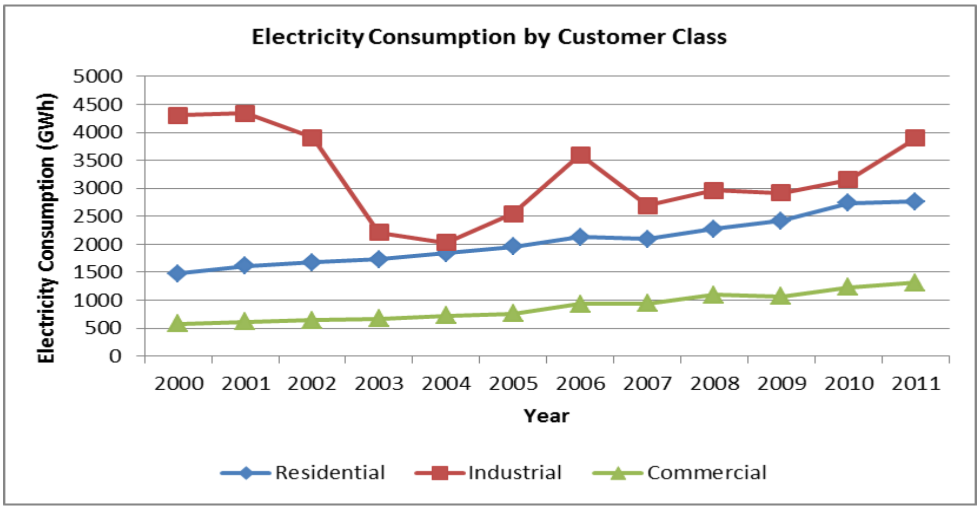

Figure 1: Electricity consumption from 2000 – 2011 Source: Energy Commission, 2013

There is however great potential to also reduce national demand through energy efficiency programmes. In 2007 when the country experienced a power crisis, there was a justification for the Government of Ghana to improve energy efficiency by distributing six million pieces of compact fluorescent lamps (CFLs) free of charge to replace an equivalent number of incandescent bulbs throughout the country. This intervention saved approximately 124.2MW in peak demand and about 112,320 tCO_2 per annum [4]

Another achievement of the exercise was the significant increase in the penetration of CFLs in the country. As at 2009, the penetration of CFLs had increased from 20% in 2007 to 79%, with a corresponding decrease in the penetration of incandescent lamps from 58% in 2007 to just 3% in 2009 [4].

Energy efficiency standards and labelling regulations have been introduced for lighting, domestic refrigeration and air conditioning Ghana is now operating a mandatory appliance standards and labelling regime under which importers and retailers of air conditioners, compact fluorescent lamps (CFLs) and domestic refrigerators are required to import and sell only products that meet minimum energy efficiency and performance standards. Legislative instruments (LI's) prohibiting the importation and sale of inefficient incandescent bulbs, used refrigerators and air conditioners has also been introduced to ensure that only domestic appliances that meet the minimum energy efficiency standards enter the Ghanaian market. The energy efficiency LIs that have come into effect in Ghana are:

- Energy efficiency Standards and Labelling (Non-ducted Air Conditioners and Self ballasted fluorescent Lamps) Regulations, 2005 (LI 1815)
- Energy Efficiency Standards and Labelling (Household Refrigerating Appliances) Regulations, 2009 (LI 1958)
- Energy Efficiency (Prohibition of Manufacture, sale or Importation of Incandescent Filament Lamps, Used Refrigerator, Used Refrigerator-Freezer, Used Freezer and Used Air Conditioner) Regulations, 2008 (LI 1932).

These first sets of LI's focused on Light bulbs, refrigerators and air conditioners because of the fact that they are the major sources of electricity consumption in the domestic sector of the economy.

The first two legislative instruments 1815 and 1958 prohibit the importation into the country of air conditioners, refrigerators and CFLs that are not properly labelled and do not meet specified minimum energy efficiency and performance standards. The purpose of the labels is to help the public make informed decisions about the appliances they intend to purchase.

The third legislative instrument (LI 1932) prohibits the importation and sale of incandescent lamps, used air conditioners and used refrigerators in the country. This legislative instrument has succeeded in eliminating the energy inefficient incandescent lamps from the Ghanaian market and will eventually do the same to used air conditioners and refrigerators. In addition to these actions, programmes have been implemented to improve the power factors of commercial buildings and industrial facilities to at least 0.9.

A study conducted by the Centre for Scientific and Industrial Research (CSIR) on consumption of Refrigerating appliances established that refrigerators consume an average of 1,140 kWh/year in Ghana, or approximately three times more energy than the maximum allowed in countries with robust standards and labeling programs.[5] Such inefficient appliances result in US$50 to US$100 per year of potentially unnecessary electricity expenses for a typical owner, which he/she can ill-afford. The wasteful consumption of electricity results in more than 0.7 tons per year of CO_2 emissions per appliance, and uncontrolled release of ozone depletion substances (ODS) from used appliances can result in the equivalent of another 2 tons of CO_2 every time an inefficient, used appliance is improperly disposed or replaced.

Refrigerators and Freezers account for as much as 25% to 30% of household electricity bill as such there is room to substantially reduce household electricity consumption in the Country[5].

It is for these reasons that the UNDP and the Global Environmental Facility is supporting Ghana through a project titled ***"Promoting Appliance Energy Efficiency and Transformation of the Refrigerating Appliances Market in Ghana"***. The project involves among others the introduction of energy efficiency standards and labels for refrigerating appliances, establishment of test facilities and market tools such as rebate schemes. The implementation of the project indicates that the potential exist in developing countries to adapt measures that have been successful in some developed countries for the local environment.

Implementation of the Refrigerator Project in Ghana

Based on the significant strides made in the area of energy efficiency, UNDP-GEF is supporting a project titled: ***"Promoting Appliance Energy Efficiency and Transformation of the Refrigerating Appliances Market in Ghana".*** The global objective of the project is to reduce Ghana's energy-related CO_2 and ozone depleting substance (ODS) emissions by mitigating the demand for energy in household refrigeration and by encouraging recovery, recycling and/or destruction of environmentally damaging refrigerants.

The project has eight components namely:

- Component 1 - Strengthening of regulatory and institutional framework
- Component 2 - Design of certification, labelling and enforcement systems
- Component 3 - Training and public outreach
- Component 4 - Establishment of refrigerating appliance test facility
- Component 5 - Used appliance collection and disposal facilities
- Component 6 - Efficiency program evaluation and monitoring capacity development
- Component 7: - Conduct of refrigeration appliance rebate and exchange program
- Component 8: Financial design of follow-up national market transformation programs

The project commenced in July, 2011 and has a life-span of three years. The significant progress made under each of the eight components named above at the half life point of the project is discussed in the following sectionsof this report .

Component 1 Strengthening of regulatory and institutional framework

The project has fostered strong collaboration between Ministries, Departments and Agencies required to develop and implement regulations that will provide a good foundation to transform the refrigerator market. The Ministries of Energy, Environment and Trade are providing policy direction whilst the Energy Commission, Environmental Prevention Authority and the Ghana Standards Authority is involved in planning, implementation and enforcement. All such institutions have been involved on the Steering Committee of the project to promote institutional buy-in, provide general direction and enhance quick feedback on deliverables.

The Energy Commission and the Ghana Standards Authority in particular have also built their capacity in developing regulations and policy options to address the issues involved. This has been done through seminars, workshops and practical engagement in the development of the regulations.

Component 2 - Design of certification, labelling and enforcement systems

The Ghana Standards Authority has adopted GS IEC 62552 which outlines the test methods for checking the performance characteristics of household refrigerators. The Country has also developed labels to reflect the particular circumstance of Ghana where black stars have been used to indicate the efficiency rating. In Ghana, the black star, which is a prominent feature in the national flag, is recognised for its relevance in building confidence. As such the more stars on the label the more efficient the refrigerator. Fig 2 shows a sample of the label for refrigerating appliances.

In 2011, the labelling of new refrigerators and freezers for sale was commenced. The take-off of the mandatory labelling requirement commenced with a few market leaders who were already importing refrigerating appliances that met the minimum energy performance standards. In the few months after enforcement of the regulations, the Commission continued to educate importers and retailers on the requirements. As part of activities to enforce the regulations, the Energy Commission has also trained custom officials at all the major entry points to stop at the point of entry all refrigerators without labels from entering the market. Custom officials have also been educated on the labelling requirements.

The Inspectorate Unit at the Energy Commission has also received a boost in their personnel and capacity to conduct compliance monitoring. There is however the need to recruit more staff to this department.

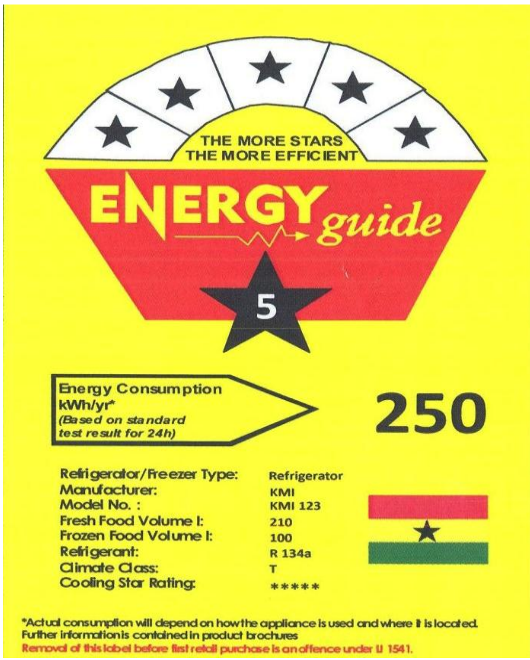

Fig 2: Energy Efficiency Standards and Label Source: Energy Commission

Component 3 - Training and public outreach

Even though most Ghanaians are familiar with appliance labels due to previous labelling requirements on CFLs and air conditioners, most customers could not realise the huge potential for energy savings with the high efficient refrigerating appliances. The project had employed a mix of strategies to publicize the refrigerator labels and its benefits to a greater section of the public. Publicity was therefore focused on Radio, TV, Newspapers and Billboards. For radio, a 60-second jingle was produced to broadcast the newly introduced labels for refrigerators/freezers and their benefits. Several radio interviews were granted on morning shows at major radio stations with wide listenership.

On television, a documentary was produced to underscore the impacts of old refrigerators on energy use and environment. It also addressed the newly introduced energy efficiency labels with explanations on the useful information that could be gleaned from it to enable customers make informed purchasing decision. In addition, a captivating animation on the labels was commissioned and shown on TV for over two months to simplify the message and create an appeal to the whole family. The project also employed the large captive power of local sitcoms and incorporated aspects of energy efficiency and the newly introduced labels in the story line. This was merged in the running story of the sitcom which was aired in five weekly episodes. All the videos acquired have become very useful tools during training seminars.

To compliment radio and television, newspaper articles and adverts were also employed to target the mid to upper segments of the public. In addition to all the above, retailers and refrigerator technicians are continuously trained by the Energy Commission to enhance their knowledge and selling skills of refrigerators.

Component 4 - Establishment of refrigerating appliance test facility

The project is in the process of establishing a refrigerator test facility that will enhance enforcement of the refrigerator standards and labelling. With the establishment of the refrigerator test facility, any suspicious item on the shop floor can be picked up and tested for compliance. Samples can also be collected from imported units to confirm their energy performance levels. It is expected that the facility will be operational by the end of 2013.

Component 5 - Used appliance collection and disposal facilities

A company has been selected to provide support in collecting turned-in refrigerators, recovering refrigerants and properly dismantling the refrigerators for recycling. The company has invested in a stage-1 refrigerator recovery facility specifically for the project. This facility has the capacity to recover refrigerants from 200 refrigerators per day. The refrigerator dismantling company is responsible for transporting all refrigerators that are turned-in as part of the refrigerator rebate and exchange scheme.

Component 6 - Efficiency program evaluation and monitoring capacity development

Monitoring and evaluation plays a critical role in the implementation of the Refrigerator Energy Efficiency Project. In order to realize the indicators ascribed to the various outcomes, project monitoring has been tailored to derive specific results that would feed into the evaluation process as well. The project has developed a monitoring and evaluation matrix to collect data that will assist in evaluating the scheme to gauge the impacts.

Component 7 - Refrigeration appliance rebate and exchange program

A refrigerator rebate and exchange scheme was launched in the Country on 19th September 2012 on a pilot basis in the regional capital of Accra. The rebate programme is geared to provide an incentive for buyers to purchase new energy star refrigerators to replace old high consuming refrigerators. In designing the refrigerator rebate scheme, a review of similar programmes in the U.S.A, Malaysia and Brazil were studied and some adjustments were made to accommodate the local conditions in Ghana.

Under the scheme, customers send their old but functional refrigerators to the participating shops where tests are carried out to confirm functionality. Customers who pass the test are awarded an instant discount of US$75 towards the purchase of a 2-star rated refrigerator or US$100 for the purchase of 3-5 star rated refrigerators. Customers then pay the difference after the face-value on the refrigerator/freezer has been discounted. The project has made an arrangement with a Bank to provide consumer loans for customers who still require financial support to complete the purchase.

All returned refrigerators are collected by the dismantling company at scheduled times. The retailer will then send their sales reports to the Energy Commission to claim the total amount of discounts offered for the period. Verification is done at the Energy Commission to confirm that the dismantling company has received all the turned-in refrigerators covering each claim before payment is made.

To promote the scheme, the project invested in a number of advertisements on the rebate scheme on TV, radio and newspapers, and participating retail outlet. Various marketing channels of the retail outlets were also used to publicize the scheme. After three months of implementing the scheme, a little over 1000 refrigerators were turned-in for purchase of energy efficient refrigerators at the two participating retail outlets, which operated a total of 17 outlets in the city.

Based on the success of the pilot phase which was restricted to the national capital and only two retail shops was scaled-up nationwide in May, 2013. The number of retailers was increased from 2 to 4 and all regional capitals were included.

Component 8: Financial design of follow-up national market transformation programs

The refrigerator project is a work in progress and so far the results show that certain portions of the project could be replicated to fit not only national conditions but also the African sub-region.

Initial Results

The following are some of the major results from the project:

- A dipstick survey conducted by the Energy Commission indicated that out of 1,000 people who were interviewed, over 90% were aware of the energy efficiency labels.
- The major household appliance dealers in the country have also been trained on the energy efficiency labels and the potential to use the label to market their products.

- Also, over 600 refrigerator technicians have been trained in proper maintenance of refrigerators to prevent emission of refrigerants during repairs. The technicians were also taken through the details on the labels and the potential benefits to clients.
- The project had recovered over 2,200 old high energy consuming refrigerators and replaced it with energy efficient appliances after six months of implementing the pilot phase.

Challenges

- Enforcement on the ban on the importation of used refrigerating appliances had to be postponed for four years after the law was established due to petition by importers to Government to scrap the law. The importers of used Government were initially strongly opposed to the law and it required numerous rounds of meetings with Government officials to address their issues. The Energy Commission has been instrumental in providing training to members on the need for energy efficient appliances and providing some channels to enable them to market new appliances. The target is to ultimately promote the establishment of a local manufacturing facility in Ghana that will reduce prices of new refrigerators and tap into the wide distribution network of the importers.
- Due to the high influx of substandard appliances prior to establishment of regulations, there is a general perception from customers that used appliances are more durable. A lot of work therefore remain to sieve out all the low-quality appliances marketed as new and promote quality brands to enable customers to make the right switch.

Conclusion

The project will continue to use the lessons learnt from the initial phase of implementation to continually enhance the impacts expected from the intervention. The initial feedback promises positive results for the remaining project period. There exist a potential electricity savings of 216MWh and CO_2 reduction of 251.6 kilotonness over the project period if a substantial amount of over 50,000 units of refrigerators could be replaced[6]. This is certainly an interesting prospect for making energy efficiency the new power generation plants to support the slow pace of investment in power generation capacity.

The West African Energy Efficiency Policy: Using Efficiency To Achieve Universal Energy Access

Mahama Kappiah, Executive Director, ECOWAS Centre for Renewable Energy and Energy Efficiency (ECREEE)

Ibrahim Soumaïla, ECREEE

Anne Rialhe, AERE

Cristina Clain, AERE

Edgar Blaustein

Abstract

The West African energy system is facing serious interrelated challenges of energy access, energy security and climate change adaptation and mitigation. To address these multiple challenges, ECOWAS has taken action to adopt and implement a Regional Energy Efficiency Policy. The ECOWAS energy efficiency action plan is based on five flagship energy initiatives, each including policy, capacity building, awareness raising and financing elements.

Introduction

The ECOWAS region, comprising 15 countries[1] in West Africa, is faced with a multifaceted energy crisis. About 60% of the population does not have access to electricity, and over 80% cooks with traditional biomass causing serious health and environmental problems.

The ECOWAS region governments have initiated an ambitious programme to achieve “Sustainable Energy for All”, within the framework of the UN Secretary General’s initiative. The ECOWAS approach is built on three regional policies: access to energy, renewable energy and energy efficiency.

The regional energy efficiency policy (EEP developed by the ECOWAS Centre for Renewable Energy and Energy Efficiency (ECREEE), was approved by the Ministers of Energy in October 2012. The EEP strategy focuses on policy, capacity building, awareness raising and finance. The EEP is targeting areas where short and medium term action can bring substantive impact on economic development and well being of the region’s people. For each target, the EEP action plan includes an initiative.

The five targets and initiatives of EEP are:

- Phase out inefficient incandescent lighting;
- Reduce electricity distribution losses to under 10%;
- Achieve universal access to safe, clean, affordable, efficient and sustainable cooking;
- Adopt initial region-wide standards and labels for major energy equipment;
- Create instruments for financing sustainable energy.

---

[1] ECOWAS is a Regional Economic Community, the West African institution equivalent of the European Union. The ECOWAS member states are Benin, Burkina Faso, Cape Verde, the Gambia, Ghana, Guinea, Guinea Bissau, Ivory Coast, Liberia, Mali, Niger, Nigeria, Senegal, Sierra Leone, Togo ECOWAS has built partnerships with major public and private organizations to implement the EEP action plan, including: European Commission, ADEME, AEA, UNDP, ENERGIA, Copper Alliance, UNEP en.lighten, and CLASP.

The Energy and Development Challenge in West Africa

ECOWAS countries are faced with an immense development challenge. They must meet development needs - job creation, education, health, drinking water – for a rapidly growing population of more than 300 millions, despite the numerous institutional weaknesses of the region.

Supplying access to clean energy involves the following. To:

- Allow everyone access to vital services
- Guarantee the reliability of energy supply and distribution systems
- Maximize the contribution of energy to economic development, to gender equality and to social equity
- Protect the local and global environment from the negative aspects of energy value chains.

Indeed, it will not be possible for the region's countries to progress without electricity in schools, adequate mechanical power for industry and water pumping, or without sustainable supply of clean fuels for cooking. Nonetheless, today, 2/3 of the population of the region does not have access to electricity [1], nor to mechanical power other than from human and animal muscular force.

Furthermore, over ¾ of families cook using wood or charcoal, with rudimentary stoves that emit highly harmful smoke [2], affecting both the women who cook and the young children that accompany them (See Fig 1). Two energy related tasks – carrying water and collecting cooking fuel – require substantial amounts of time from women and girls, limiting their opportunities for educational and economic activities, and often exposing them to life threatening dangers.

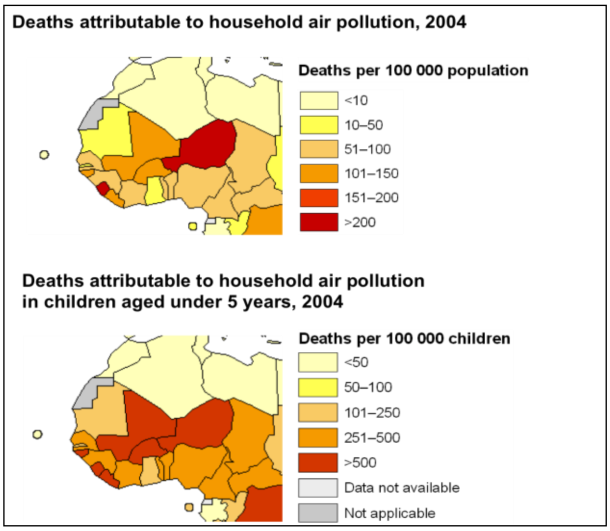

Figure 1: Deaths attributable to household air pollution, Source: World Health Organization

The region's governments, acting within the framework of ECOWAS have clearly understood this challenge. Thus, in January 2006, ECOWAS adopted the ECOWAS-UEMOA "White Paper for a Regional Policy for Increasing Access to Energy Services for Populations in Rural and Peri-Urban Areas in Order to Achieve the Millennium Development Goals" [3], that included ambitious objectives for access to energy by 2015, for electricity, cooking, and power for productive activities and social services. Because of weak institutions and lack of means and political commitment, the region has not progressed as rapidly as planned to achieve these goals. Consequently, ECOWAS acted to create the ECOWAS Centre for Renewable Energy and Energy Efficiency (ECREEE) in 2007. ECREEE is responsible for leading regional action in favour of renewable energy and energy efficiency. ECREEE - with the support of the European Commission, ADEME, the UNDP, Austria and Spain – has acted to harness the enormous potential of energy efficiency, through a five-step approach:

- stock taking missions in the fifteen countries of the region. These missions reached the following main conclusions:
    - Most of the region's countries, to different degrees, suffer from a crisis situation in the energy sector. Power cuts affect users for an average of 56 days per year. The World Bank estimates that the resulting loss in production amounts to a reduction of growth

by 2% annually[2]. Supply of cooking fuels is in danger in the long term: indeed, many city dwellers already spend as much for fuel as for food.

  - The energy efficiency potential in the region is quite substantial. With just two measures – phasing out incandescent lamps and reducing electricity distribution losses to under 10%[3] - savings of as much as 20% overall could be achieved.

  - The majority of countries have not acted effectively to capture the potential of energy savings, with less than half disposing of institutions responsible for implementation of concrete programs, and only Ghana having achieved substantial results.

- drafting of a political strategic document on energy efficiency on the basis of data collected;

- validation of the draft energy efficiency strategy by the competent national political authorities;

- submission for consideration and adoption by the region's Energy Ministers;

- implementation of the policy.

ECOWAS and ECREEE have now engaged the last step of this process, with implementation of the Energy Efficiency Policy's (EEP) recommendations.

A policy and an action plan for energy efficiency

On the basis of the stock taking conclusions, ECREEE developed a draft policy document on energy efficiency. This included the current situation, analysis of energy efficiency at the level of major economic sectors (transport and city planning, industry and services, households) and the public action necessary to capture the potential savings. The document concludes with a regional strategy composed of: political and policy actions; awareness raising for energy efficiency; human and institutional capacity building; financial measures; an action plan.

The EEP includes five concrete initiatives, each with partners, an action plan, and a financing framework in order to maximise the probability of success of the policy, given that Ministerial approval of a policy document does not guaranty implementation. These initiatives focus on lighting, electricity distribution, cooking, standards and labels, and finally environmental finance for sustainable energy.

1. The initiative on lighting focuses on the one electrical appliance that represents the single biggest component of power consumption in West Africa: indeed, for the region's electrified households, lighting is the first, and sometimes the only, use of electricity [4]. The initiative aims at replacing incandescent bulbs with high efficiency bulbs: CFLs in the short term. Ghana has already carried out a successful programme on lighting, substantially achieving market transformation, with a 70% penetration in the market of standard neon and CFL bulbs. The Ghana programme consisted of a massive initial distribution of 5 million CFLs, coordinated with an awareness raising campaign. Teams spread out across the country to remove and replace the incandescent bulbs, and destroy them with steam rollers in city and village public places. The programme achieved a 10% reduction in peak power demand, with corresponding savings for the government in avoided investment in power plants and lines more than paying for the programme. It is expected that the key elements of the Ghanaian programme can be replicated throughout the region.

2. The initiative on electricity distribution is of a different nature. Whereas lightbulbs concern tens of millions of households, distribution losses directly concern only a few dozen enterprises. The nature of the challenge is also different. While lighting is a low cost consumer good, distribution systems are highly capitalistic and complex. The distribution infrastructure of the region suffers from chronic underinvestment, as well as insufficient maintenance. The initiative aims at supporting utilities in implementing global programmes in two areas. Investment in infrastructure – power lines,

[2] Fact Sheet -The World Bank and Energy in Africa: http://go.worldbank.org/8VI6E7MRU0

[3] Current distribution losses in the region vary from 15% to 40%, as compared to losses in developed countries of around 7%.

transformers, sub-stations – and institutional capacity for preventive maintenance, effective billing and collection of payment. Guaranteeing payment for services is a major challenge, since non-payment and theft of electricity are so widespread. In some cases, technical solutions can play a role in improving commercial performance. Prepayment meters have proved to be effective in aiding households in controlling budgets for electricity. High voltage distribution systems, that replace 220 V lines with higher voltage lines, both reduce line losses and make theft more difficult. The potential gains are large. Whereas well run systems have distribution losses of approximately 7 to 8%, distribution losses in West Africa range from 15% to 40%[4].

3. Another initiative addresses the complex challenge of cooking, an absolutely vital issue. Despite its importance, long term supply of cooking fuel is in danger in West Africa. The forest resources that supply wood and charcoal are declining, due to the conjunction of a variety of factors: conversion of forests to agricultural land; desertification due to the advance of the Sahara; climate change; overcutting near cities that prevent regrowth. Liquid petroleum gas, the major alternative to wood and charcoal fuel, is too expensive for the majority of the population[5]. The cooking initiative aims to address sustainability of cooking at each link of the cooking value chain as shown in Figure 2

Sustainable forest management → controlled wood cutting → (improved charcoal transformation) →

Optimised transport and distribution → clean and efficient cook stoves

Fig 2: Title

4. The region also intends to create a coherent regional system of standards for energy using equipment. Such a system is an essential basis for consumer labels for energy efficiency, for testing and certification of products, and for Minimum Energy Performance Standards (MEPS). In the short term, the newly established regional Technical Committee on Standards and Labels plans to concentrate on MEPS to support the lighting initiative.

5. Finally, the initiative on environmental finance aims to mobilise the various existing financial instruments that could provide support for energy efficiency efforts. The most important is climate finance, since energy efficiency translates directly into reduction of emissions of the Green House Gases carbon dioxide and methane in most cases. In West Africa, reduction of methane is particularly pertinent, since methane emissions from uncontrolled waste dumping could be converted into useful fuel, notably for cooking, as well as for power generation. Furthermore, proper recycling of refrigerant gases (CFLs) could benefit from the financial instruments of the Montreal Protocol on ozone depleting substances. Similarly, the CILSS (Comité permanent Inter-Etats de Lutte contre la Sécheresse), a regional organisation fighting desertification, could support efforts in the field of sustainable forest management for cooking fuels. Finally, on-going negotiations on a convention to control mercury pollution could finance efforts to capture emissions from coal-fired power stations, as well as for the recycling of mercury containing light bulbs.

---

[4] Given the nature of West African power systems, notably the large distances covered by lines and the low population density, it is considered that a reasonable goal is to reduce losses to 10%.

[5] It is perhaps useful to recall, that although LPG is a fossil fuel, cooking with LPG emits less Green House Gases than poorly burned wood. Indeed, poorly burned wood emits both CO_2 and large quantities of powerful GHGs such as methane and NO_2, as well as black carbon. A typical meal cooked on a 3 stone fire emits over 800 g CO_2 equiv of GHG, of which over half is in non CO_2 GHGs, as compared to less that 200 g CO_2 equiv for a meal cooked with LPG [5].

Conclusion

The Energy Efficiency Policy, including the five initiatives, was adopted by the ECOWAS Energy Ministers at their meeting in Accra from 29 to 31 October 2012. This meeting was organised in parallel with a "Global Forum on Sustainable Energy[6]" meeting on the theme "Towards Sustainable Energy For All in West Africa: Paving the Way through Renewable Energy and Energy Efficiency". Representatives of the international community, private sector and civil society, participated along with the region's public authorities in discussion on the contribution of energy efficiency and renewable energy to meet the challenge of achieving universal access to energy in West Africa.

Maximizing Climate Benefits through Energy Efficiency and Refrigerant Regulations for Air Conditioners: A case from India

Amit Khare, Ana Maria Carreño

Collaborative Labeling and Appliance Standards Program (CLASP)

Abstract

The ownership and usage of room Air Conditioners (ACs) in India is increasing rapidly mainly due to a growing economy and a high number of cooling days per year. Today air conditioning accounts for a significant share of peak electricity demand during the summer months in many Indian cities. In response to growing AC usage, the Indian Bureau of Energy Efficiency (BEE) launched a voluntary energy efficiency labeling program for room ACs in 2006, which became mandatory in 2010.

Most ACs globally use hydrochlorofluorocarbons (HCFCs), ozone depleting substances expected to be phased-out in developed countries by 2020 and in developing countries by 2030, per the Montreal Protocol. Hydrofluorocarbons (HFCs), commercially available alternatives to HCFCs, do not deplete the ozone layer but are potent greenhouse gases. If all the AC manufacturers in India switch over to HFCs the greenhouse gas (GHG) emissions would increase by at least 15%[1]. If HCFCs could be cost effectively replaced by "climate friendly refrigerants" such as natural refrigerants instead of HFCs, the climate benefits of the HCFC phase-out would be maximized.

This paper develops three policy scenarios for room ACs in India analyzing their impact in terms of GHG emissions reductions due to electricity savings and usage of climate friendly refrigerants, and its cost-effectiveness. The scenarios examine a business as usual approach, using current and planned efficiency standards for room ACs, and additional climate benefits by introducing the requirements for the mandatory use of climate friendly refrigerants. GHG emissions savings are estimated using the methodology provided by the Total Equivalent Warming Impact (TEWI) indicator. The paper identifies the scenario that will result in maximum reduction of GHG emissions and still be cost-effective if adopted, which corresponds to a policy scenario of doubling the current pace of efficiency increases and requiring the use of refrigerants with low Global Warming Potential (GWP < 150) in 2016.

Introduction

The ownership and usage of Room Air Conditioners (ACs) in India is increasing rapidly mainly due to a growing economy and a high number of cooling days per year. The AC industry estimates sales of 3.5 million new units in 2012 and forecasts sales in 2020 and 2030 of more than 12 million and 40 million units respectively [1].

BEE's labeling program for room ACs has resulted in savings over 5000 MW [2] and related greenhouse gas (GHG) emissions reductions so far, but the standards do not include any requirements to use climate-friendly refrigerants to further lower overall GHG emissions. Adding such requirements would help India in achieving its commitment of cost-effectively reducing emissions per unit of GDP by 20 to 25 percent below 2005 levels by 2020 [3].

This paper develops three policy scenarios for energy efficient room ACs in India, analyzing their impacts in-terms of GHG emissions reductions due to electricity savings and usage of climate friendly refrigerants, and its cost-effectiveness. This approach is expected to serve as a foundation for designing future policies to maximize climate benefits considering not only the emissions derived from energy use but also climate impacts from refrigerants. Finally, the results will be presented to BEE and the Ozone Cell[2] in India for their consideration prior to the launch of the next revision of AC energy efficiency standards in 2014.

---

[1] Estimated from the rate of GWP_{HFC}/GWP_{HCFC}

[2] The Indian Ministry of Environment and Forests has set up Ozone Cell in India for the work related to protection of ozone layer and implementation of the Montreal Protocol

The Residential Room Air Conditioners market in India

The current market in India is divided between two types of room ACs: window units and split units. Their rated cooling capacity is usually up to 11 kW. In 2012, window ACs sales were nearly 25% of the total market, down from 50% of the market in 2007, showing the increased popularity of split ACs over the past years[3]. Nonetheless, sales of the two air conditioner types in India grew steadily from 2007 to 2011, as can be seen in Figure 1, with a drop in 2011-12 possibly due to a cooler summer and an early arrival of the monsoons. Larger sales in the previous period, 2010-11, might have also negatively affected sales the following year. This is thought to be the result of a bonus offered by the Indian Government to federal employees, which translated in higher purchases of appliances for that period.

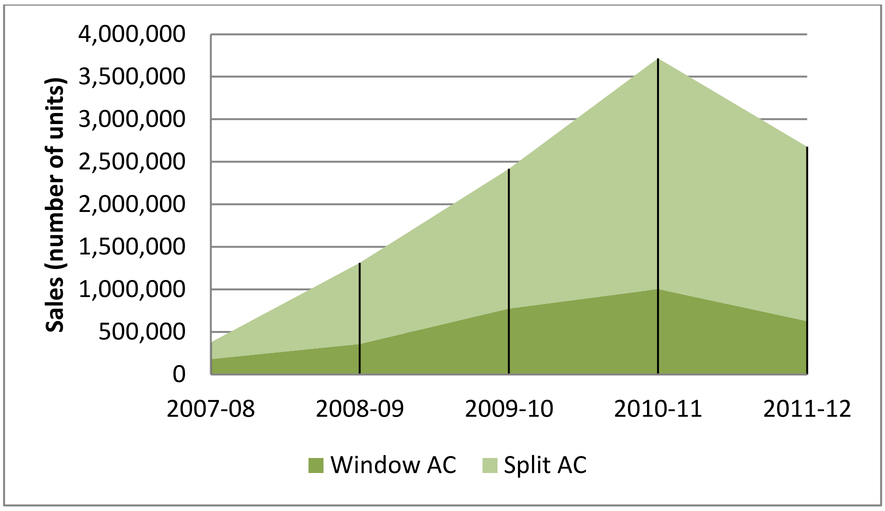

Figure 1: Room Air Conditioner Sales in India (2007-2012)

Over the five year period in Figure 1, sales of window air conditioners more than tripled, from over 180,000 units in 2007-08[4] to 626,000 units in 2011-12. Sales of split air conditioners increased more rapidly; for the same period, sales in 2011-12 were ten times more than those in 2007-08 (from 195,000 to more than 2,000,000).

At a global level, sales of ACs in India are still significantly lower than countries like Japan and the United States which have annual sales of more than 6 million and 9 million units respectively, and economies like China, and Brazil which are expected to reach similar market sizes in the coming years. The room ACs market (for the residential sector) is dominated by split units worldwide; inverter units[5] are available in developed economies and their popularity is increasing among developing economies [4]. The market in India is still dominated by fixed-speed units.

However, India's annual sales of ACs are expected to increase dramatically in the next 20 years. Ownership of ACs in India is estimated to be between 4 – 5%[6]. The market penetration potential is still very large and thus growth in the coming years is only expected to rise. Sales forecasts in 2020 and 2030 are of more than 12 million and 40 million units respectively, corresponding to a 13% increase per year [5].

The Standards and Labeling program for ACs in India

The standards and labeling (S&L) program in India was initiated in 2006 as a response to growing energy demand by refrigerators and air conditioners. The energy performance standard for room ACs applies to single-phase split and unitary (window) air conditioners of the vapor compression type for household use up to a rated cooling capacity of 11 kW being manufactured, imported or sold in India

[3] Sales data from BEE records: *Production Data: Financial Year: 2007-08, 2008-09, 2009-10, 2010-11, 2011-12.*
[4] BEE's production data over the financial year period covers April 1st Year X to March 31st Year X+1.
[5] Units with variable-speed drives
[6] Population: 1.2 billion; average household size: 4 – 5 people; access to electricity: 60 – 65%; Stock in 2011 ~ 8 million units.

[6]. Energy efficiency is rated by the number of stars displayed in the energy label, between a minimum of one and a maximum of five.

Comparative labeling requirements for room ACs were voluntary until 2010; from the period between January 7, 2010 to December 31, 2011 the mandatory minimum energy performance standard (MEPS) for room ACs under this regulation was of EER[7] (W/W) 2.3. The next update occurred in January 1, 2012 when the minimum EER became 2.5. An additional scheduled update will take place in January 1, 2014, as per Table 1 below.

Table 1: Energy Performance Standard for Room ACs in India

	07 January 2010 to 31 December 2011		01 January 2012 to 31 December 2013		01 January 2014 to 31 December 2015	
	EER(W/W)		EER(W/W)		EER(W/W)	
Star Rating	Min.	Max.	Min.	Max.	Min.	Max.
1 star	2.3	2.49	2.5	2.69	2.7	2.89
2 star	2.5	2.69	2.7	2.89	2.9	3.09
3 star	2.7	2.89	2.9	3.09	3.1	3.29
4 star	2.9	3.09	3.1	3.29	3.3	3.49
5 star	3.1		3.3		3.5	

The schedule above requires an increase in the minimum efficiency level of 8% each 2-year period until 2015.

Room ACs efficiency levels and other parameters

Today, air conditioning accounts for a significant share of peak electricity demand during the summer months in many Indian cities [7]. BEE's labeling program aims to reduce ACs energy demand and there is actually a slow shift to more efficient units since the program began.

The average Energy Efficiency Ratio (EER) values for both split and window units increased over time, as shown in Figure 2, illustrating the shift to more efficient units. The average efficiency of split ACs increased 27% (or an average of 4% per year) from 2.30 in 2006 to 2.91 in 2012. The average efficiency of window units has increased at a slower pace of 17% over the same period (or 3% per year), from 2.30 in 2006 to 2.68 in 2012.

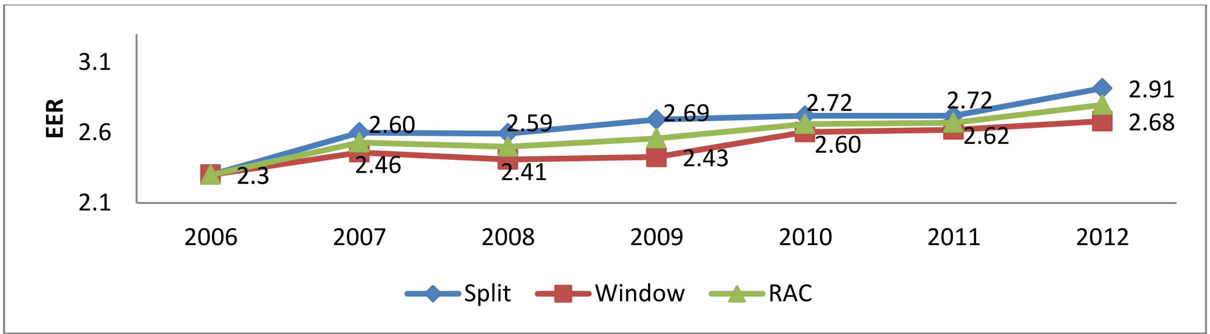

Figure 2: Average EER of Room ACs in India

Interestingly, the increase rate displayed by the market average EER levels from 2006 to 2012 in Figure 2 above (an increase of 4% per year) corresponds to the increase required by BEE on the minimum efficiency level of 8% each 2-year period. One could argue that BEE's program is driving the market towards higher efficiency levels and the market's response is closely linked to the level of standards required. It could also be the other way around, and observations of the market behavior

[7] Energy Efficiency Ratio (EER) is the ratio of the cooling capacity to the electricity consumption when measured at full load at a specific outdoor temperature (usually 95 degree Fahrenheit).

before the introduction of the labeling program drove BEE to choose a policy that reflected this trend. The average EER level of Room ACs on the market in any year (during the period 2010-2012) was on average 0.3 units above the minimum EER of that year (this is 16% better than the minimum energy performance standard – MEPS - in 2010 or 12% better than the MEPS in 2012).

The labeling program requires that products on the market are rated using a scale from 1 star (least efficient) to 5 stars (most efficient). Figure 3 and Figure 4 show the trends of room ACs sales according to their efficiency level over a five year period. Split air conditioners in star level 5, the most efficient level, had a 25% market share for the first time in 2012. However, star levels 2 and 3 remain very popular as shown in Figure 3. For window ACs, the more efficient levels (5 and 4) still have a very low market share (see Figure 4), an indication that the production of more efficient window AC units is not taking place under current market conditions[8]. This is a trend also present in other countries: while the market share of window ACs is decreasing globally, efficiency levels have remained the same or even decreased over the past years [4]. In Europe, for instance, the market share of window units stagnated since 2005 at 200,000 units per year; the average EER level reached a maximum of 2.9 in 2005 and then decreased to 2.7 in 2011.

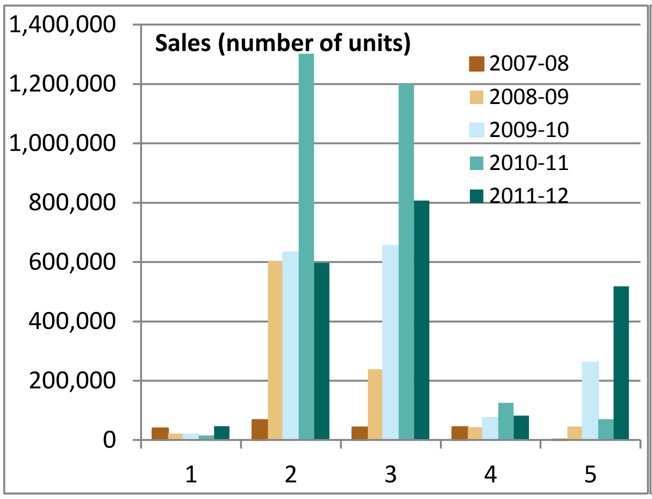

Figure 3: Efficiency levels of split ACs sales [4]

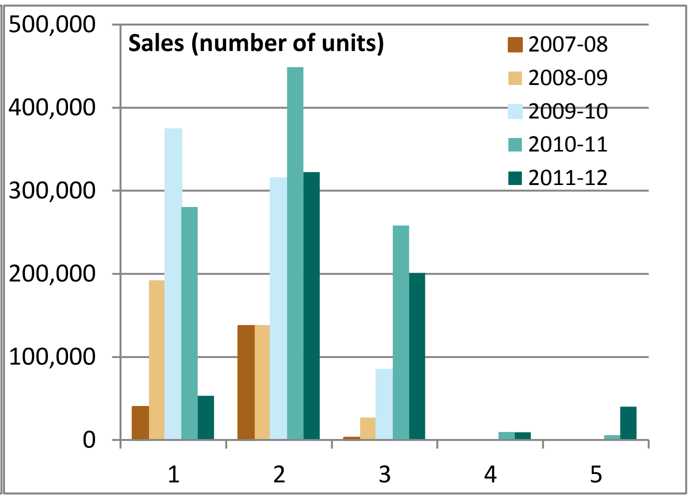

Figure 4: Efficiency levels of window ACs sales [4]

Another relevant parameter to characterize room ACs is the size (cooling capacity). The most recent available data (from 2009) indicates that rooms ACs below 3kW have minor market shares in both types (window and split units).

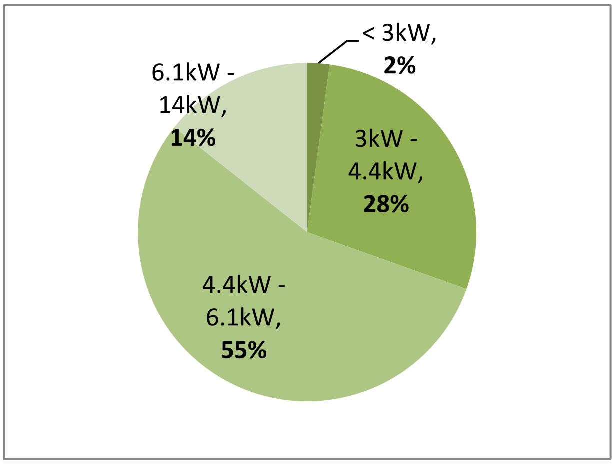

Figure 5: Sales of split units by size, 2009 [4]

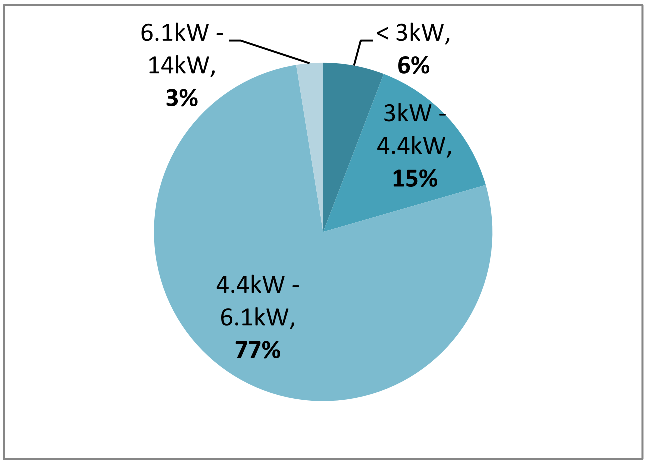

Figure 6: Sales of window units by size, 2009 [4]

[8] Manufacturers' feedback is that due to technology constraints it becomes very costly to produce 4 and 5 star window ACs.

The most popular sizes are 4.4kW to 6.1kW, followed by 3.0 to 4.4kW. Window units over 6.1kW are not very common, while split ACs from 6.1 to 14kW accounted for 14% of the split AC market in 2009. Figure 5 and Figure 6 above show market shares of various sizes by type of AC [4].

Refrigerants in ACs

Most ACs globally use fluorocarbon refrigerants to facilitate the heat transfer process; hydrochlorofluorocarbons (HCFCs) are among those commonly used in air conditioning applications and have been used as transitional substitutes for the now phased-out chlorofluorocarbons (CFCs) for a host of applications. In 2007, the Parties to the Montreal Protocol decided to accelerate the phase-out of HCFCs. The Decision also encourages Parties to maximize other environmental benefits of the HCFC phase out, including those related to climate change.

HCFCs are scheduled to be totally phased out in developed countries by 2020 and in developing countries by 2030. Non-ozone depleting hydrofluorocarbons (HFCs) are commercially available alternatives to HCFCs; annual consumption of HFCs has doubled over the last decade. While they do not deplete the ozone layer, they are potent greenhouse gases and are about 2,000 times more powerful in trapping heat in the atmosphere than carbon dioxide. If HCFCs could be replaced by “climate friendly refrigerants” such as natural refrigerants (hydrocarbons, carbon dioxide, ammonia) and/or by new very low-GWP hydrofluoroolefins (HFOs, e.g. HFO-1234yf, HFO-1234ze, etc.) cost effectively, then the climate benefits of the HCFC phase-out could be maximized.

HCFC-22 (R-22) is still the most commonly-used refrigerant in ACs in developing countries, with an Ozone Depleting Potential (ODP) of 0.055 and a Global Warming Potential (GWP) of 1,810 [8]. Developed countries are transitioning to HFC-410A (R-410A), with zero ODP but a GWP of 2,088, which can adversely impact the climate due to its large capacity as greenhouse gas. Some of the alternatives considered for transitioning to lower GWP refrigerants in room ACs, which pose a lower burden to the global climate, include carbon dioxide (R-744), propane (R-290), HFC-32 (R-32), and HFO blends.

Table 2 shows, in a very simplified manner, technical characteristics and economic considerations for various refrigerants and how they ranked in comparison to others. This is only indicative and aims to highlight the potential challenges of a transition to any of those alternative refrigerants.

Table 2: Technical characteristics and economic considerations for some refrigerants[9]

	GWP	Flammability	Toxicity	Price of Refrigerants	Price of System	Volumetric Refrigeration Capacity	Theoretical System Efficiency
Hydrofluoro-carbons (HFCs)	High	No	No	Moderate	Low	Medium	Good
Hydrocarbons (HCs)	Low	Yes	No	Low	Medium	Medium	Good
Carbon Dioxide	Low	No	Only at high concentration	Low	Medium	High	Medium

Table 2 shows that a transition to hydrocarbons or carbon dioxide as AC refrigerants will increase equipment cost, as the price of the refrigeration system for these refrigerants is higher than that of HFCs. There are impacts on efficiency, especially in the case of carbon dioxide, and flammability issues linked to the use of hydrocarbons. Even though the use of these alternatives poses technical challenges, leading AC manufacturers are proving the feasibility of this transition. In China, Gree announced the completion of a demonstration production line for split ACs using R-290, while Midea is ready to commercialize products also using R-290 [1]. In India, one of the domestic appliance manufacturers “Godrej” has started production of R-290 based split ACs system with energy efficiency ratio close to 3.7 (i.e. 6% better than the 5 star level of the 2014-15 standard).

[9] Author’s interpretation from Kauffeld, 2011. [12]

Assessing the impacts of a transition to climate friendly refrigerants in India

BEE's labeling program for room ACs has resulted in savings over 5000 MW [2] and related GHG emissions reductions, but the standards do not include any requirements to use climate friendly refrigerants to further lower overall GHG emissions. Adding such requirements would help India achieve its voluntary commitment of cost-effectively reducing emissions per unit of GDP by 20 to 25 percent below 2005 levels by 2020 [3].

To examine the impacts of a transition to lower GWP refrigerants, this paper develops three policy scenarios for room ACs in India:

- **Base case**: Energy efficiency requirements for room ACs after 2015 continue to increase by 8% every two years to reach a minimum efficiency level EER = 3.3 in 2020. This is consistent with the previous schedule adopted by BEE, where efficiency increases 8% in two-year intervals. There are no requirements for the GWP of refrigerants used in Room ACs in this scenario.

- **Policy option 1**: BEE adopts a schedule that will reach the minimum efficiency levels of the current best available technology in the Korean market[10], EER = 5.7[11], in 2020. There are no requirements for the GWP of refrigerants used in room ACs in this scenario.

- **Policy option 2**: BEE adopts a schedule that will increase the minimum efficiency levels to an EER = 4.2 in 2020. This is the result of doubling the current pace of efficiency increases, from 8% every two years to 16%. In addition, this policy option requires the use of refrigerants with GWP < 150[12] in 2016.

- **Policy option 3**: Policy option 1 and requires the use of refrigerants with GWP < 150 in 2016.

Table 3: Summary of policy scenarios

	Minimum Efficiency levels in EER			
	Base case	**Policy 1**	**Policy 2**	**Policy 3**
2010	2.3	2.3	2.3	2.3
2011	2.3	2.3	2.3	2.3
2012	2.5	2.5	2.5	2.5
2013	2.5	2.5	2.5	2.5
2014	2.7	2.7	2.7	2.7
2015	2.7	2.7	2.7	2.7
2016	2.9	3.7	3.1	3.7
2017	2.9	3.7	3.1	3.7
2018	3.1	4.7	3.6	4.7
2019	3.1	4.7	3.6	4.7
2020	3.3	5.7	4.2	5.7
GWP < 150 starting in 2016	No	No	Yes	Yes

For the three policy options, we analyze energy savings and GHG emissions reductions from the base case by forecasting energy use of ACs sold from 2012 to 2020 and 2030. We assume that every unit

[10] The market in India is dominated by Korean and Japanese manufacturers.
[11] Maximum EER reported in Korea in 2010-2011 [13]
[12] Two regulations in the EU currently use this threshold (GWP<150): i) Regulation (EC) No 842/2006 of the European Parliament and of the Council of 17 May 2006 on certain fluorinated greenhouse gases, exempts preparations where the total global warming potential is less than 150, and ii) Commission Regulation (EU) No 206/2012 of 6 March 2012 with regard to ecodesign requirements for air conditioners and comfort fans, requires different (less stringent) minimum energy efficiencies for appliances if GWP of refrigerant ≤ 150.

sold in a specific year has an EER equal to the minimum energy performance requirement as per Table 3 above. This means we do not estimate additional energy savings from the labeling program. This is a conservative approach given that the labeling program has effectively shifted the market towards higher efficiency levels (on average 0.3 units above the minimum EER level for any specific year) as discussed earlier.

We also consider that the stock has a survival function based on a normal distribution of the median life of ACs (10 years) and a sales growth of 13% per year. Figure 7 shows the sales forecast per year, the portion of the stock (from those annual sales) that survives in 2030 and the portion that has been retired[13].

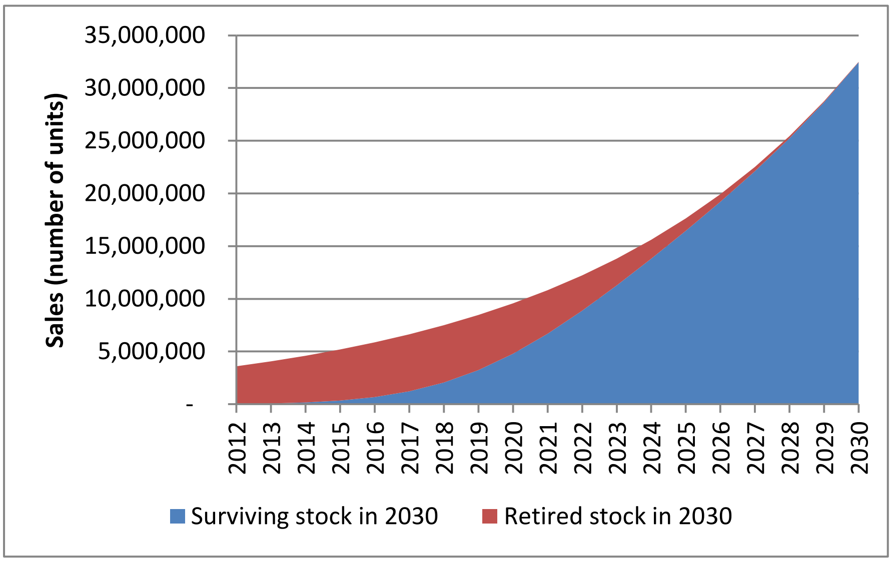

Figure 7: Room ACs sales forecast 2012 – 2030

The Total Equivalent Warming Impact (TEWI), an indicator used to estimate the global warming impact of room ACs (and other equipment using refrigerants), is based on the emissions of greenhouse gases during the operation (use) and the disposal of the refrigerants at the end-of-life [9]. The method of calculating the TEWI is the following:

TEWI = GWP (**direct** *emissions from refrigerant leaks and end of life treatment*) + GWP (**indirect** *emissions from the operation of the equipment*)[14]

Indirect emissions

Indirect emissions, corresponding to GHG emissions resulting from the operation of room ACs throughout their lifetime, were estimated as follows.

The room AC unit energy consumption (UEC) is estimated for a typical 1.5T unit [10], considered representative of the AC market, with the following parameters[15]:

Hours of operation (residential): 5 months/year x 30days/month x 8hrs/day = 1200hrs/year[16]

Average cooling capacity (CC): 4,580 kW

Operating at 75% of full capacity

---

[13] Surviving stock in 2030 refers to the number of units purchased in a year X that are still operating in 2030. Retired stock refers to the units that are no longer operating due to failure.
[14] The terms direct and indirect emissions used here are as per the TEWI method of calculation best practice guidelines [9]
[15] The typical unit size and operation conditions are as per McNeil and Iyer.
[16] As per BEE's assumption when calculating ACs labeling program impacts (energy consumption and savings).

$$UEC(y) = \frac{CC}{EER(y)} \times 0.75 \times 1200 \quad (kWh/y)$$

The Total Energy Consumption (TEC) in a year is estimated with the surviving stock in that year and the corresponding unit energy consumption. The following equation uses 2030 as the year for the calculations.

$$TEC_{\ 2030} = \sum_{y=2012}^{2030} Surviving\ stock\ in\ 2030\ (y) \times UEC\ (y) \qquad (kWh/y)$$

GHG emissions savings are estimated with the total energy consumption and an emissions factor of 0.82 tonnes of CO2 eq per MWh [11].

$$GHG\ savings\ in\ 2030 = TEC_{2030} \times 0.82 \quad (tCO2e)$$

Results from the analysis above are presented in Table 4 for 2020 and 2030.

Table 4: Energy and GHG emissions savings due to ACs operation from policy scenarios

	Base case	Policy Option 1	Policy Option 2	Policy Option 3
Total energy consumption in 2020 (GWh)	73,739	57,786	67,133	57,786
Total energy savings in 2020 (GWh)	-	15,953	6,606	15,953
GHG savings in 2020 (Mtonnes of CO2 eq)	-	13.1	5.4	13.1
Total energy consumption in 2030 (GWh)	247,406	133,791	195,528	133,791
Total energy savings in 2030 (GWh)	-	113,615	51,878	113,615
GHG savings in 2030 (Mtonnes of CO2 eq)	-	93.2	42.5	93.2

Direct emissions

To analyze the climate benefits of introducing a requirement for the use of refrigerants with lower GWP, emissions of greenhouse gases from the refrigerants need to be considered.

In the previous section we estimated the GHG emissions from the operation of ACs (indirect emissions) and provided a total GHG savings in 2020 and 2030; in this section we will only consider the first part of the TEWI equation to estimate emissions from the refrigerants.

$$GWPdirect = GWP \times m \times L_{annual} \times n + GWP \times m \times (1 - \alpha_{recovery})$$

Where:

GWP = Global Warming Potential of the refrigerant
m = refrigerant charge
L_{annual} = leakage rate per annum
n = operating life
$\alpha_{recovery}$ = recycling factor from 0 to 1

The recycling factor in India is considered to be 0, thus we assume that all the refrigerant charge will be released at the end-of-life[17] (disposal of the AC), and only estimate the right side of the equation. For the analysis, two parameters are considered: the refrigerant charge and the GWP.

The typical refrigerant charge of AC units relevant to the Indian market is shown in Table 5 and the GWP values for current and alternative refrigerants are shown in Table 6.

Table 5: Typical refrigerant charges in ACs[18]

		Average charge (kg)			
Unit	**Capacity**	**R-410A**	**R-22**	**R-32**	**R-290**
Mini-split	1.5 T	1.5	1.2	1.3	0.4

Table 6: GWP values for selected refrigerants [8]

Refrigerant	GWP
R-410A	2088
R-22	1810
R-407C	1774
HFO Blends	<1,032
R-32	675
R-1234ze	6
R-1234yf	4
R-290 (propane)	3.3
R-744 (CO2)	1

For the policy options (Base Case and Policy Option 1) for which there is no requirement to transition to lower GWP refrigerants, we consider a GWP that corresponds to that of R-22 until 2020 (as scheduled by the Montreal Protocol) and is replaced by R-410A from 2020 (which is the current trend). For the policy options where a refrigerant requirement will be in place in 2016, we consider the GWP of R-22 until 2015, and the propane GWP of 3.3 from then onwards. The refrigerant charge varies depending on the refrigerant as per Table 5.

Table 7: Summary of policy scenarios in the transition to lower GWP refrigerants

	GWP values			
	Base case	**Policy 1**	**Policy 2**	**Policy 3**
2012-2015	1810	1810	1810	1810
2016-2019	1810	1810	3.3	3.3
2020-2030	2088	2088	3.3	3.3

Using the retired stock of ACs from 2012 – 2030, and the corresponding *GWPdirect*, we estimate the cumulative value of greenhouse gas emissions by 2030 from their refrigerants charge as:

$$Cumulative\ GHG_{2030} = \sum_{y=2012}^{2030} Retired\ stock\ in\ 2030\ (y) \times GWPdirect\ (y)$$

The same calculation is done for the year 2020 using the retired stock from 2012- 2020. Results from the analysis above are presented in Table 8.

[17] If a recycling program for ACs were in place, the recovery rate will be > 0. There are no recycling or recovery policies as of today in India.
[18] Based on discussion with key AC and chemical manufacturers in India

Table 8: GHG emissions savings from the transition to lower GWP refrigerants

	Base case	Policy Option 1	Policy Option 2	Policy Option 3
Cumulative GHG emissions by 2020 (Mtonnes of CO2 eq)	7	7	6	6
Cumulative GHG savings by 2020 (Mtonnes of CO2 eq)	-	-	1	1
Cumulative GHG emissions by 2030 (Mtonnes of CO2 eq)	143	143	37	37
Cumulative GHG savings by 2030 (Mtonnes of CO2 eq)	-	-	106	106

Cost considerations and feasibility analysis

Technology options for improving efficiency of ACs

Typically, the options for improving the energy efficiency of ACs focus on changes in the following components:

- Compressor
- Heat exchanger
- Fan motor

Both efficiency and cost implications associated with improvements in these components largely vary from manufacturer to manufacturer and are based on overall system design.

Improvements in compressor: The two major types of compressors used in ACs are rotary and scroll compressors. Rotary compressors are manufactured locally in India and are also imported. At present rotary compressors with an EER of 3.6 are already being used by some Indian manufacturers. According to compressor suppliers, both 1st stage and 2nd stage rotary compressors can achieve a gain of 0.2 units in the EER. However the incremental costs associated with 1st stage and 2nd stage rotary compressors are 10% and 20% respectively, over base case.

Scroll compressors are 15-20% more efficient than rotary compressors but they are not manufactured locally in India. A USD 20 increase in manufacturing cost is likely with the use of scroll compressor over rotary compressor.

Improvements in heat exchanger: Currently manufactured ACs use copper tube aluminum fin CTAF technology for heat exchangers. But new technologies like Brazed Aluminium Micro Channel (BAM) can achieve same efficiency with 25-30% less area and thus reduce costs of achieving higher efficiency in ACs. A few manufacturers in India are importing BAM heat exchangers but its applicability for RACs is yet to be established.

Improved fan motors: Brush Less DC (BLDC) fan motors are 50% more efficient than the conventional AC motors. However the cost difference between the two types of AC motors is substantial. Each unit of BLDC fan motor costs approx. USD 40 compared to USD 6-8 for an AC fan motor. Besides, BLDC fan motors are not locally manufactured and have to be imported.

Efficiency, cost and feasibility considerations under policy scenarios

Under policy option 1, minimum efficiency levels for ACs would increase to an EER of 5.7 by 2020 from the base case EER of 3.3. This 70% improvement in minimum efficiency levels can be achieved by incorporation of BLDC fan motors that lead to 50 to 60% improvement in energy efficiency compared to AC fan motors uses in currently manufactured ACs in India. However, use of BLDC fan motor will increase the manufacturing cost by 5 times. Besides, manufacturers will have to rely on importing this technology as there are limited numbers of BLDC fan motor suppliers in India. However, production of BLDC fan motors in India will lead to cost-effective improvements in energy efficiency.

Under policy option 2, BEE adopts a schedule that increases the minimum efficiency levels to an EER of 4.2 in 2020 and also requires the use of refrigerants with GWP < 150 by 2016. In India, a leading AC manufacturer has recently produced an AC which has a GWP < 150 and an EER of 3.7. Further increase in EER from 3.7 to 4.2 can be achieved by using a combination of improved compressor technology like scroll compressor and use of BLDC fan motors.

The use of climate friendly refrigerants with GWP < 150 will lead to substantial reductions in CO_2 emissions over the life of the AC. An Indian manufacturer is already producing R-290 (GWP < 20) based ACs. It has been found that the cost of R-290 is more than that of conventional HFC refrigerants like R-410a in the current scenario. However, if adopted on a large scale, the cost will drastically come down due to economies of scale and will be at part with the conventional refrigerants. Propane is also a byproduct of some of the industries in India, although in impure form. If AC industry starts using propane by extracting the pure chemical from the byproduct, the cost can come down significantly. The application of propane is limited currently because of safety concerns due to its flammable nature.

Under policy option 3, BEE adopts policy option 1 and requires the use of refrigerants with GWP < 150 in 2016. This can be achieved by using the measures identified under policy option 1 and option 2.

Summary of Results

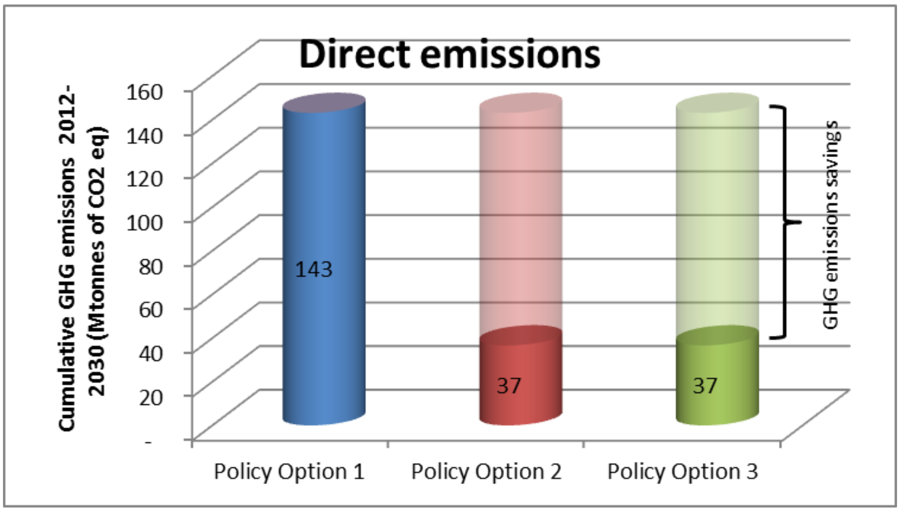

Figure 8: Direct emissions – cumulative GHG emissions from 2012 - 2030

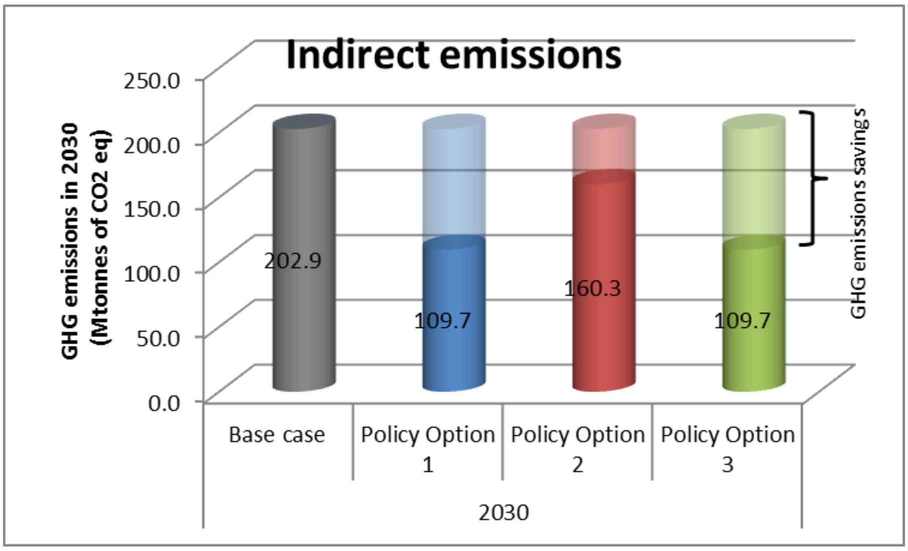

Figure 9: Indirect emissions – Annual GHG emission in 2030

Conclusions

Including the use of climate friendly refrigerants as part of the energy efficiency requirements for room ACs can have a great impact on the long term emissions from this equipment. This analysis showed that in 2020 (only 4 years after the proposed implementation date of 2016) the savings are not significant since the retired appliances over that period are very few. However, there are considerable savings from the transition to lower GWP refrigerants in the long term. If implemented, the cumulative savings from direct emissions by 2030 (106 Mtonnes of CO2 eq.) could be nearly 75% of the cumulative emissions (143 Mtonnes of CO2 eq.) of the base case (if no policy was implemented).

From the energy savings point of view, policy options 1 and 3 result in total energy savings of 113,615 GWh in 2030 (and corresponding GHG emissions mitigation = 93.2 Mtonnes of CO2 eq.). Policy option 3 offers additional GHG emissions savings from direct emissions (106 Mtonnes of CO2 eq. cumulative by 2030). However, in the context of an emerging market, adopting the measures to increase the energy efficiency of ACs by 70% in a time frame of 6 years with the use of climate friendly refrigerants (GWP<150) would be quite challenging and costly. It could increase the price of the retail product significantly, making efficient ACs out of reach for an average consumer. Policy option 1 presents the same challenges as option 3 in terms of increasing AC efficiency (without the additional cost of transitioning to low GWP refrigerants) and it offers the least GHG mitigation potential; hence it is not the recommended policy option.

Policy option 2 is the most suited option for the Indian scenario: it is a cost effective option (one of the Indian manufacturer has already started the production of such units) and has significant impact in terms of GHG emissions reduction. It results in GHG emissions savings of over 93.2 Mtonnes of CO2 eq. per year after 2030 (from indirect emissions) and additional cumulative savings of 106 Mtonnes of CO2 eq by 2030 (from direct emissions).

Therefore, this paper identifies policy option 2 as the recommended option for future AC regulations in India. It also recognizes implementation challenges since it would require enhanced coordination and communications between two agencies, BEE and Ozone Cell, which until now regulate energy efficiency and consumption of refrigerants in India independently. However, if these challenges could be addressed, India's ACs policy would result in long term sustainability through significant GHG emissions reduction from energy savings and the use of climate friendly refrigerants.

The Turkish Energy Efficiency Plan – an ex-ante assessment of the residential sector

ELSLAND, Rainer; DIVRAK, Can; FLEITER, Tobias

Fraunhofer Institute for Systems and Innovation Research ISI

Abstract

The aim of this study is to analyse the impact of the Strategic Energy-Efficiency Plan (SEEP) on residential energy demand in Turkey until 2030. For this purpose, three different explorative scenarios have been developed: a reference scenario (REF-S); a scenario based on the SEEP (SEEP-S) and a scenario which includes even more ambitious policies (HiEff-S). The scenarios are being compared in terms of energy demand and allow conclusions about the potential impact of the policy packages. For the analysis, a detailed bottom-up modelling approach is applied. The results show that the final energy demand decreases in all scenarios from about 944 PJ in 2008 to 851 PJ (REF-S), 736 PJ (SEEP-S) and 659 PJ (HiEff-S) in 2030. The decreasing demand even in the REF-S reflects a structural break with the past and mainly comes from the building sector and is driven by a very high demolition rate and a very low level of efficiency in the existing building stock. This drastic policy induces a fast building turnover, which is a window of opportunity from an energy efficiency point of view – which, however, is not taken into account by current legislation and not particularly addressed in the SEEP. Both the share of electricity but also the total demand in all scenarios is increasing – mainly driven by the growing ownership of various electric appliances. The SEEP-S will achieve 10 TWh of savings in 2030 compared to the REF-S which mainly comes from more ambitious appliance and lighting standards. Generally, the scenarios assumed a relatively high rate of compliance and a strong enforcement of policies, which might not be the case in reality (as already indicated by the observed slow progress of building certification by 2013 which is running far behind schedule).

Introduction

In recent years, Turkey has become one of the largest emerging markets in the world with high economic growth and a relatively young as well as fast-growing population. In 2010 GDP rose by 9 % and GDP per capita has tripled since 2002 (after the financial crisis in 2001), reaching 10,500 US$ in 2010 [1]. In the same year, Turkey's population reached the level of 74.7 million compared to 56.5 million in 1990. As a result, Turkey has become the sixth biggest economy in Europe [2, 3]. As could be witnessed in the past, economic growth came together with an increase in energy demand. Final energy demand increased by approximately 4 % per annum between the years 2009 and 2011, while growth of electricity demand has been even higher, 4.7 % per annum for the same years and expected to rise [23]. This dynamic development induces high pressure on the Turkish energy system, as Turkey depends on foreign resources for 72 % of its demand in 2010 [43].

In 2012 the Turkish government developed the strategic energy efficiency plan (SEEP) to cope with the increasing demand [34]. The plan sets targets for the coming ten years until 2023 and requires policies to be implemented in all demand sectors, such as market transformation of energy-using products (following the EU Eco-design Directive [27, 28]) or energy usage in buildings [18, 19]. To reach the goals defined in the SEEP, i.e. improving energy efficiency in the residential sector, plays a significant role. In 2010, 35% of final energy demand in Turkey was attributed to the residential sector and the importance of this sector is expected to grow even more. Not only because of its high percentage share in final energy demand, but also due to rising living standards, decreasing average size of households and as a result of an increasing demand for new buildings due to high urbanization rates [4].

The aim of this study is to analyse the impact of the SEEP on residential energy demand in Turkey until 2030 based on three explorative scenarios. The reference scenario (REF-S) is used as a baseline, the scenario SEEP-S simulates the impact of the SEEP policies, and the scenario HiEff-S includes even more ambitious policies than the SEEP requires. For the analysis the bottom-up model, FORECAST-Residential is applied that uses empirical data such as the ownership rate of appliances, the building typology or the efficiency development of heating systems to determine final energy demand projections [5, 6]. The explicit consideration of individual end-uses allows a very detailed modelling of the individual policy measures defined in the SEEP. Besides techno-economic parameters and socio-economic parameters, such as the number of households, are also taken into account in the simulation. Thus, the main determinants of Turkish energy demand are considered in this approach.

Status quo of energy-efficiency policies for the residential sector in Turkey

In the last decades, Turkey has reacted to the expanding energy demand with increasing the import of fossil fuels. As a result, Turkey has become more import-dependent and CO_2 emissions have increased drastically. However, a significant share of energy demand could have been avoided by reducing the energy losses in production, transportation/distribution and final demand by lowering the need for fossil fuel use and import. This point of view has become more central in recent years in Turkey and a mix of energy-efficiency policies has been implemented, of which several measures address the residential sector.

Laws and regulations in force

The legal framework and its key laws and regulations that aim to improve energy efficiency in the residential sector in Turkey are summarized in Table 1.

Table 1: Overview of regulations addressing energy efficiency in the residential sector in Turkey

Law / regulation	**Aim and scope with regard to residential sector**	**Implementation (latest revision)**
Laws and regulations addressing residential buildings		
Energy Efficiency Law (no. 5627) [15]	A broad frame for energy-efficiency policies in all sectors and the implementation of more specific regulations.	2007
Energy Efficiency Regulation [16, 17]	Authorization and standards for ESCOs including training curricula for energy managers, public entities energy efficiency programs.	2008 (revised 2011)
Building Energy Performance Regulation [18, 19]	Setting minimum energy performance standards (MEPS) for buildings, regulation of MEPS calculation, use of renewable energies and HVAC systems.	2008 (superseded Reg. on Heat Insulation in 2009, revised 2010)
Regulation on Heat Insulation in Buildings [20, 21]	Requirements for thermal performance of building insulation.	2000 (superseded in 2009)
National Standard of Thermal Insulation Requirements for Buildings (TS 825) [22]	Calculation procedures for standards for building insulation.	2000 (revised 2008)
Laws and regulations addressing residential appliances		
Directive on Eco-Design Requirements for Energy-Related Products [24]	Defines MEPS for energy-related products (refrigerators, freezers, dish washers, washing machines and televisions) and stand-by and off-mode losses of electronic equipment. Related to relevant EU Directive and Regulations.	2010
Directive on Displaying Standard Product Information and Labelling [25]	Requires energy labels for energy-related products (currently refrigerators, dish washers, washing machines and televisions) also aligned to EU law.	2011

The ***Energy Efficiency Law*** implemented in 2007 [15] covers principles and procedures applicable to increasing and promoting energy efficiency and renewable energies in all sectors and sets the framework for further implementation of more specific policies.

For the building sector, this law aims to create an institutional framework for supporting energy efficiency measures, including the establishment of an Energy Efficiency Coordination Board. Trainings, audits, consultancy, monitoring activities, and other support and/or incentives for energy efficiency projects are regulated by this law as well. The main entity assigned responsible for the implementation of the law is the General Directorate of Electrical Power Resources Survey and Development Administration (EIE). The provisions of the Energy Efficiency law which specifically addresses buildings include:

- Appointment of energy managers at commercial and public buildings over specified size and accreditation and support of ESCOs;
- implementation of minimum energy performance standards (MEPS) for buildings;
- establishment of ‘Building Energy Performance Certificates’; and
- application of individual heat meters for buildings with central heating systems.

Additional regulations and notifications have been published to implement the law, of which the most important are the Energy Efficiency Regulation and the Buildings Energy Performance Regulation. Both regulations were implemented in 2008 and revised a few years later.

The ***Energy Efficiency Regulation*** [16, 17] published in October 2008 describes mainly how ESCOs will be established, their training curricula set, and how they will be authorized. This regulation was fundamentally revised three years later after its first publication (October 2011). Although this regulation mainly focuses on the industrial, commercial and public buildings, it is also relevant for the residential sector as it requires labelling systems for energy-related appliances and equipment.

The ***Building Energy Performance (BEP)*** **Regulation** [18, 19] was implemented by the Ministry of Public Works and Settlement (MoPWS) in 2008 according to the requirements of the Energy Efficiency Law. It superseded the former Regulation on Heat Insulation in Buildings in 2009 and is designed in accordance with the European Union Energy Performance of Buildings Directive (EPBD). The BEP Regulation’s main objectives are:

- defining the calculation methods for the overall energy use of buildings;
- defining the performance criteria and their application principles and classifying the buildings with respect to the primary energy use and CO_2 emissions;
- determining the minimum energy performance (MEPs) requirements of existing buildings that undergo a major renovation;
- requiring new buildings to comply with efficiency class C;
- encouraging use of renewable energy sources (RES); and
- demanding from house owners to conduct periodic inspections of heating and cooling systems.

According to the BEP Regulation all buildings have to have a ‘Building Energy Performance Certificate’ by 2017, which includes information about the thermal efficiency, emissions, energy performance classification (A, B, C, D, E; F and G), insulation properties, heating and/or cooling systems of the buildings. Since January 2011 owning energy performance certificates has been mandatory for new buildings. The certificates are valid for 10 years [18, 19]. Until the end of February 2013 energy performance certificates have been given to 64,805 existing and new buildings [26]. In the light of this slow progress, the goal of 9 million certified buildings by 2017 seems relatively unrealistic.

Some other features of the BEP are:

- Central heating systems are mandatory for new buildings over 2000 m².
- Buildings with central heating systems have to use central or local heat/temperature control equipment as well as systems enabling the distribution of heating costs on the basis of heat utilization quantities.
- In buildings, single spaces or self-contained houses with gas fuelled space heating, or of a size of 250 m² and more the use of condensing gas boilers with integrated economizers is mandatory.

Compared to the EU countries with similar climate conditions the MEPS (i.e. heat transfer/U-Value) defined for new buildings is still lower in Turkey [47].

Another key legal act for building efficiency is the *National Standard of Thermal Insulation Requirements for Buildings TS 825*, which became mandatory in June 2000. Together with BEP, TS 825 provides the backbone for improving energy performance in buildings. It complies with international standards (ISO 9164 and EN 832) and:

- sets the thermal insulation requirement for new and existing buildings where renovation of at least 15% of the total area is carried out;
- defines the rules for the calculation methods of heating energy requirements in buildings

In addition to the mentioned regulations addressing buildings, the Turkish government also published regulations to encourage the use of energy-efficient home appliances.

These regulations mainly follow the standards and requirements set out in the EU Eco-Design Directives on Energy Using Products [27] and its successor on Energy-Related Products [28]. They are specified in the ***Regulation on Eco-Design Requirements for Energy-Related Products*** published by the Ministry of Science, Industry and Technology (MoSIT) in 2010 [24]. The regulation sets MEPS for refrigerators, freezers, dish washers, washing machines and televisions. It also regulates the stand-by and turned-off energy consumption of electronic home and office appliances. The MEPS require from retail sellers that all products of the above categories sold on the market in Turkey comply with the standards.

Furthermore, in December 2011 the Directive on displaying standard product information and labelling [25] was implemented, which requires energy labels for refrigerators, dishwashers, washing machines and televisions - aligned with EU labelling requirements.

The Strategic Energy Efficiency Plan (SEEP) 2010-2023

In 2004 an energy efficiency plan was drafted by the Government that has never been published. The Strategic Energy Efficiency Plan (SEEP) was not published until 2012 [34]. It provides a framework for the development of energy-efficiency policy until 2023 and targets for the improvement of energy efficiency combined with actions necessary to reach these targets. The main target is to reduce the amount of energy consumed per unit of GDP (energy intensity) by at least 20% until 2023 compared to 2011. The SEEP contains a total of seven strategic aims (SA) of which the following address the residential sector in particular.

- SA-2: Decrease energy demand and carbon emissions of buildings and promote sustainable environment-friendly buildings using renewable energy sources.
- SA-3: Achieve market transformation of energy efficient appliances.

SA-2 comprises two main targets.

First, it requires more ambitious efficiency standards for a particular category of existing buildings until 2023 (excluding small buildings, buildings in the scope of the urban transformation plan and rural buildings). To reach this target, the actions defined by the Government are:

- Revision of the current legislation on the energy performance of buildings (BEP) parallel to the EU regulations.
- Limiting the maximum energy demand and maximum CO_2 emissions of buildings.
- Defining the maximum energy demand of buildings according to their functions (hotels, dwellings, schools etc.), to the climate conditions of the region, to their architectural design and to the current mandatory standards considering heating, cooling and lightning.
- Determining the maximum CO_2 emissions for new buildings. Furthermore, in 2017 penalties will be applied to those buildings which exceed the defined CO_2 emission standards.
- Encouraging refurbishment of existing buildings to comply with CO_2 emission standards

Second, it requires that at least one fourth of the building stock from 2010 will be sustainable by 2023, while sustainability is not exactly defined.

SA-3 aims to complete the market transformation of lamps, refrigerators and electrical motors until the end of 2012 and for heating/cooling systems and other energy efficient products parallel to the EU regulations. To reach this target, MEPS are defined for each product group and controlled via market surveillance.

The General Directorate of Renewable Energy (YEGM) is responsible for realizing defined actions, applying the measures and evaluating the results for the next 11 years. The aims, targets and actions of the SEEP are going to be revised annually according to changes in governmental and EU policies.

Despite the positive intention of the government to improve energy efficiency, some questions regarding the application and time plan of the defined actions still remain open. According to the Chamber of Mechanical Engineers (TMMOB), many actions in the strategy plan are defined without analysing the present situation or without questioning the practicability in a short period such as 11 years in terms of capacity and budget. The time plan can be questioned even more for the building related measures, given the long lifetime of buildings. Taking these critics into account we extend our model-based analysis to the year 2035 to assess a possible long-term impact of the SEEP even after 2023.

Methodology

Structural framework and drivers

The applied bottom-up model for the Turkish residential sector – FORECAST-Residential – is based on a simulation approach. FORECAST-Residential includes a module for ‘household appliances, lighting and air conditioning’ (*Module 1*), and another module for ‘heating systems’ (*Module 2*). FORECAST-Residential is set up as a vintage stock model with detailed techno-economic parameters of energy end-uses in the residential sector (Figure 1). *Module 1* covers the appliance categories of white appliances, stoves, ICT appliances, lighting and air conditioning systems. The appliance categories listed contain exclusively electricity-based devices apart from stoves. The technological structure in *Module 1* considers three hierarchical levels of household appliances (e.g. televisions) on the highest level of aggregation, which are further differentiated by technology (e.g. plasma, LCD) and then divided again into efficiency classes (e.g. A++, A+). The *Module 2* for heating systems is based on the existing useful energy demand, which is derived from the Turkish building typology. The building typology is subdivided by construction period, building type and multiple refurbishment levels. The heating systems are discretely assigned to the different building segments.

Modelling of technology diffusion

Decision-making in private households is based on the observation that each decision maker selects the option which offers the highest individual benefits or utility from a large number of alternatives [8]. This concept is based on the studies of Thurstone, who examined the influence of psychological stimuli on individual’s decision behaviour [9]. Ultimately, this concept was further developed by Marschak, who interpreted the stimuli as individual benefits and then derived the phenomenon of maximizing utility from this [41]. Due to the fact that the decision makers in private households differ with regard to their preferences, lifestyles, available information and other characteristics, individual utility is a complex variable and to a certain extent not quantifiable [42]. However, because satisfying a utility always results from the decision in favour of one alternative, at the macroeconomic level, the sum of all decisions can be described if this is linked to measurable variables. Logit models are used to illustrate this type of decision logic in energy models [7]. The market share of substitution alternatives can be determined from a market perspective using a Logit model by means of observable variables (e.g. investments). Three properties have to be given for a Logit model to be applied [42].

- The substitution alternatives have to mutually exclude one another from the decision maker’s perspective.
- All the substitution alternatives have to be included in the decision-making.
- The number of substitution alternatives has to be finite.

In line with the heterogeneous utility function of the decision maker, the Logit approach delivers a distribution of market shares as the result, which takes all the substitution alternatives into account. The main descriptive factor which influences the utility function is the Total Cost of Ownership (TCO): the investment sum plus payments for energy and maintenance [13, 14]. By determining the correlation between TCO and the market shares of competing technologies the price elasticity is

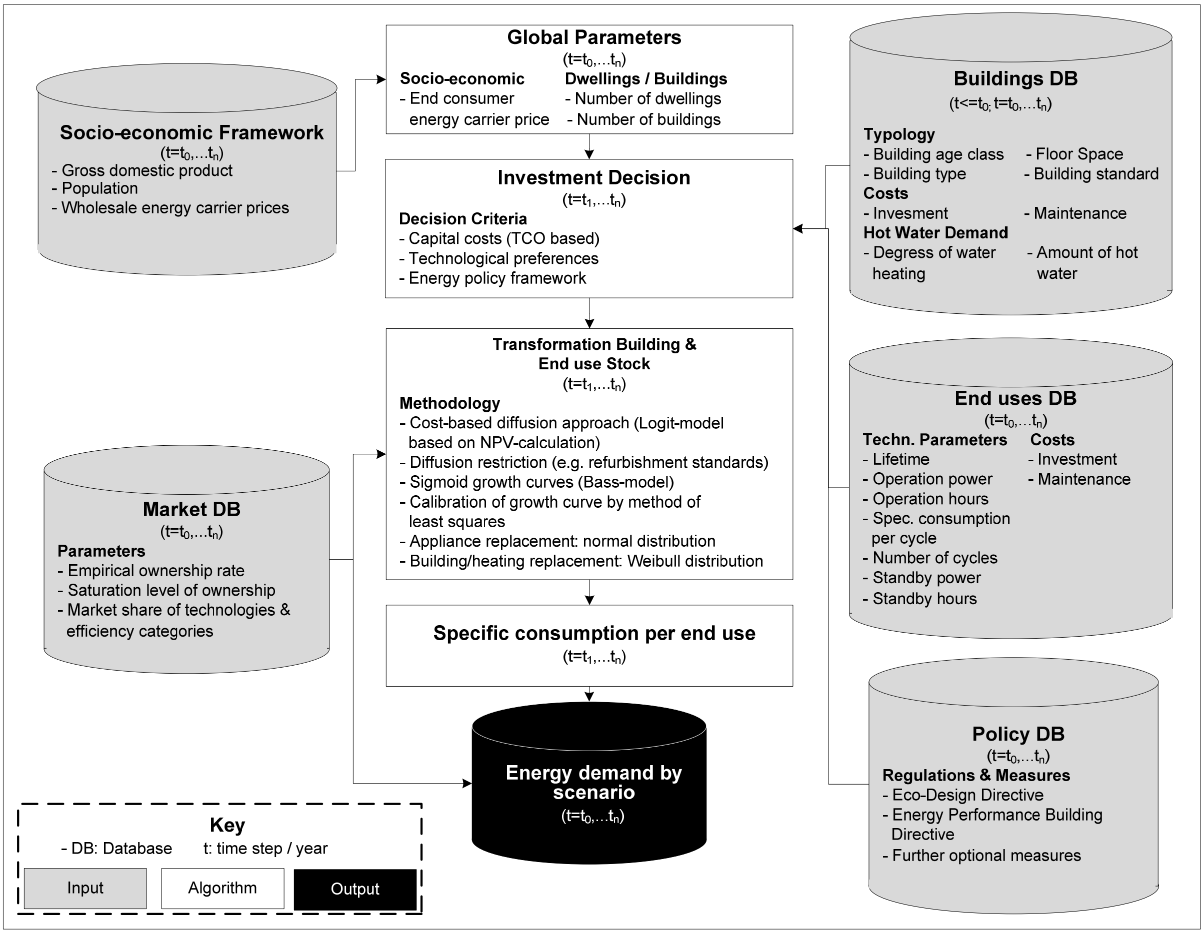

Figure 1: Structural framework of FORECAST-Residential

explicitly taken into account using the Logit approach [7]. As in a real investment decision only limited knowledge is available about the period of the investment cycle the investment decision is based on a calculation with myopic information [10]. Calculating the TCO is done using a dynamic net present value calculation and subsequently an annuity calculation, which makes it possible to compare different investment alternatives in monetary terms.

The Logit approach aims at quantifying the market shares of rival alternatives (e.g. replacement of heating systems). Furthermore, growth curves are used to determine the total number of investment decisions in each year, if there is no substitution relationship between end-uses. This is the case for all end-uses captured by *Module 1*. Another function of the growth curves is to consider market dynamic and saturation effects. Growth curves are based on an epidemic interpretation of market growth, which uses the empirical market growth as the basis for projecting the growth curve [8]. These generally S-shaped curves can be described by different explanatory approaches of technology diffusion. Since a large number of analyses has already revealed that word-of-mouth represents the main driver of technology diffusion, an extended version of the Bass function was chosen, which also takes income elasticity into account [11, 12, 46]. The saturation point of equipment penetration rates was derived, among other things, from the disposable income [12, 45]. The Bass function is fitted by a least squares deviation based on empirical stock development and the saturation point. The stock turnover of appliances is calculated by a normal distributed failure probability, which is used to determine the point in time at which the lifetime of an old appliance ends [7]. The probability of building demolition and heating replacement is calculated based on the age distribution using a Weibull distribution [44].

The final energy demand of appliances is calculated according to the average penetration rate (for lighting, this corresponds to the share of lighting points per dwelling), the market share of the technologies and efficiency classes, the specific consumption (based either on the number of operating hours, for example, of televisions, or on the number of cycles per year, for example, of dishwashers), and the number of dwellings. The final energy demand of heating systems is calculated in two steps: in a first step the useful energy demand is quantified based on the building typology and in a second step it is transformed into the final energy demand by the heating systems.

Scenario analysis

Scenario definition

To analyse the impact of alternative policy strategies on the residential energy demand in Turkey an ex ante scenario analysis is applied. For all scenarios similar assumptions are taken for the socio-economic parameters such as population, GDP or number of dwellings. As only the techno-economic parameters depend on the scenario specific policy framework, the difference in energy demand between the scenarios equals the impact of the analysed policy packages. The three explorative scenarios are distinguished as follows:

- *Reference scenario (REF-S)*: technological changes are driven by autonomous progress and policies implemented until 2012 are considered (see Table 1). The SEEP is explicitly excluded.
- *Strategic Energy Efficiency Plan scenario (SEEP-S)*: according to the SEEP more ambitious efficiency standards and new regulations regarding energy efficiency are included.
- *High efficiency scenario (HiEff-S)*: based on the SEEP scenario, but assumes more ambitious policies in fields where the SEEP still remains at a lower level of ambition. This scenario shows what is possible beyond the current Turkish strategy.

The policy-related assumptions are discussed in the following and summarized in Table 2 and Table 3.

Buildings

Thermal efficiency of buildings (kWh/m²a): According to the BEP regulation, the efficiency of new buildings must correspond at least to energy class C. The thermal efficiency of a class depends on the climatic zones, the architectural design and the building type. We used the reference parameters for different climatic zones defined in the BEP to calculate average thermal efficiencies of building envelopes for energy class C for single-family houses (SFH) and multi-family houses (MFH). To receive an average value for the thermal efficiency per building segment, the thermal efficiency per climate zone is weighted by the number of residents living in this zone. The resulting MEPS for single-family and multi-family houses are approximately 269 kWh/m²a and 254 kWh/m²a, respectively. For existing buildings, the REF-S contains no restrictions. In the SEEP-S existing buildings have to comply with efficiency class C, if they are multi-family houses with a floor area above 10.000 m². The HiEff-S is more ambitious and applies thermal efficiency standards for both types of existing buildings.

Refurbishment rate (%): The refurbishment rate only describes the energetic refurbishment of buildings. Empirical data on the refurbishment rate in Turkey is scarce. The REF-S assumes a business as usual refurbishment rate of 0.9%, based on analogous assumptions from other European countries [29]. In the SEEP-S the refurbishment rate starts at 0.9% and then approaches its maximum of 2.08% in 2023 and remains at this level. The increase is derived from the SEEP goal to make at least a quarter of the 2010 building stock sustainable until 2023. In the HiEff scenario the refurbishment rate increases earlier to 2.08% and then remains at this level.

Demolition rate (%): The demolition rate gives the share of the building stock demolished each year. The Urban Transformation Plan [30] requires that a number of 6.5 million buildings are demolished until 2030. The resulting demolition rate equals 1.71% and is assumed constant for all scenarios. The related construction rate is calculated endogenously based on the exogenously given number of dwellings per year or building stock, respectively.

Other parameters like the *interest rate* [32], *investment subsidies* [33] and the *compliance rate* [29], which are not mentioned in the policy measures of Turkey, are quantified related to other studies for each scenario.

Table 2: Relation of model parameters and scenarios – buildings

Category	Parameter	Unit	REF-S	SEEP-S	HiEff-S
Buildings	**Control and Regulatory mechanisms**				
	Thermal efficiency (existing buildings)	kWh/m²a	No restrictions	Minimum efficiency class C (MFH: 254 kWh/m²a)	Minimum efficiency class A (SFH: 107 kWh/m²a, MFH: 101 kWh/m²a)
	Thermal efficiency (new buildings)	kWh/m²a	Minimum efficiency class C (SFH: 269 kWh/m²a, MFH: 254 kWh/m²a)	Minimum efficiency class A (SFH: 107 kWh/m²a, MFH:101 kWh/m²a)	Minimum efficiency of 30–80 kWh/m²a for SFH and MFH
	Refurbishment rate	%	Constant at 0.9%	0.9 % until 2012, increase to 2.08 % until 2023 and remains constant	0.9 % until 2012, instantaneous increase to 2.08 % in 2013 and remains constant
	Compliance rate	%	Increases from 60 to 70 % until 2030	Increases from 60 to 85 % until 2030	Increases from 60 to 90 % until 2030
	Demolition rate	%	Constant over time (1.71 %)		
	Financial instruments and incentives				
	Interest Rate	%	7%	7%	3%
	Investment Subsidies	%	No subsidies provided	No subsidies provided	15% of investment

Heating systems

Diffusion restrictions for heating technologies: According to the BEP regulation, existing buildings with a floor area of 250 m² and more must use a condensing boiler with integrated economizer [19]. We calculate the affected building stock based on the floor area distribution as given in the building census from 2000 [31] resulting in a share of 4.78% for the existing buildings. For new buildings of 2000 m² and more the BEP regulation requires central heating systems. We assume that 2000 m² correspond to multi-family houses with 8 or more dwellings. In 2010 this building class made up 62.5% of all multi-family houses that received a construction permit in that year [35]. We assume the share to remain constant over time. Both requirements are assumed to be similar for all scenarios.

Other parameters like *interest rate* and *investment subsidies*, which are not part of the current policy mix in Turkey, are assumed for the HiEff-S to arrive at a similar level as in Germany. Accordingly, the HiEff-S foresees a lower interest rate and an investment subsidy of about 16.4 percent for heat pump systems [32].

Appliances

MEPS: In the REF-S MEPS are defined for seven residential appliances (refrigerators, freezers, dish washers, washing machines, dryers, air-conditioners and televisions). In the SEEP-S MEPS are additionally set for lamps and the standards for the other products are updated according to EU Eco-Design law. For the HiEff-S we assume that MEPS are not set according to least lifecycle cost, but instead based on the best available technology (BAT).

Other parameters like *interest rate* and *investment subsidies*, which are not part of the current policy mix in Turkey, are assumed for the HiEff to arrive at a similar level as in Germany.

Table 3: Relation of model parameters and scenarios – heating systems and appliances

Category	Parameter	Unit	REF-S	SEEP-S	HiEff-S
Heating systems	**Control and Regulatory mechanisms**				
	Diffusion restriction (Existing Buildings)	%	4.78% of existing building stock must use condensing type of heaters		
	Diffusion restriction (New buildings)	%	62.5% of new buildings after 2009 must have central heating system		
	Financial instruments and incentives				
	Interest Rate	%	7%	7%	3%
	Investment Subsidies	%	No subsidies provided	No subsidies provided	16.4 % of investment for heat pump systems in existing and new buildings
Appliances	**Control and Regulatory mechanisms**				
	MEPS	%	MEPS for refrigerators, freezers, dish washers, washing machines, dryers, air-conditioners and televisions	Additional MEPS for lamps and more ambitious MEPS for other appliances	Standards more ambitious than SEEP scenario based on BAT
	Financial Instruments and Incentives				
	Interest Rate	%	7%	7%	7%
	Investment Subsidies	%	No subsidies provided	No subsidies provided	20% of investment for high-efficient appliances combined with duty to return the old appliances

Socio-economic and techno-economic parameters

The socio-economic parameters including the population, number of households, gross domestic product (GDP), and energy carrier prices are similar across the three scenarios (see Table 4) [1, 3, 36, 52, own calculation]. Turkey's population will continue to rise in the future and is estimated to reach 86.7 million in 2030. The demand for new houses will also increase, resulting from the rising population. Energy carrier prices for households are expected to increase as well.

Table 4: Summary of socio-economic model parameters and energy carrier prices in the period 2008-2030

	Unit	2008	2010	2015	2020	2025	2030
Socio-economic parameters							
Population	Million	70.9	72.8	77.0	80.8	83.9	86.7
Pers. per household	Pers./HH	4.01	3.95	3.79	3.66	3.53	3.42
Number of households	Million	17.7	18.4	20.3	22.1	23.8	25.3
GDP	Billion Euro ‘05	798	726	857	987	1117	1247
Energy carrier prices							
Electricity	Cent / kWh ‘10	12.2	12.7	12.7	14.3	15.6	16.3
Light fuel oil	Cent / kWh ‘10	13.3	12.3	12.0	12.5	13.6	13.9
Coal / lignite	Cent / kWh ‘10	3.66	4.19	4.56	4.47	4.61	4.70
Natural gas	Cent / kWh ‘10	4.67	4.38	4.81	4.74	5.00	5.24
Biomass	Cent / kWh ‘10	3.63	4.69	5.42	5.25	5.53	5.70
District heating	Cent / kWh ‘10	7.62	7.63	9.80	9.50	10.7	11.8

Assumptions on technological parameters (e.g. operation hours and operation power, lifetime) are based on various market and technology studies, particularly for large appliances, ICT-appliances, air-conditioning as well as lighting [37, 38, 39, 40]. The stock of residential appliances in 2008 is represented by multiplying the ownership rate with the amount of households. The ownership rate and the specific energy consumption (SEC) of appliances in 2008 are listed in Table 5.

Regarding the prospective development of technological parameters until 2030, the ownership rate is developing identically in all scenarios, whereas the SEC of appliances depends on the scenario. For many appliances (except for freezers, wash machines, dishwashers and dryers) the ownership rate has almost reached the level of saturation. The ownership rate of ICT appliances will increase significantly during the next decades. For ICT appliances the saturation level of ownership is derived from the amount of people living in a household whereas for large appliances the saturation rate is linked to the overall household. Due to an increasing demand of individual comfort the market share of air conditioners will continue to grow in the future.

Table 5: Ownership rate and specific energy consumption (SEC) of appliances in 2008

Appliance group	Appliance	Ownership rate [number/household]	SEC [kWh/year]
Large appliances	Refrigerator [37]	1.01	233
	Freezer [37]	0.06	373
	Dryer [37]	0.05	271
	Dishwasher [37]	0.36	194
	Washing machine [37]	0.87	174
ICT appliances	Desktop Computer [1]	0.27	154
	PC screen [1]	0.27	90
	Laptop [1]	0.11	73
	Television [39, 48, 49]	1.04	243
	Set-Top Box [39, 48, 49]	0.35	76
	Modem/Router [1]	0.23	88
Lighting	Lighting [51]	1.00	438
Air-Conditioner	Air Conditioner [40, 50]	0.11	633

Results

The results for the future development of energy demand are shown in Figure 2. All scenarios show a decreasing demand starting from the level of 944 PJ in 2008. In the REF-S final energy demand decreases to about 851 PJ by 2030, while the SEEP-S adds additional savings of about 13% and arrives at about 736 PJ in 2030. The more ambitious HiEff-S results in 659 PJ in 2030 equal additional savings of about 10%.

In the SEEP scenario, the share of electricity and solar thermal energy increases continuously until 2030. Electricity demand increases from 143 PJ to 190 PJ (33 %) by 2030 and solar thermal energy reaches about 0.3 PJ in 2030, starting from nearly zero. On the other hand, conventional fuels decrease over time. The demand for oil diminishes from 63 PJ to 22 PJ (-65 %), coal and lignite decrease from 248 PJ to 152 PJ (-39 %) and natural gas from 272 PJ to 224 (-18 %). Also the energy demand for (mostly traditional) biomass decreases constantly (-38%), losing its position as the third most important energy carrier. It is substituted by electricity, district heating, and solar thermal heating. Thus, conventional fuels lose their share and decrease in absolute numbers, while the share of renewable energy sources (RES) and electricity increases. In the HiEff-S, the trends by energy carrier are similar, but even more pronounced.

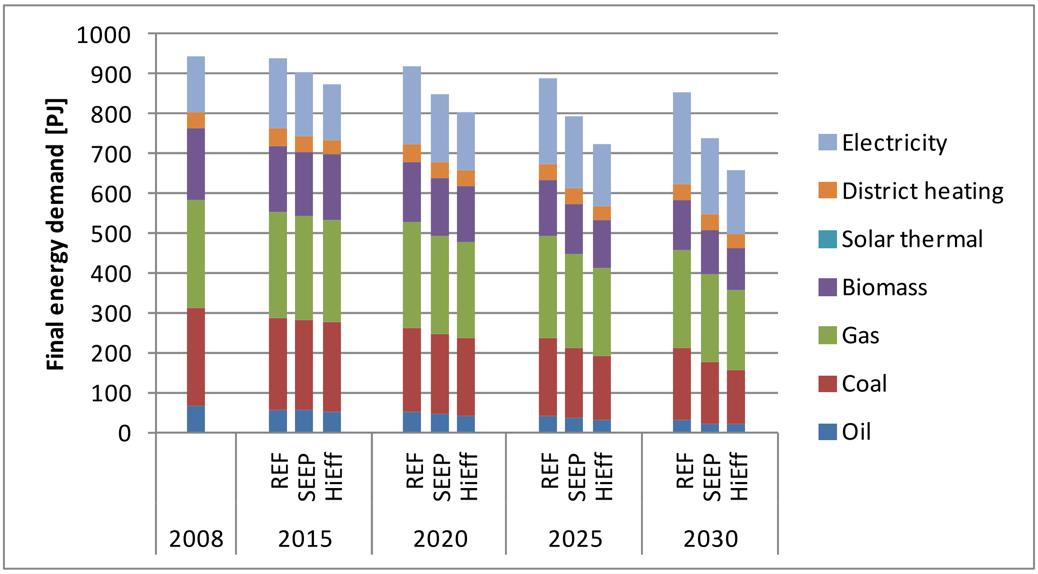

Figure 2: Final energy demand by energy carrier and by scenario for the period 2008-2030

As discussed above, demand for energy sources mainly used for space heating decreases in all scenarios. This development marks a structural break with the increasing demand in the past and is mainly due to a falling useful energy demand for space heating in buildings. Two main factors can be identified that drive space heating demand down: the (very ambitious) urban transformation plan resulting in very high demolition rates and a quick stock turnover as well as the low efficiency level of the existing building stock. In combination with the assumption of a relatively high compliance rate, space heating demand decreases significantly – even in the REF-S (see Figure 3).

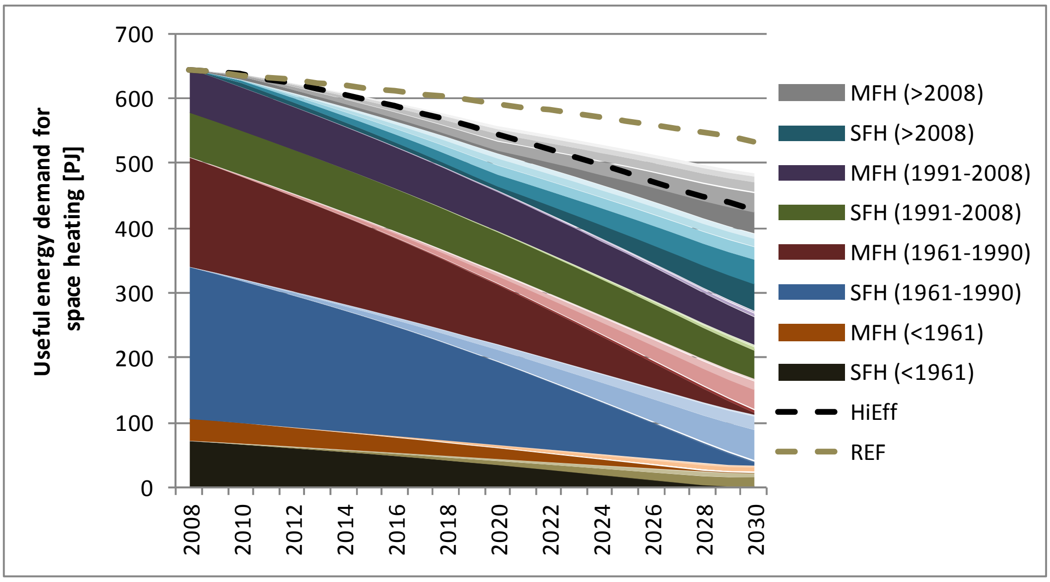

Figure 3: Useful energy demand for space heating by construction period and building type for the period 2008-2030

The SEEP-S assumes more ambitious MEPS for buildings and a high refurbishment rate resulting in additional useful energy savings of about 10% until 2030. The development of space heating demand by building type in Figure 3 reflects the high refurbishment rate and stock turnover, as the existing building categories are mostly refurbished or replaced by 2030. As a result, new buildings account for about one half of the space heating demand in 2030. While the SEEP-S is already relatively ambitious, the HiEff-S achieves an even faster efficiency improvements induced by a higher refurbishment rate and more ambitious standards.

Figure 4 shows the results for heating energy demand until 2030, which in total follows the shape of the useful energy demand for space heating. In the SEEP-S, the distribution among energy carriers changes only slowly. Natural gas and district heating increase continuously, at the cost of coal, oil and biomass. Also the use of heat pumps and solar thermal energy grows substantially, but remains on a very low level. Generally, the substitution among energy carriers is relatively low because no policy measure particularly addresses individual heating systems. This is different in the HiEff-S where a subsidy is provided for the installation of heat pump systems. But even in this case, only marginal changes are induced and the sensitivity analysis reveals that subsidies for heat pumps must be substantially higher to have any effect on heating system shares.

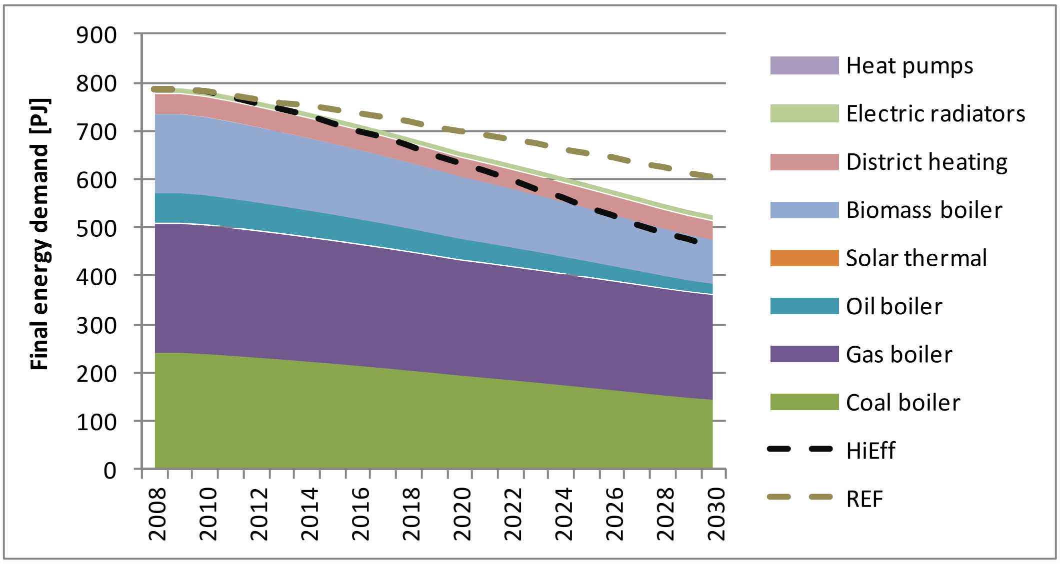

Figure 4: Final energy demand of heating systems by system type and by scenario for the period 2008-2030

Figure 5 shows the electricity consumption of large appliances, lighting and other appliances under different scenarios. In the REF-S, the electricity consumption of large appliances increases from 10 TWh in 2008 to 12 TWh in 2030. Also in the SEEP-S, electricity demand increases continuously, but is 15% lower in 2030 than in the REF-S, mainly due to more ambitious MEPS. The HiEff-S reveals further saving potentials of about 19% by 2030 compared to the SEEP-S resulting from more ambitious MEPS set at BAT level.

Electricity consumption of lighting increases in the REF-S from 8 TWh to 9 TWh in 2030, whereas in the SEEP-S it decreases to 4 TWh in 2030, resulting in savings of 54% compared to REF-S. These high savings mainly result from the fact that the REF-S does not contain MEPS for lighting, which are introduced in the SEEP scenario in line with EU legislation. In the HiEff-S, consumption decreases even more to 2 TWh (-75% compared to REF-S), reflecting MEPS based on BAT which results in a fast diffusion of LED technology.

A third groups comprises the remaining appliances including IT, air-conditioning but also a high number of small appliances not individually modelled as well as potential new appliances arising in the future. These groups of appliances generally show a growing trend, which also is reflected in the scenarios, as even in the HiEff-S demand increases substantially until 2030. The policies defined in the SEEP only induce a small mitigation of about 8% compared to REF-S, resulting in a growth of 68% compared to 2008. This increase indicates the importance to regulate this heterogeneous group of appliances as well as the difficulty to do so.

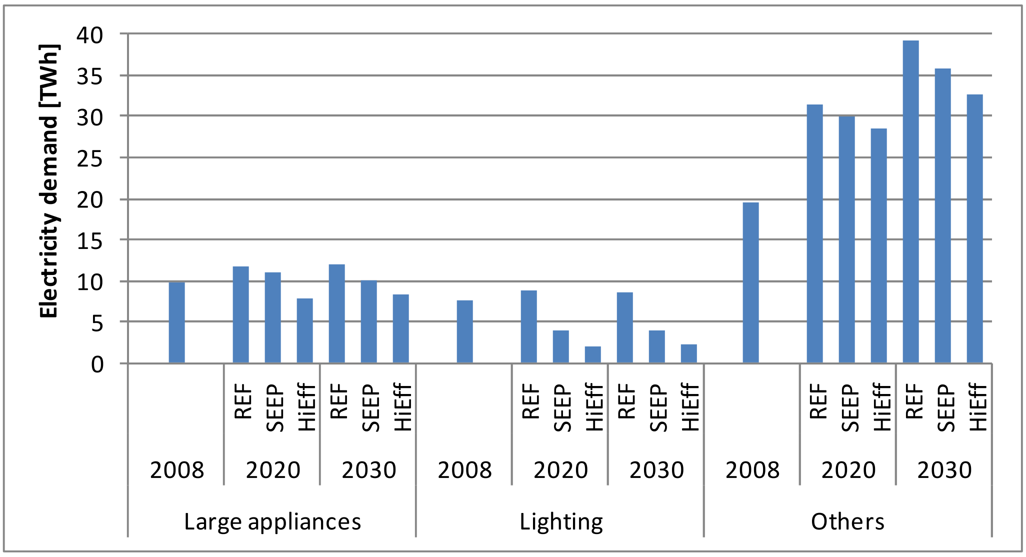

Figure 5: Electricity demand of large appliances, lighting and others electricity user by scenario for the period 2008-2030

Figure 6 shows the share of individual efficiency classes and its evolution in the stock of dryers for the SEEP-S. It shows that MEPS introduced in the SEEP result in a complete phase-out of class E and D appliances by 2020 and class C appliances by 2025. On the other hand, in the long term even new efficiency classes (A+++ and beyond) emerge and gain substantial shares in the stock of dryers.

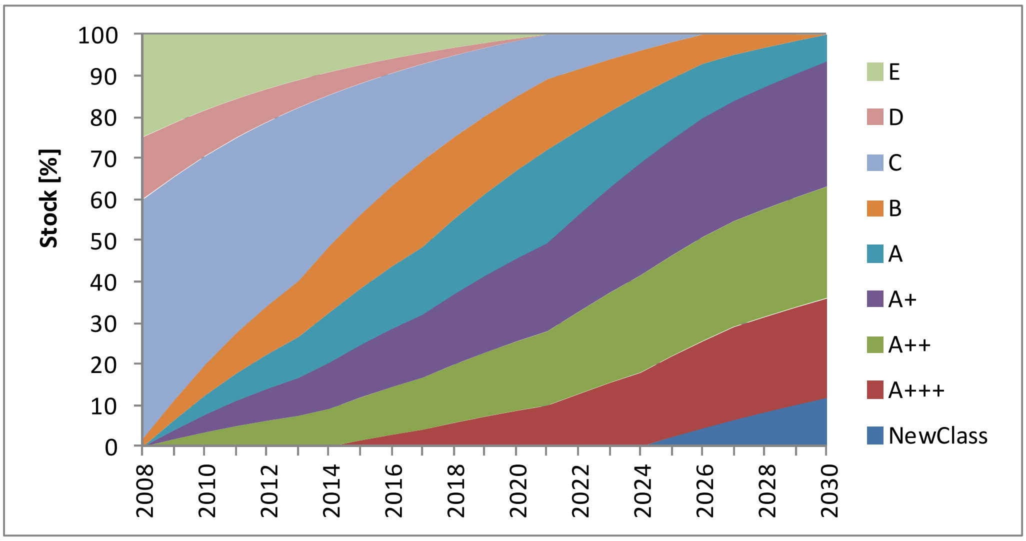

Figure 6: Share of efficiency classes in the stock of dryers for the SEEP-S and its evolution

Conclusion and Outlook

We applied an explorative scenario analysis to assess the ex-ante impact of the current and future energy-efficiency policies in Turkey on the final energy demand of the residential sector until 2030. The three scenarios use the same socio-economic framework data, but differ regarding techno-economic data depending on the policy design. The reference scenario (REF-S) represents the basis for impact calculation and considers the current policy-mix. The second scenario SEEP-S is based on the policy measures of the strategic energy efficiency plan (SEEP), which was published in 2012 by the Turkish Government and provides the framework for an energy-efficiency strategy until 2023. The third scenario (HiEff-S) assumes even more ambitious efficiency standards (such as BAT assumption for MEPS) and aims to identify potentials for efficiency improvement beyond the SEEP.

The results show that the final energy demand decreases in all scenarios from about 944 PJ in 2008 to 851 PJ (REF-S), 736 PJ (SEEP-S) and 659 PJ (HiEff-S) in 2030. The decreasing demand even in the REF-S reflects a structural break with the past and is mainly coming from the building sector driven by a very high demolition rate (due to the urban transformation plan) and a very low level of efficiency in the existing building stock. In the SEEP-S, most existing buildings will be either refurbished or demolished by 2030 indicating the high level of ambition behind these assumptions.

Electricity not only gains in its share but also increases in terms of total demand in all scenarios - driven by ownership growth of various electric appliances. The SEEP-S achieves 10 TWh of savings in 2030 compared to the REF-S, mainly originating in more ambitious appliance and lighting standards.

Thus, regarding the policy mix we can conclude that the SEEP achieves considerable energy savings, but also significant saving potentials still remain. 6.5 million buildings will be demolished until 2030 through the Urban Transformation Plan, and new buildings have to comply with thermal efficiency standards. This window of opportunity is, however, not addressed by the current building efficiency standards that on average require a minimum thermal efficiency of around 254 kWh/m²*a for single family houses. The SEEP is not very specific with regard to the thermal efficiency required, besides demanding higher standards from future building regulations. A central conclusion from our analysis is to apply more ambitious standards for buildings in this framework and make use of the current window of opportunity. The results of the SEEP scenario, however, have to be interpreted with caution, as the SEEP is still rather vague in many aspects (e.g. sustainability of buildings is not exactly defined) and open to interpretation in order to translate it into model parameters.

The analysis also contains elements of uncertainty. The outline of the scenarios follows very closely the policy requirements as described in the various legislative documents including a high rate of building demolition and refurbishment and an assumed compliance rate on a similar level as observed in EU countries. Thus, the scenarios assume a strong enforcement which might not be the case in the coming years. Still, the comparison of the scenarios shows the order of magnitude of the SEEP's impact and the fields where it has the strongest effect (building standards, refurbishment rate, lighting standards).

From the methodological point of view, it is worth mentioning that our analysis is the most detailed bottom-up assessment of the Turkish residential sector – at least to the knowledge of the authors. Most other studies rely on top-down approaches, which have the disadvantage that they are not able to model policies that address particular technology parameters like the thermal efficiency of buildings. One disadvantage, however, of the bottom-up approach is the high need for very detailed data. While we were generally able to fill all required model input parameters with sufficiently reliable data, room for improvement certainly remains. Sometimes even data sources differ from one another as it is the case with the number of households.

Nigerian Energy Efficiency Standards and Labels Initiative: Progress So Far and Lessons Learnt

Etiosa Uyigue, Jason Yapp, Benoit Lebot and Muyiwa Odele

United Nations Development Programme

Abstract

With support from the Global Environment Facility (GEF), the United Nations Development Programme (UNDP) in collaboration with relevant government agencies has commenced the implementation of a project in Nigeria. The overall objective of the Project is to improve the energy efficiency of selected end-use appliances used in residential and public sector in Nigeria through the introduction of appropriate energy efficiency policies such as standards and labels (S&L) and demand-side management programs. Such interventions will help to reduce Nigeria's energy-related CO_2 emissions by reducing the demand for energy (electricity). An understanding of the national level of efficiency of targeted appliances is imperative to establish the baseline for Minimum Energy Performance Standard (MEPS) in any country. This initiated the end-use monitoring study across the six geopolitical zones of Nigeria to assess the current level of energy efficiency of selected appliances (lighting, refrigerators and air conditioners). A total of 200 households were monitored during the study. The household volunteers were selected at random and based on income status. Data logger devices such as serial wattmeter, wattmeter with ammeter pliers, lamp meters and temperature sensors were used to collect energy related data over a period of one month (30 days) from each household. This paper will present the preliminary report of the study in Abuja while comparing data with other countries where similar studies were done. The paper will also enumerate the challenges and lessons learnt in the process of introducing standards and label to transform the appliance market in Nigerian.

Introduction

With a population of well over 160 million people, only about 40% of Nigerians have access to electricity. In places where there is access to electricity (mainly in the urban areas), consumers of electricity suffer from frequent power outages that last for several hours. The survey conducted in three large cities in Nigeria – Abuja, Lagos and Benin City revealed that over 80% of those interviewed do not get electricity supply for up to 24 hours a day (CREDC, 2009).

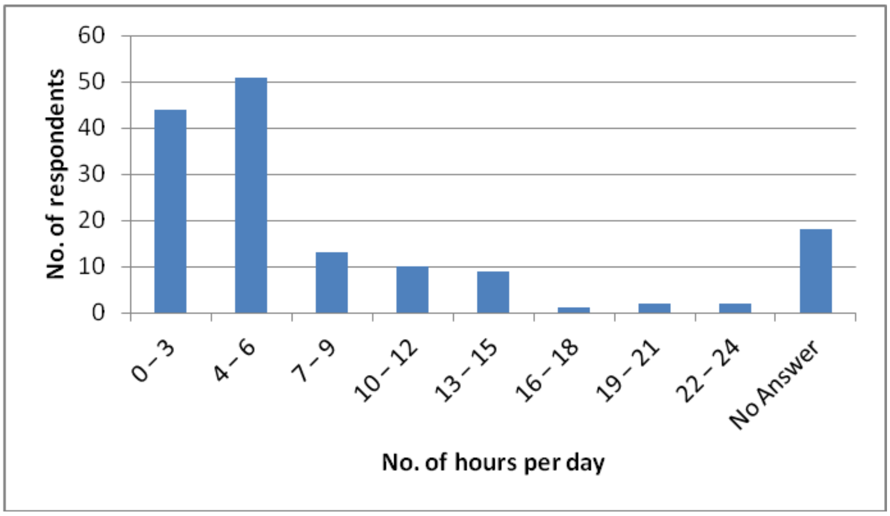

Fig. 1: The numbers of hour respondents get electricity per day

It was reported in 2012 that Nigeria reached grid generating capacity of about 4,477.7 MW of electricity (Daily Times, August 15th, 2012); this capacity however fluctuates for reasons such as shortage of gas supply, lack of maintenance, technical hitches etc. Apparently, this is grossly inadequate for the Nigerian population, which is about 25% of the population of sub-Sahara Africa. The unstable and inadequate power supply have forced a large portion of the industry, businesses and households to rely on diesel and petrol generators as primary or back-up source of electricity. This is expensive and a source of noise and air pollutions. More also, a large part of the energy generated is wasted due to the wasteful behaviour and the use of energy intensive technologies.

Energy consumption contributes to about 25% to 30% of energy-related CO_2 emission, accounting for 26% of all anthropogenic CO_2 emission and 14% of global net contribution to climate change from greenhouse gases (Wiel, 1998). Energy efficiency programmes/projects are ways that have been identified to reduce the impacts of energy generation on the fragile environment and at the same time increase access to electricity. Moreover, energy efficiency will play a pivotal role in the mitigation of climate change as asserted in the Fourth Assessment Report (AR4) of the Intergovernmental Panel on Climate Change (IPCC). Energy efficiency measures have the potential to promote economic development and can lead to job creation and create opportunities for savings of personal income. The efficient use of energy will help to reduce family energy bill. It will avoid the need to build more power stations, thus the money saved could be spent on other sectors of the economy and the energy saved will make it possible for more people will have access to energy.

It is against this background that the United Nations Development Programme (UNDP) with support from the Global Environment Facility (GEF) and in Collaboration with the Federal Ministry of Environment (FME), the Energy Commission of Nigeria (ECN), and the National Centre for Energy Efficiency and Conservation (NCEEC) commenced the implementation of a project to promote energy efficiency best practices in Nigeria. The overall objective of the Project is to improve the energy efficiency of selected end-use appliances used in residential and public sector in Nigeria (refrigeration appliances, air conditioners, lighting, electric motors, etc.) through the introduction of appropriate energy efficiency policies and measures, such as standards and labels (S&L) and demand-side management programs. The project is to reduce Nigeria's energy-related CO_2 emissions by reducing the demand for energy (electricity) in the country's residential and public sectors through the introduction of energy labels and minimum energy performance standards (MEPS) for new equipment and appliances (UNDP GEF, 2011).

The on-going UNDP GEF project will assist the Nigerian government to set MEPS for selected appliances. MEPS are useless if there are no mechanism and facilities to enforce them. Consequently, the Project will assist the Nigerian government in the area of enforcement of energy efficiency policies and laws by helping to set up testing centres in Nigeria to test the energy efficiency of appliances. The project is also designed to create awareness to change behaviour and build the capacity of relevant stakeholders in the country to promote energy efficiency. The objective of this paper is to share the progress made so far as well as share the success stories and lesson learnt. The paper will give the preliminary report of the end-use energy monitoring study which was conducted in the six geopolitical zones of Nigeria. The study is on-going, thus the paper will present the report of the study that was conducted in the Federal Capital Territory, Abuja to represent the North-Central Geopolitical Zone of Nigeria. The data collected will be compared with data collected in other part of the world where similar study has been carried out.

Methodology for the Study

The locations for metering study were assigned to six geopolitical zones of Nigeria– from Abuja (North Central), Sokoto (North West), Bauchi (North East), Benin City (South South), Nsukka (South East) and Lagos (South West)- (see figure 2 below). As part of the study, a total of 200 households were monitored and surveyed, an average of 35 households from each of the six geopolitical zones of Nigeria. Another 20 households will be monitored continuously for 12 months to study seasonality impact. The criteria for choosing households included the size of the family and the socio-economic status such as the income level. A total of 35 households were monitored during the study in Abuja. The data logger devices were used to collect data for a period of one month (30 days) from each household. The baseline data of each household were recorded that included name, address, annual income, family size, age and type of appliances, size (volume capacity), energy rating on the nameplate (where exist) and brand/made.

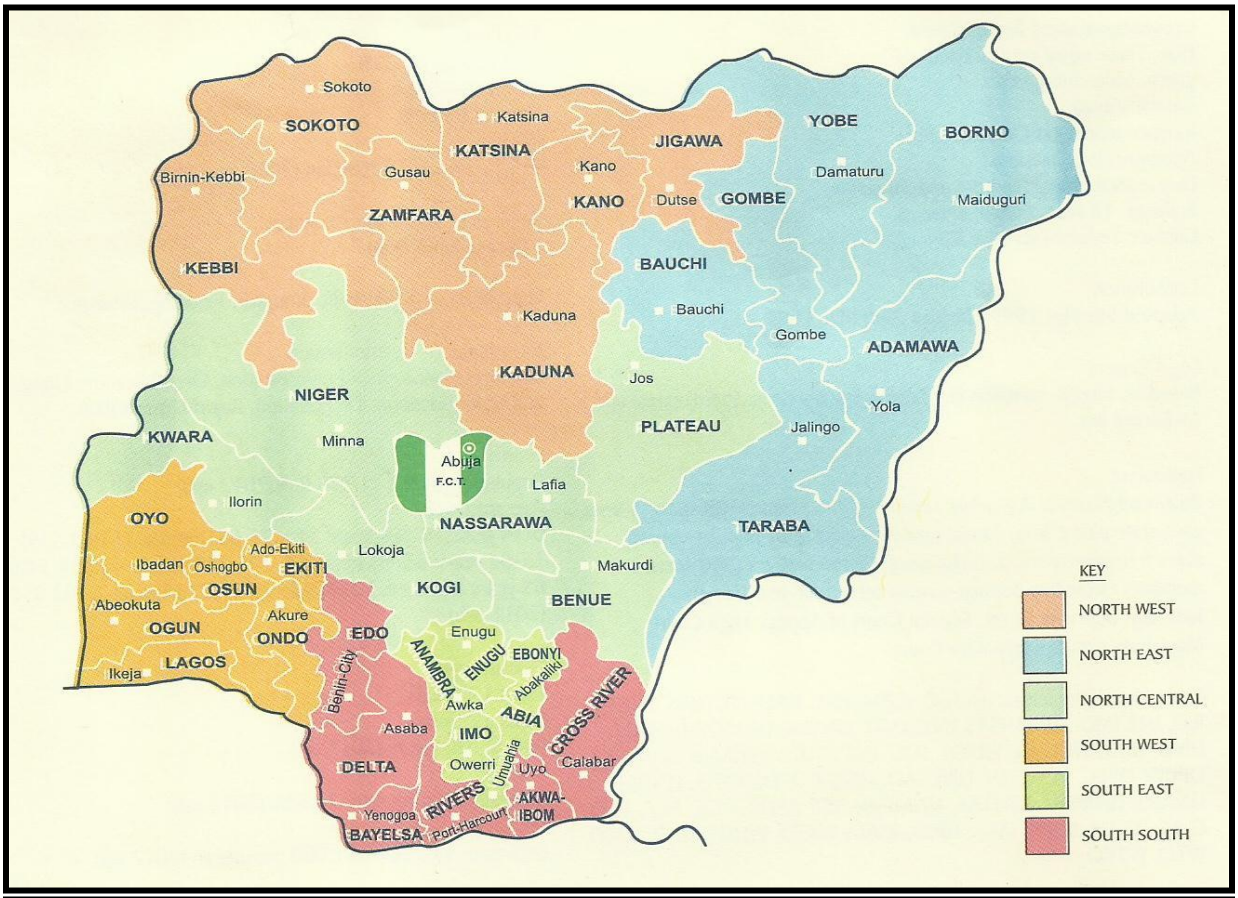

Figure 2: Map of Nigeria showing the six geopolical zones

The study team collected data using different electronic data logger devices. Data logger devices are portable devices used to directly measure electric consumption of different appliances. Three different data loggers were used for monitoring during the study. They included a *serial wattmeter,* which was designed to measure the active energy and voltage for single-phase appliances with power level lower than 2.6 kW. The device was placed in serial between the standard socket-outlet (designed to accommodate voltage from 0-250 V) and the plug of the appliance to be measured. The *serial wattmeter* can be left in place several months according to the frequency of the selected data memory - memory can record data for up to 13 months. At the end of the measurement period, the data recorded were uploaded to a computer for analysis using the Oscar software. The Serial Wattmeter was used to collect data from refrigerators and lighting equipment that are plugged to wall sockets.

The other equipment used was the Multivoies (multichannel) meter device, that is designed for the measurement of a large number of channels of power consumption and energies from electrical switch boxes. It includes a Din rail mounted concentrator to measure voltages and supplied power to the system, and several modules equipped with current sensors. The memory of the Multivoies can collect data for up to 4 months. If recording is required for more than 4 months, the device can be reset to collect more data. The Multivoies system can interface with Personal Data Assistant (PDA) using infrared communication or low power radio (Bluetooth). The Multivoies meter helped to collect the total consumption from the household, energy consumption from air conditioners and lighting equipment that are not connected to wall socket.

The third equipment was the electronic thermometers, that were installed in all the houses monitored to provide information on the temperature changes during the time of measurement. The thermometer is an autonomous electronic data logger of reduced size provided with temperature sensor. It takes regularly measurements and stores at selected time steps the average of several measurements (2 minutes interval between each measurement). The thermometer has a very broad range of measurements (-50°C to 120°C). The data are stored in a non volatile memory of strong capacity (64Ko) allowing a recording going up to 65,000 measurements (1 byte per data, for an autonomy of approximately 1 year and 3 months for recordings with the step of 10 minutes).

Result of Study

Only preliminary results are presented here to illustrate the types of data that could be collected and presented. Out of the 35 households monitored during the study in Abuja, 18 of them had air conditioners installed in them. From Fig. 3 below, the highest energy consuming air conditioner was recorded as 3,307 kwh/annum while the lowest was approximately 92 Kwh/annum to give an average of 1387 kWh/annum.

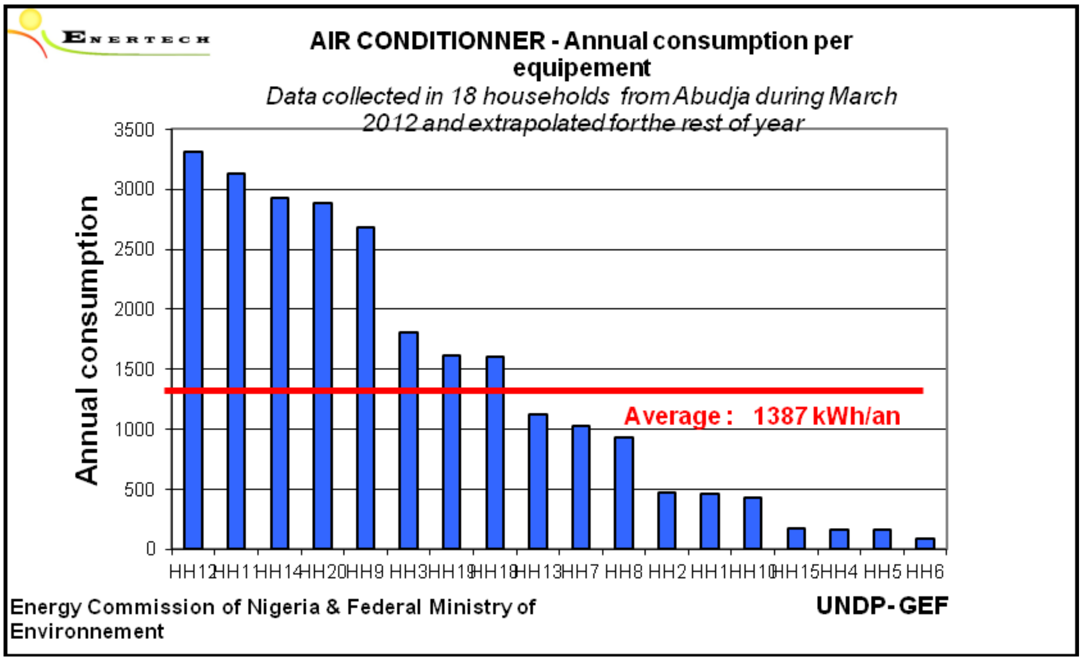

Fig 3: Annual consumption of air conditioners monitored in Abuja

Many of the houses monitored had one or more of the following appliances – fridge-Freezer (having both a fridge and freezer compartment), Fridge (only fridge compartment) and freezer (having only freezer compartment). A total of 13 households had fridge-freezer cooling systems. The average annual consumption for fridge-freezer was recorded as 698 kWh/annum; the highest consumption was recorded as 1230 kWh/annum while the lowest was 427 kWh/annum.

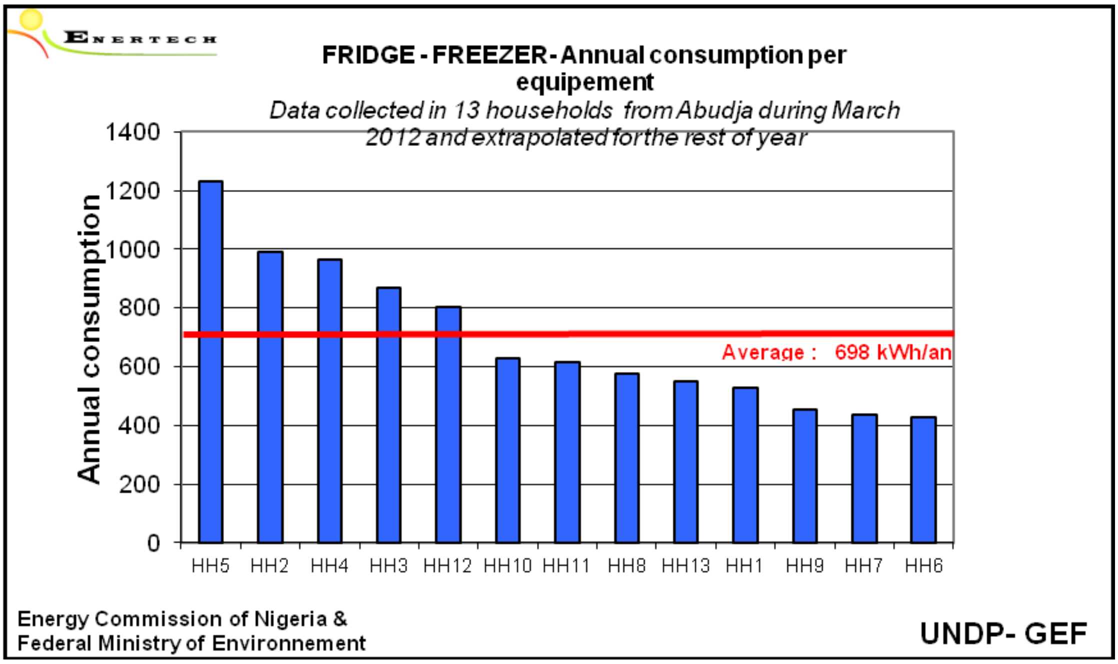

Fig. 4: Annual consumption of fridge-freezer monitored in Abuja

Freezers (popularly called deep freezers) were found in 16 households out of the 35 households monitored. The average annual consumption for freezers was 756 kWh/annum, the highest consumption was approximately 1318 kWh/annum, while the lowest was 212.50 kWh/annum.

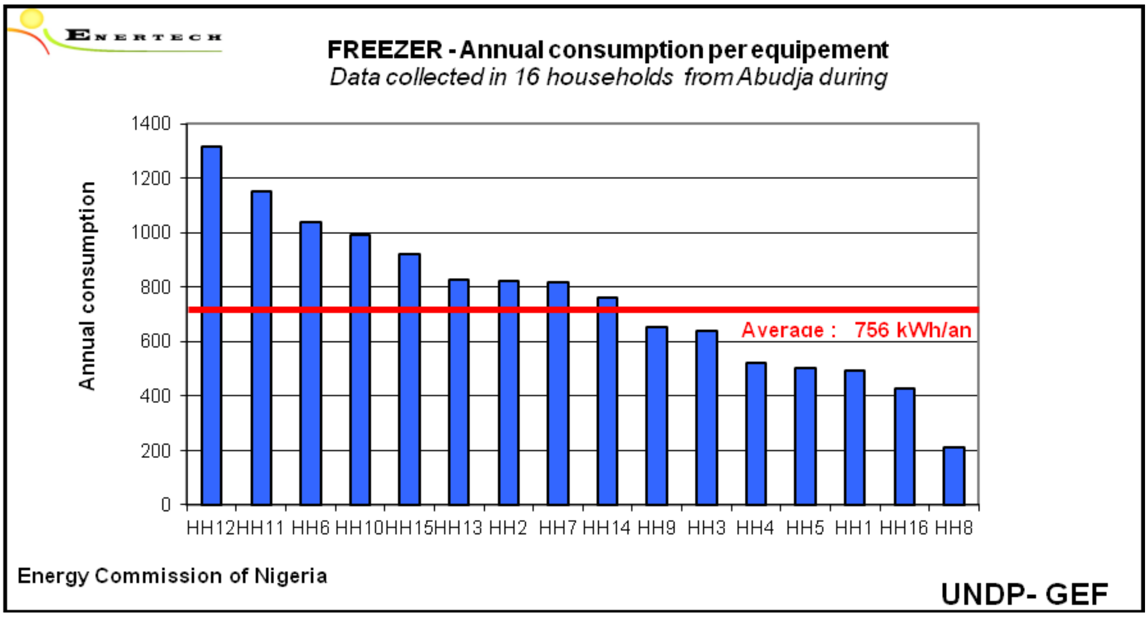

Fig. 5: Annual consumption of freezers monitored in Abuja

Sixteen (16) fridges were monitored during the study and the average annual consumption for was 420 kWh/annum; the highest reading was 941 kWh/annum and the lowest was 125 kWh/annum.

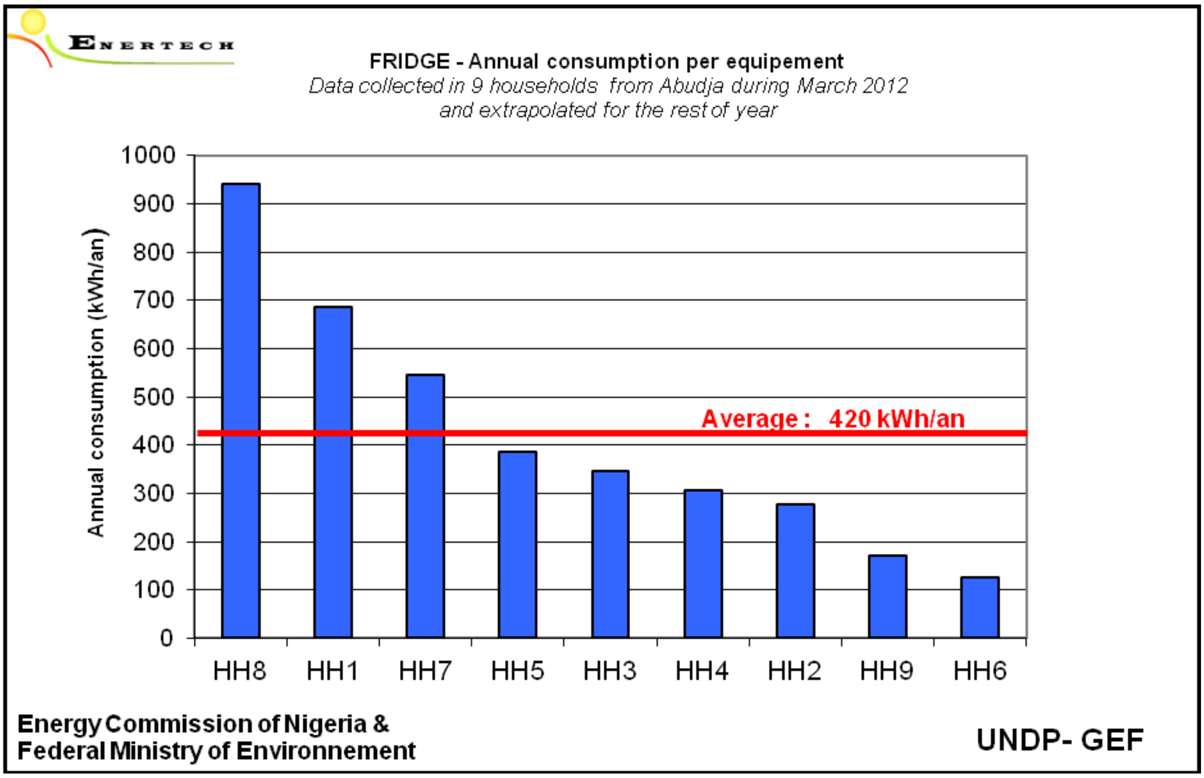

Fig 6: Annual consumption of fridges monitor in Abuja, Nigeria

Challenges and Lessons Learnt

The study in the Nigerian Federal Capital Territory revealed that the energy consumption of appliances is still very high compared to countries where effective energy efficiency measures had been put in place. Similar studies have been carried out in France (2007), Sweden (2007) and England (2011). Compared to these countries in, the average annual consumption of fridges, fridge-freezers and freezers in Nigeria is the highest. The lowest records were for these appliances were in England in 2011.

Table 1: Average annual consumption for Nigeria and European countries

	Annual consumption per equipment (kWh/an)		
	Fridge	Fridge-freezer	Freezer
FRANCE 2007	253	460	556
SWEDEN 2007	225	469	470
ENGLAND 2011	162	427	344
NIGERIA 2012	**420**	**698**	**756**

Table 1 above also revealed that the average annual consumption for cooling appliances in European countries decreases with time. From the study conducted in France in 2007, the average annual consumption of fridge, fridge-freezer and freezer were 253, 460 and 556 kWh/annum respectively. The study conducted in England in 2011 (about four years after the study in France) reveal a considerable fall in the annual energy consumption of domestic cold appliances. This may be as a result of several energy efficiency measures such as standard and label which have been introduced in many European countries. From the study in France (2007) and the study in England (2011), there was 36%, 7% and 38% decrease in average annual consumption for fridges, fridge-freezer and freezer respectively.

These preliminary study in Abuja (2012) compared to the study in England (2011) revealed that the average annual consumption recorded in the current study are significantly higher than that recorded in England (2011). For instance, the study revealed that the average annual energy consumption for fridge, fridge-freezer and freezer for Nigeria was 61%, 39% and 54% respectively higher compared to the study in England. This call for the need to embark on energy efficiency programmes in Nigeria. This further justifies the objective of the on-going UNDP GEF Nigeria Energy Efficiency Programme, on the need to introduce measures to promote energy efficiency in end-use appliances.

The on-going UNDP GEF project is positioned to transform the Nigerian market and lay the foundation for developing an energy efficient culture in Nigeria. To develop and implement an effective and efficiency standard and labelling programme will require collaboration between different agencies of government and stakeholders. For instance, the Standard Organization of Nigeria has the mandate within the national law to develop and enforce standards. The enforcement of appliance standards will not be possible without the involvement of the Nigerian Custom Services, having the mandate to protect the Nigerian border from substandard and unaccredited goods.

One of the challenges encountered so far in developing the S& L initiative in Nigeria was bringing all actors to the ‘table’ to pursue one course. To address this, the project implementation has adopted the bottom-top approach where the project activities were driven by stakeholders who will be directly affected by the policy. Through adequate consultation and capacity enhancement, the Project received the support and buy-in of state and non-state actors, most especially the central government in Nigeria; this has been a major achievement in this project. The Project Team aligned with relevant state and non-state actors to execute the various activities of the project.

CONCLUSION

These preliminary results has clearly demonstrated the benefits of using metering study for the monitoring of the electricity consumption of selected appliances in the households based on different income groups in Nigeria. The choice of equipment chosen did not only allow continuous monitoring but allowed huge amount of baseline data to be collected and stored. These baseline data are currently being analysed in detail and a full report will be available in September 2013. These results will subsequently be used for the designing of the MEPS for lighting, AC and refrigerators.

Effects of Appliance Standby Electricity Consumption on Turkish Residential Electricity Sector

Mustafa Cagri Sahin, Gul Nihal Gugul, and Merih Aydinalp Koksal

Hacettepe University

Abstract

Turkey's rapidly growing population and economy have resulted in a rapidly growing demand for energy, especially for electricity. Currently, residential electricity consumption has the second highest share and accounts for about 25% of the national electricity consumption. The increase in residential electricity consumption is mainly due to the increase in household income levels and decrease in the costs of household appliances which resulted in a dramatic increase in appliance ownership in recent years. There is very limited number of studies on residential electricity consumption, and there is currently no study on residential end-use and specifically standby electricity consumption for Turkish households. Studies on standby electricity consumption conducted in many other countries show that standby electricity consumption accounts for about 7 to 15% of the total household electricity consumption. Thus, the objective of this study is to determine the standby electricity consumption of urban Turkish households, which is carried out by conducting surveys and standby power measurements at 260 households in Ankara, Turkey. Among 260 households, 1746 appliances with standby electricity consumption are determined and their standby powers are measured; and type, power, and hourly usage information of 3423 bulbs are gathered. The average household active appliance, standby appliance, and lighting electricity consumption and associated CO_2 emissions are estimated as 2448, 95, 209 kWh/year, and 1021, 45, and 100 kg CO_2/year, respectively. It was also found that standby electricity consumptions of the households accounts for about 4% of the total household electricity consumption, whereas active appliance and lighting end-uses account for 88 and 8% of the total, respectively.

Introduction

Research on determining the electricity consumption of household appliances that were either switched off or not performing their main function started in early 1990's [1,2,3]. Standby electricity consumption (SEC) is the best known and widely used term for this type of residential electricity end-use. Many more studies are later conducted to determine SEC consumption of various new and stock household appliances [4,5,6,7,8,9,10], amount of household and national SEC and/or standby power [11,12,13,14,15,16,17,18,19,20,21,22,23], and associated CO_2 emissions [21,24]. Due to the increasing trend in electricity consumption of standby end-use, many countries and non-governmental bodies have taken steps to reduce standby power of new appliances in the market, such as implementing appliance energy efficiency standards and labels [25,26,27,28,29,30,31,32]. The effects of these steps in reducing the household and national electricity consumption, electricity expenditures, and associated CO_2 emissions are also studied by many researchers [9,10,12,14,20,33,34].

The share of residential sector in total electricity consumption has been increasing and currently accounts for about one fourth of the total electricity consumption in Turkey. The residential electricity consumption was 1.0566 TWh and 14.5% of the total consumption in 1970 and increased by about 10% per year to 41.4107 TWh and became 24.1% of the total in 2010, whereas the national electricity consumption was increased by about 8% per year in this period [35].

Due to the significant increase in per capita income levels from €4805 in 1990 to €12,046 in 2010 [36] and decrease in the costs of household appliances; new appliance purchases have increased from 2.8 million in 2002 to 6.18 million in 2010 in Turkey [37]. As the number of appliances increases, the amount of electricity consumed by appliances at standby mode also increases. In a study that estimated the SEC of Turkish households using the bottom-up approach, Lebot et al. [24] assumed an average standby power of 10 W per household for Turkey for 1997. Also assuming that this standby electricity consumption is for 24 hours, the authors estimated that residential SEC accounts for 1.5% of the national electricity consumption in 1997. In another study conducted by International Energy Agency in 2001, the standby power estimate for Turkey is taken as 20 W, which increases the SEC share to 3% for 1997 [38]. Other than these studies, no other study has yet been conducted using either whole-house measurement or bottom-up approach to determine the amount and percentage of SEC for Turkish households.

In this study, the average standby power and electricity consumption of urban Turkish households are determined using whole-house measurements approach. Surveys and measurements are conducted at 260 homes in Ankara, the capital city of Turkey. The SEC fraction in the total household electricity consumption is also determined and compared with results of other whole-house measurements studies. These results are also extrapolated to the national urban housing stock to determine the reductions in national residential electricity consumption and total CO_2 emissions.

Methodology

Currently two approaches are used in determining the standby electricity consumption of the households, namely whole-house measurements approach or bottom-up estimates approach. The whole-house measurements approach mostly involves visiting a number of sample houses, conducting a detailed survey about appliances characteristics and occupant electricity consumption behavior, and measuring standby power of the appliances in the homes. The total household electricity consumption is calculated by using the data gathered while conducting the survey and billing data of the households. The standby power of the appliances determined from measurements is multiplied by the number of hours the appliances are left at standby mode, which was obtained from the surveys, to determine the SEC of the household. By using these information, the share of SEC to the total household electricity consumption is then determined.

Bottom-up estimates approach is used when detailed appliance saturation and appliance standby power data is available. In this approach, the appliance saturation data is multiplied by the average estimated appliance standby power and standby hours. This approach is mostly accurate for major appliances for which detailed saturation and power data are available; but not very accurate for minor appliances due to lack of saturation and power data , which actually constitute most of the SEC of the households [39].

The primary objective of this study is to determine average standby power and electricity consumption, and fraction of SEC to the total household electricity consumption for urban Turkish households using whole-house measurements approach. Thus, during house visits data on lighting and appliances of the household is documented, and all appliances with standby power are measured, where available (*i.e.* if the appliance is hard wired into the electrical system it is not measured, such as door bells, security alarms, intercoms, furnace/boilers fans). The standby power measurements are conducted with a true RMS power Extech 380803 power analyzer [40]. This is a dual range meter (0–200 and 200–2000 W) with 0.1 W resolution for the low range and 1 W resolution for the high range. The accuracy of the measurements is ±0.9% of reading + 0.4 W for the low range and ±0.9% of reading + 4 W. for the high range. The meter also has a built-in data logger, which can store up to 1012 readings during continuous data logging.

The standby power measurements of the appliances are conducted when the appliances are plugged to the power, not performing their main functions but can be activated or switched on by a remote control, can be performing some secondary function (e.g. could have a display or clock which is active in this mode), and in their lowest power consuming mode. This type of mode of the appliances is also called as “passive standby power” [41, 42].

The volunteer households for the whole-house measurements are identified mainly based on their household income levels, since income is the main contributor to the number of appliances owned by the home owners and the consumption levels of the occupants [49]. It is desired that the sample of this study would be a representative of the income distribution of the urban Turkish household stock so that the number of homes surveys in each income category will be similar. The other criterion is that these households do not use electricity for space heating. A survey with 45 questions and a section to tabulate the standby power measurements is prepared. The survey questions are prepared to get detailed information of the dwelling (house type, area, and ownership), occupants (income, age, education, gender, and “at home” profile), appliances (type, age, model, size, power, and usage) and lighting (power, number, type, and usage), consumption behavior (plug-off , turn off or leave the appliances at standby when not in use), and billing data.

In order to determine the total household electricity consumption, average electricity consumption of major household appliances are gathered from open literature based on their size, model, brand, age, *etc*. For example; the refrigerators are categorized based on their type (top or bottom freezer, single or two doors, etc.), volume, and age; and average annual electricity consumption for each category is determined from the web sites of local and international retailers and government agencies such as *Natural Resources of Canada* and *U.S. Federal Trade Commission*. The active appliance electricity consumption is calculated by summing the electricity consumption of all appliances in the household when they are performing their primary functions. The lighting electricity consumption of each household is determined by multiplying the power of each lamp with its usage (number of hours per day). Similar to the household lighting electricity consumption, SEC is determined by multiplying the standby power of appliance with the number of hours it is left at standby mode.

The total annual household electricity is then calculated by adding the lighting, active and standby appliance electricity consumptions. This estimated total annual electricity consumption determined using the survey and appliance consumption data is then compared with the billing data, where available.

The carbon emission factor for Turkey is taken as 476 kg CO_2/MWh, which is calculated by taking the fuel specific emission factors from [43] and 2011 electricity generation by primary energy resources data from Turkish Electricity Transmission Company [44]. The cost of electricity is calculated by using tariffs that were in use by April 2012 [45]. Detailed information on methodology of the study can be found in [46].

Results and Discussion

The results of the study are presented in two sections; namely appliance and household standby power and consumption statistics.

Appliance and Household Standby Power Statistics

A total of 1746 appliances with SEC are identified and measured in the surveyed 260 households which yields on average 6.7 appliances with standby power per household. The average standby power of various appliances measured at the surveyed households, appliance saturation levels (number of appliances in the surveyed homes divided by the number of surveyed homes) and average household standby power based on saturation levels are presented in Table 1.

Table 1. Appliance Average Standby Power, Saturation Level, and Household Standby Power Based on Saturation Level

Appliance	Average Standby Power, W	Saturation Level, %	Average Household Standby Power Based on Saturation Level, W
Satellite Receiver	7.7	106	8.1
CRT TV	4.8	154	7.4
Modem/Router	4.6	71	3.2
Plasma TV	4.3	9	0.4
Stereo Tape/ CD Player	3.6	27	1.0
Desktop PC	3.4	46	1.6
Home Audio System	3.2	23	0.7
Rechargeable Vacuum Cleaner	3.1	27	0.9
Laptop Computer	2.8	49	1.4
DVD, VCD Player	2.7	37	1.0
Printer/Scanner	2.6	18	0.5
Furnace Fan	2.6	44	1.1
Cordless Phone	2.4	64	1.5
Desktop PC Monitor	2.3	45	1.0
Water Cooler	2.3	4	0.1
Air Conditioner	2.1	3	0.1
Clothes Dryer	2.0	0	0.0
Dishwasher	2.0	7	0.1
Alarmed Clock	1.9	4	0.1
Radio	1.8	12	0.2
Oven	1.7	17	0.3
LCD TV	1.6	73	1.2
Game Console	1.6	4	0.1
Home Theater	1.5	4	0.1
Clothes Washer	1.5	8	0.1
Microwave Oven	1.3	8	0.1
LED TV	0.3	4	0.0
Total		-	32.2

As seen in this table, the satellite receivers have the highest average standby power values (7.7 W) and the CRT TV are the appliances with the highest saturation levels among the appliances measured in the surveyed homes. The average standby power for DVD players and receivers are found to be lower than the values stated in other studies [6,9,34,48], since DVD players are found in this survey were purchased by households in more recent years and exhibit lower standby power. The ranges of the standby power for the remaining appliances are similar to those reported in [6,15,17,34].

The average standby powers of the appliances are multiplied by the appliance saturation levels to determine the average household standby power. When these values are summed up, the average household standby power is calculated as 32.2 W, as presented in Table 1. This shows that the based on the saturation levels determined in this study, the average household standby power is 32.2 W.

The distribution of the household standby powers determined for 260 homes is presented in Figure 1. As seen here, the majority of the surveyed households have standby powers between 15 and 30 W, and the maximum value is 120 W. The geometric mean of this distribution is 22 W. As seen here and also based on Chi-squared and Kolmogorov–Smirnov tests, the distribution of these households presents a log-normal distribution. Thus, the average household standby power of these households can be taken as 22 W. The average household standby power was estimated as 20 W in a previous study conducted by IEA [38]. Thus, it shows that this estimate is close to the one estimated by EIA [38].

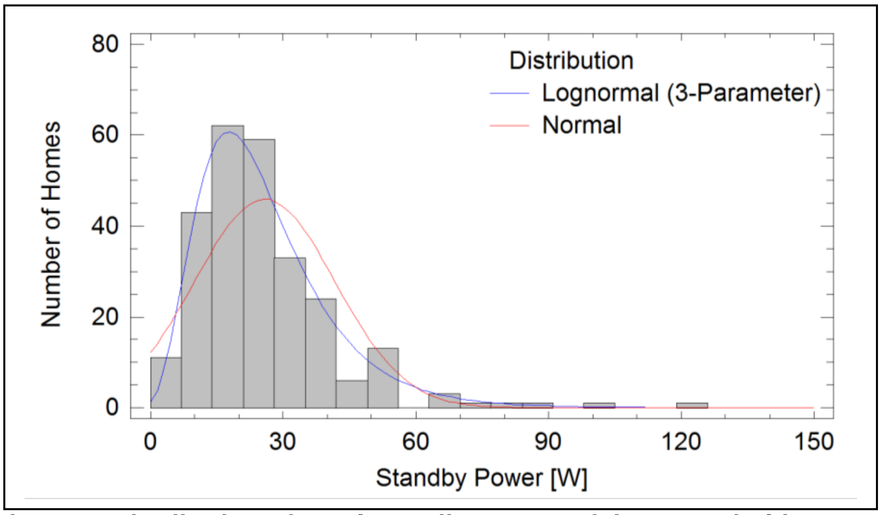

Figure 1. Distribution of Total Standby Power of the Households

The average household standby power and the number of surveyed in this study are presented together with the results of other studies based on whole-house approach in Figure 2. As seen in this figure, the average standby power estimated in this study presents one of the lowest values after the ones found for Romania and Argentina, where the household income levels are lower than the countries in which higher standby power results were obtained.

The whole-house measurement approach involves uncertainties mainly due to defining and measuring standby power. Each study has its own definition for standby power and conducts measurements based on the appliances that fit in their definition. Some studies included continuous and hard wired appliance standby loads, which resulted in higher estimate for the household standby power. In some studies, only major appliances are measured and smaller electronic appliances are ignored, which led to lower estimates of standby power [28], in addition to the effect of lower household income levels.

Among the appliances of which standby power measurements were conducted, 39% of them were used for entertainment, 20% used in kitchen, 20% used in home office, 10% used for communication, and 11% were used for other purposes.

Appliance and Household Standby Electricity Consumption Statistics

The factors that determine the amount of SEC of the homes are appliance standby power and saturation levels, and the amount of hours that these appliances are left at standby mode. As presented in the *Methodology* section, the SECs of the appliances are calculated by multiplying the appliances' standby powers and the numbers of hours the appliances are left at standby mode, which was obtained from the declaration of the occupants during the survey. Thus, the amount of hours the appliances left at standby mode is as important as the standby power of the appliances. The average number of hours of the various appliances left at standby mode, average appliance SECs, appliance saturation levels, and household SEC based on saturation levels are shown in Table 2.

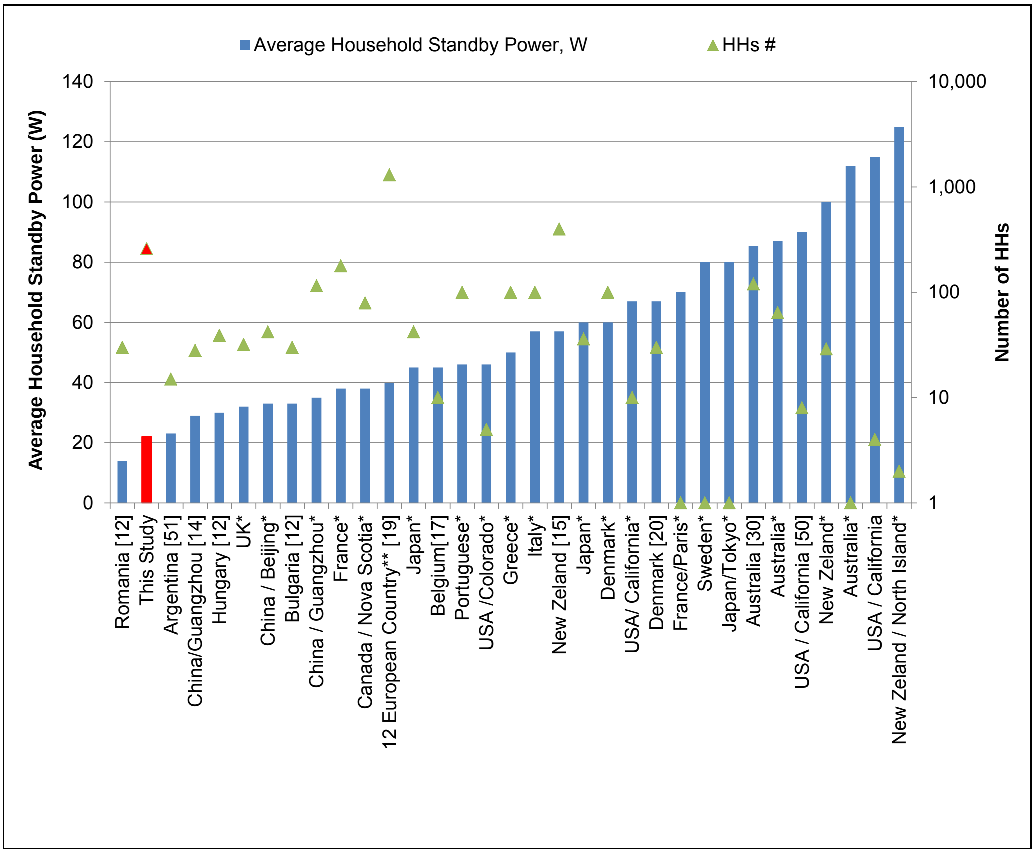

Figure 2. Household Standby Power (W) Results of Studies Based on Whole-house Measurement Approach

Based on the results presented in Table 2, the satellite receivers have the highest SEC in the surveyed homes, which also presented the highest standby powers. Their saturation level is second to that of CRT TV's. The SECs of the satellite receivers are found as 41 kWh/year, whereas their active electricity consumption is calculated as 38 kWh/year using the power and active usage hours data obtained during surveys. This shows that these appliances are left on standby more than they are actively used in a day and have very similar active and standby powers (2-3 W). Even though CRT TVs are one of the second highest standby powers, their SECs are not high due to their low standby usage (average 9 hours per day). This is probably because these old technology TVs are typically not the main TVs in the homes and have easy to reach on/off buttons. Thus the occupants can easily turn them off when not in use. Modems/routers have the second highest SEC among the appliances in the surveyed households with a saturation of 55%, and they are left on standby mode on average 16 hours per day. The average SECs of the appliances are multiplied by the appliance saturation levels to determine the average household SEC. When these values are summed up, the average household SEC is calculated as 156 kWh/year, as presented in Table 2. This shows that the based on the saturation levels determined in this study, the average household SEC is 156 kWh/year.

Table 2. Appliance Average Standby Power, Saturation Level, and Household Standby Power Based on Saturation Level

Appliance	Saturation Level, %	Avg. # Hours Appl. Left at Standby Mode, hours/day	Avg. SEC, kWh/year	Average Household SEC Based on Saturation Level, kWh/year
Satellite Receiver	106	15	41	43
Modem/Router	71	16	26	19
Rechargeable Vacuum Cleaner	27	21	23	6
Furnace Fan	44	23	21	9

Total			376	156

The distribution of the household SECs determined for 260 homes is presented in Figure 3. As seen here, the majority of the surveyed households have SECs between 50 and 150 kWh/year, and the maximum value is 1180 kWh/year. The geometric mean of this distribution is 95 kWh/year. As seen here and also based on Chi-squared and Kolmogorov-Smirnov tests, the distribution of these households presents more of a log-normal distribution. Thus, the average household SEC of these homes can be taken as 95 kWh/year. Using the emission factor for Turkish electricity sector given in *Methodology* section, the CO_2 emission associated with SEC for an average household is calculated as 45 kg CO2 /year. The cost of SEC for an average Turkish household is calculated as 18 USD/year.

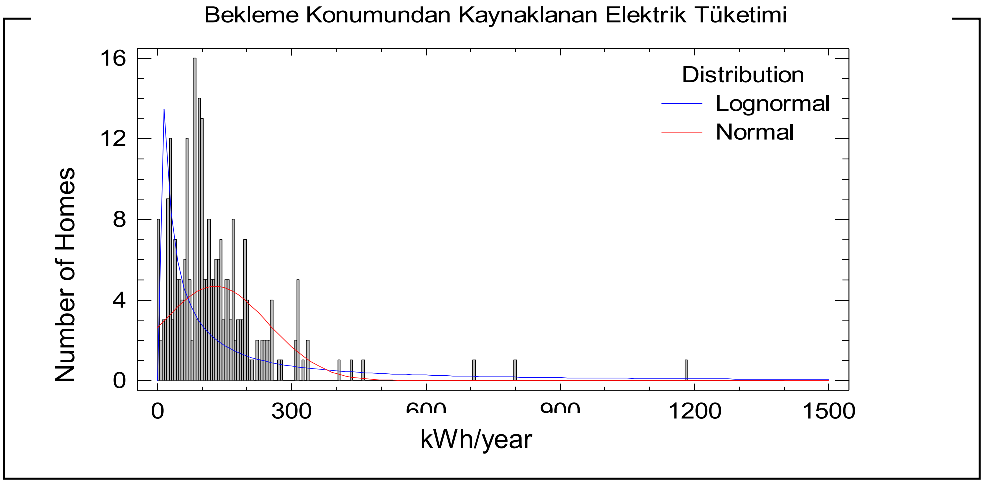

Figure 3. Distribution of Total SEC of the Households

The average household SEC and the number of surveyed homes in this study are presented together with the results of other studies based on whole-house approach in Figure 4. As seen in this figure, similar to average standby power results, the average SEC estimated in this study presents the lowest values after the SEC estimated for China [14]. The SEC results are low due to the electricity consumption habits of urban Turkish households. Most occupants of the surveyed household stated that they turn off or unplug their appliances when not in used for a safety measure to protect them against possible voltage fluctuations. This habit reduces the household SEC.

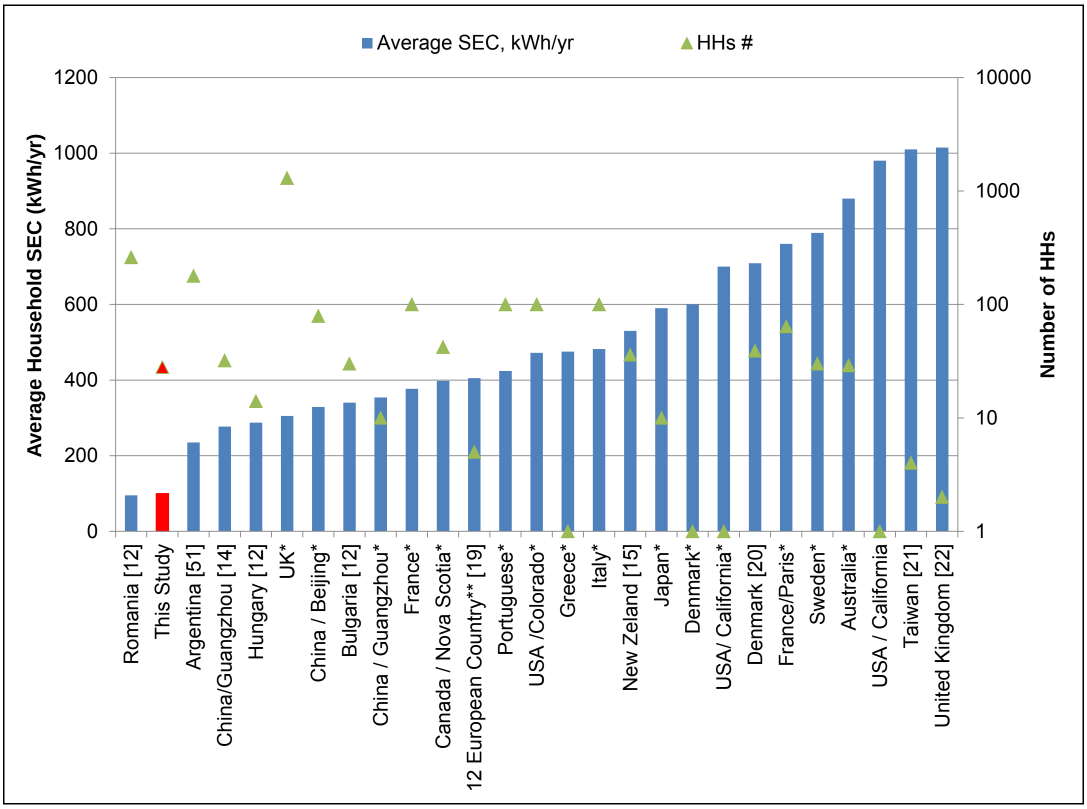

Figure 4. Household SEC (kWh/year) Results of Some Whole-house Measurement Studies

*Sources: [17,24,26,27,39]
**Belgium, Bulgaria, Czech Rep, Denmark, France, Germany, Greece, Hungary, Italy, Norway, Portugal, Romania

The lighting and active appliance end-uses are calculated for each household and summed with the SEC to determine the fraction of SEC in the total household electricity consumption. The average annual household end-use and total electricity consumptions, costs, CO_2 emissions, and their distributions are presented in Table 3. As seen here the average household SEC is 4% of the total household electricity consumption for the surveyed households.

Table 3. Appliance Average Standby Power, Saturation Level, and Household Standby Power Based on Saturation Level

End-use	Consumption, kWh/year	Cost, €/year	CO_2 Emissions, kg/year	Distribution, %
Standby	95	13	45	4
Lighting	209	29	100	8
Active	2144	295	1021	88
Total	2448	337	1166	

The number of urban households is determined as 22,278,548 in 2011 for Turkey [47]. Using the average SEC per household results, the amount of electricity and associated CO_2 emissions from the appliances left at standby at all urban households in Turkey can be estimated as 2116 GWh (5% of the total electricity consumed in Turkish residential sector in 2011 [35]) and 1003 thousand tons, respective (1% of the electricity generation associated CO_2 emission in 2009 [43]). The cost of this end use accounts for about 305 million € based on 2012 electricity tariffs in Turkey [44]. The amount of electricity estimated for standby end-use is very close to the amount of electricity generated in 2011 at Kangal Power Plant which uses lignite as fuel [44].

Conclusions

In this study, to the authors' knowledge for the first time, average standby power and SEC of urban Turkish households, and the fraction SEC in the total electricity consumption are determined using whole-house measurements approaches. The study is conducted by surveying 260 homes in Ankara, Turkey. A total of 1746 appliance standby power measurements are conducted, which makes about seven appliances with standby power per household. The satellite receiver was found to be the appliance with the highest average standby power and also SEC due to its high saturation and standby hours. The average total household standby power, SEC, and SEC fraction of the total household electricity consumption are determined as 22 W, 95 kWh/year, and 4%, respectively. The standby power found in this study is higher than the value estimated for Turkey [38], but lower than majority of the other national/regional values. It is difficult to compare the standby power and SEC estimates of the studies conducted using whole-house measurement approach since each study has its own standby definition and measurement protocol. The amount of electricity that is used by appliances left at for standby mode at urban households is estimated to account for almost 5% of the total electricity used in the residential sector in 2011 and close to the amount generated by a single lignite power plant.

Encouraging public support for smart metering through demonstrating energy saving potential of appealing home energy management

Author

Henk van Elburg

NL Agency

Abstract

Backed by raising energy demands, volatile oil prices and threat of climate change, smart metering is rapidly gaining momentum in Europe. Although considerations for large scale rollouts take place in many EU member states, public support and energy saving success should not be taken for granted. Smart meters only enable consumer satisfaction and energy efficiency if they come publicly undisputed and in the company of empowering energy feedback services. *This paper analyses the European progress on the implementation of smart metering and feedback services in general and elaborates in particular on the efforts in the Netherlands to win public support for smart meters and prove the energy saving potential.*

Following the United Kingdom (EDRP) and Ireland (CBT), the Netherlands is today the third EU-Member State to perform a set of large and scientific designed consumer live trials across the country involving more than 10000 households to deliver evidence for the energy saving potential of smart meters in combination with several kinds of innovative energy management systems and services. These trials will deliver input for the upcoming decision in Dutch parliament on how to proceed with the large scale rollout of smart meters between 2014 and 2020. *NL Agency will provide EEDAL 2013 participants a preview of the monitoring results of the trial programme and share practical lessons on the experience and expertise of relevant (market) actors.*

Introduction

Backed by rising energy demands and fears over security of supply and climate change, smart metering is rapidly gaining momentum across the world. Europe is expected to become a world leading centre of this development, thanks to the European Services Directive (ESD), Third Energy Package and Energy Efficiency Directive (EED). The 2006 Energy Services Directive laid the foundation for a European wide legislation for smart metering, by requiring individual energy meters and standards for frequent and understandable energy bills. The 2009 Third Energy Package accelerated the penetration of smart electricity metering in EU by setting a target of at least 80% of all households to have a smart meter by 2020, given a positive economic assessment. Finally, the 2012 Energy Efficiency Directive connected smart meters directly to dynamic pricing and improved feedback programs and strengthened smart meter and consumer feedback regulation.

Although considerations for large-scale smart meter rollouts take place in a growing number of Member States, public support and hypothesized energy savings should not be taken for granted. Experiences in the Netherlands demonstrate that smart metering can only contribute to increasing consumer involvement and enable effective household energy savings if smart meters are publicly accepted and accompanied by empowering energy management services. Without meeting such preconditions, rollout and energy efficiency prospects will be much more uncertain.

By elaborating on these experiences in the Netherlands, this paper could provide practical lessons for stakeholders from other Member States who also face public reluctance with the imposition of smart meters. Additionally, the solution adopted in the Netherlands to learn together with relevant stakeholders and subsequently arrive at better policy proposals that also acknowledge end-user needs and ensure more promising prospects for energy savings, could help other Member States to develop regulatory frameworks that are more likely contribute to consumer satisfaction and increased energy efficiency.

This paper starts with a brief introduction on smart metering and a short European wide overview of Member States where large-scale smart meter penetration are already underway or being considered. This overview is extracted from the new European Smart Metering Landscape Report (2nd ed.), a deliverable of the SmartRegions project. SmartRegions, funded by Intelligent Energy Europe, focuses on promoting innovative smart metering services, such as informative billing and feedback, variable tariffs and load control services that offer most potential to bring about energy savings and peak load reduction. The SmartRegions project aims to inspire and encourage energy utilities, energy service providers as well as law makers across Europe to initiate the development of effective smart metering policies and innovative smart metering services by:

1. Monitoring the smart metering landscape in European countries and giving recommendations for regulatory frameworks.

2. Defining best practices for innovative smart metering services by analyzing their economic, environmental and social costs and benefits.

3. Promoting best practices for innovative smart metering services and exemplary smart metering regions as models for other Member States and regions.

The new European Smart Metering Landscape is a comprehensive rollout report on smart meters and metering services in Europe, including in-depth country profiles of all EU Member States and Norway together with case studies of related services for consumer feedback and peak-load shifting[1].

The main section of the paper elaborates on the experiences in the Netherlands, associated with intense political discussions in the past and defining the most important causes. The paper concludes with a brief overview of the actual situation and the upcoming trend of performing national scientifically designed live trials to deliver evidence for the smart metering energy saving potential and ensure a more (cost-) effective rollout.

Smart metering characteristics and European overview

Traditional meters provide less than perfect information for both consumers and suppliers. Consumers are generally only aware of consumption on a monthly, or even annual, basis, unless they make time-consuming efforts to monitor the readings on their meters frequently. Also, most suppliers only know how much energy a household consumes after a manual meter read. In addition, difficulties arising from limited data accuracy may cause disputes over bills, thereby possibly also hindering switching between suppliers and limiting market competition.

Smart meters eliminate many of these issues for consumers and suppliers by adding two dynamic key features to the functionality of the static traditional meter:

1. Storage of accurate metering data at specified time intervals.

2. Two-way communication between the consumers' smart meters and the operating system of the network operator / supplier.

By integrating storage capacity and communication technology, the smart meter allows for a radical change in customer-utility relations. In conjunction with smart technology, utilities can adopt pre-pay or innovative time-of-use pricing plan options to incentivize customers to use power more wisely.

---

1 The European Smart Metering Landscape Report can be downloaded free of charge from the project's website www.smartregions.net.

Smart meters also enable consumers to track their usage in real-time and better understand their power habits via in-home display units, web-based interfaces or both.

The benefits from a rollout of smart meters potentially fall to all actors:

1. To consumers in terms of more frequent and more accurate bills, (near) real-time information to enable household energy savings and facilitation of new energy services.

2. To suppliers in terms of more frequent and accurate information and reduced operational costs.

3. To network operators in terms of more efficient network operation and capacity control.

4. Finally, to society in terms of a better functioning energy market and reduced carbon emissions.

Smart meters also pave the way for smart grids, an allied tool to help utilities to balance loads across their electricity networks and help consumers to manage their energy demand more effectively. Smart grids integrate the actions of all users connected to an electricity power system, employing communications, innovative products and services, and intelligent monitoring and control technologies to:

1. Help utilities to efficiently manage the full array of power generation assets, including traditional generation facilities and renewable sources such as wind turbines, to meet customer needs.

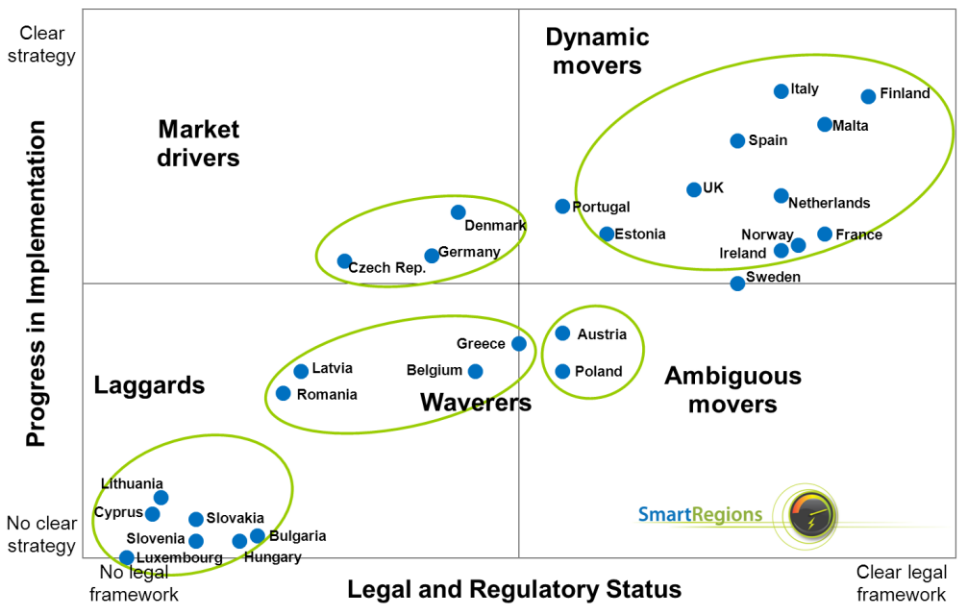
2. Provide consumers with more information about their own usage and peak demand so they can adjust their behaviour.

3. Reduce the environmental impact of power generation through incentivizing customers to reduce electricity use and/or shift electricity usage from peak to off-peak hours to avoid running costly fossil-fuelled peak generation units.

European overview

Due to legislation such as the Energy Services Directive and the 3rd Energy Package, a majority of the countries in Europe already have, or are about to implement a legal framework for the installation of smart meters. However, the topic continues to generate heated discussions in the individual EU member states. The Landscape Report 2012 depicts the developments in each country and shows the relative advance in respect of the topic of smart metering. These different approaches in the Member States are represented through the classification in the following categories: dynamic movers, market drivers, ambiguous movers, waverers, laggards.

Countries such as Estonia, Finland, France, Ireland, Italy, Malta, Netherlands, Norway, Portugal, the United Kingdom, Spain and Sweden are "dynamic movers". Most of them have already decided on a mandatory rollout with a specified timetable. "Market drivers" such as Germany, the Czech Republic and Denmark have not established legal requirements for a full rollout. There are the obligations for the introduction of smart metering only for a certain category of customers, e.g. in newly built houses and renovated houses. Nevertheless, utilities go ahead with the installation of smart meters either because of internal synergetic effects or because of customer demands. The situation in Austria and Poland can be characterized as “ambiguous”. Although significant progress is visible, there are still some important decisions lacking. In the countries called "waverers", first initiatives and pilot projects for the introduction of smart meters have been launched. In the "laggard" countries smart metering is not yet a focus. The following illustration provides an overview of the legal and regulatory situation and the implementation status in the EU countries and Norway.



Smart metering regulation in the Netherlands

The Netherlands is the first EU Member State to opt for a voluntary-based rollout of smart meters to obtain widespread consumer involvement and effective household energy management. In order to understand the argument for a voluntary-based rollout as an equally effective alternative for a mandated rollout, the course of events in the Netherlands will be chronologically presented and analyzed in more detail.

Chronological overview

In the Netherlands the smart meter rollout is part of a broader new energy market model for consumers and small business users. Apart from the desire to correct and avoid administrative problems following the liberalization of the Dutch energy market in 2004, other main drivers were to stimulate competition in the energy market, i.e. easy switching for consumers between suppliers, improve operational efficiency for market parties and support energy savings for end-use customers. Demand response related objectives, such as dynamic pricing to avoid peak loads, are not important because of the temperate climatic conditions. The Dutch tariff system is based primarily on fixed rates. Except for national reasons, the legal rollout was also designed to simultaneously meet the requirements of the European Energy End-use and Energy Services Directive (ESD).

The original plan: mandated rollout of smart meters.

In 2008, the Dutch government presented a first legislative proposal to bring the smart meter under the responsibility of network operators in the regulated domain in conjunction with a mandated rollout to all households. Following consultations in the market sector, the Ministry of Economic Affairs proposed the following meter market changes:

1. All small users will be given a smart meter.

2. The grid operators will be responsible for rollout. The grid operators will own and maintain the smart meter and be responsible for a total distribution.

3. The meters will become part of the regulated domain of the grid operator, being considered part of the physical infrastructure.

4. The cost of the hardware (meter rent) will be regulated.

5. The energy retailers will be responsible for all customer-related processes and metering data management.

6. The smart meters must comply with minimum functionality requirements and technology specifications to ensure cost-efficiency, interoperability.and consumer interests.

To meet the obligation arising from the above-mentioned ESD to provide regular feedback to consumers about energy consumption, the government stated a preference for setting a minimum frequency of 6 times per year (every two months).

The government proposed a mandated rollout as a prerequisite, because it was expected that a smart metering rollout in a liberalized market, without further regulation, would probably reach no more than about 30% penetration. In that case, several of the smart meter benefits mentioned above would not be realized.

The smart meter rollout will be partly funded from the current meter tariff. Also, the tariff will be stable in the first years of the rollout and will eventually be based on actual costs reduced by profits made in the first period. To date, the meter charge has not been regulated and has increased by up to 100% since 2001. The Dutch regulator (NMa) concluded in 2008 that there was no relation between the increased tariffs and actual costs and the meter costs should therefore be regulated.

In 2009, after an intense political debate, the Dutch Senate declined to approve a mandated rollout of smart meters because of privacy and security concerns. To solve the privacy issue, the mandatory rollout of smart meters was turned into a voluntary rollout. Furthermore, the revised proposal settled security concerns by introducing additional security guarantees.

Revised plan 2011: voluntary rollout of smart meters

In 2011 the Dutch parliament accepted a revised Electricity Act and the Gas Act, in which **network operators** (as the owners of the smart meters) are mandated to offer households and small businesses a smart meter with minimum functional and technical standards. Households and small businesses will have a legal choice to accept or refuse this meter. Legal customer options are:

1. The option to refuse the installation of a smart meter and keep the traditional meter.

2. The option to have a smart meter installed, or once it has been installed, the prerogative to opt out of sending meter readings automatically. As such, smart meter functions as a traditional meter, still requiring a meter reader.

3. The option to have a smart meter installed, with standard meter reading frequencies of which the most important are: final billing in case of switching energy supplier or moving house, once a year for annual billing and bi-monthly meter readings for additional energy advice in cost and consumption overviews.

4. The option to have a smart meter fitted, with full automatic smart meter reading.

The revised Dutch Electricity Act and the Gas Act also mandates **Energy suppliers** to provide consumers with bi-monthly cost and consumption overviews as a standard feedback service. Additional regulation has been developed to set out the minimum information requirements for these bi-monthly overviews. Providing consumers with more detailed smart metering feedback services for household energy management, such as displays and internet applications, are, however, considered to be a market responsibility without regulation. The customer is free to choose and authorize any commercial service provider offering (real-time) smart meter data services beyond the minimum regulated level. In order to give market players access to the measurement data, the network operators have set up uniform authorization and authentication procedures. These procedures ensure that individual measurement data is only used for the specific purposes for which the customer has given his or her consent.

With these legal revisions included, the national consumers' organizations and privacy campaigners expressed their contentment with the bill, assuring the freedom of choice for the consumer. After a two year delay, the Netherlands had a legal rollout scheme in place.

New cost-benefit analysis

The need to revise the legal proposal also required the Ministry of Economic Affairs to perform a recalculation of the original national cost-benefit analysis performed in 2005 regarding the business case for the introduction of smart meters in the Netherlands.[2] The two major changes that prompted a new cost-benefit analysis were:

1. The smart meter will only be read once every two months in the standard situation. Only if express and unequivocal permission has been obtained from the consumer a more detailed reading can be done. In the 2005 analysis, detailed reading was still the standard situation.

2. The consumer will have the option of refusing the smart meter. This means that the consumer in question will keep his or her traditional meter. In the case of new construction and renovations of houses and small buildings it is compulsory to install a smart meter, and there is no obligation to replace it with a traditional meter at the request of the consumer. In this case the consumer can have the smart meter treated like a traditional meter by registering it as "administratively off".

Considering a situation of almost 100% acceptance of the smart meter as well as almost 100% standard readings, the updated cost-benefit-analysis still showed a positive business case result of approximately EUR 770 million. The main benefits derive from the expected energy savings potential. Based on the analysis of previous national and international experiments and expert opinions, the average structural energy savings potentials are estimated at 3,2% for electricity and 3,7 for gas. Other beneficial items (in order of positive contribution) are savings on call centre costs, a lower cost level as a result of the market mechanism (increased switching) and savings in meter reading costs.

Two year experience phase: delivering proof for energy saving potential

Today, the Dutch smart meter rollout has started following a two-stage approach. From 2012 until 2014, a small-scale rollout is in place for experiential purposes. During the small-scale rollout, up to 500000 smart meters for electricity and gas will be installed in cases of regular meter replacements (e.g. depreciation), newly built houses, large scale renovations and on request by customers. Based on these experiences and learnings, the rollout will continue on a larger scale eventually offering every household and small business a smart meter. Despite the voluntary nature of the rollout, the target remains the same: the installation of a smart meter by at least 80% of households and small businesses by 2020, as mandated through the 3rd Energy Package.

Part of the small-scale experience phase is a set of large and scientifically designed consumer trials taking place across the country. Following similar national programs in the UK (EDRP) and Ireland (CBT), the Netherlands is now the third EU-Member State to perform such a series of consumer trials to deliver differentiated evidence for the energy efficiency potential of a wide range of smart metering-

---

[2] Prior to the original proposed changes in the Electricity Act and the Gas Act, which included a mandated rollout of the smart meter, a thorough cost-benefit analysis was conducted in 2005. This cost-benefit analysis, performed by KEMA by order of SenterNovem (now Agentschap NL), resulted in an expected positive business case of approx. EUR 1.3 billion(SenterNovem, 2005).

based feedback methods to contribute to balanced decisions favouring the future rollout of smart meters. To date, the Dutch monitoring program covers the largest and statistically most robust smart metering behavioural trials conducted nationally and is expected to provide a wealth of information on the impact of smart metering-enabled feedback initiatives on Dutch electricity and gas consumers.

The monitoring program distinguishes a range of informational stimuli on energy consumption and associated costs for dual fuel meters.

Effect of cost and consumption overviews

On the one hand, the program will focus on the actual measurable reduction effects in customers' electricity and gas demand achievable through the use of smart meters in combination with bimonthly cost and consumption overviews. As mentioned earlier, Dutch energy suppliers are legally mandated to issue six cost and consumption overviews each year. The overviews will be required to give a comprehensive account of the customer's energy usage and associated costs. Part of this will be a comparison of the customer's consumption with the equivalent period in the previous year, and a comparison with the consumption of their peer group. These comparisons should be provided in graphical format where practical. This is similar to the informative billing requirements in the EU Energy Efficiency Directive (2006/ 73).

For monitoring the energy saving effect of the cost and consumption overviews, a representative sample of over 10000 anonymous residential electricity and gas consumers with smart meters throughout the country will be involved in the trial. A control group, made up of 300000 consumers with traditional meters will be included to ensure a balanced experimental trial design. Their energy consumption will also be recorded to enable comparisons with the households that have received interventions under the trial program.

Effects of additional information stimuli

On the other hand, trials are programmed to investigate the behavioural and reduction effects in customer electricity and gas demand through the use of smart meters in combination with additional (free market) monitoring and managements systems. These interventions include in-home displays, web-based information systems and community-based concepts. In total, over 1400 residential consumers throughout the country will participate in these metering services trials. The trial participants are also allocated across different population groups and connected to control groups to ensure a balanced experimental trial design. Although the relatively small trials are not fully representative, the program is expected to deliver relevant and fact-based information about the possible energy saving merits of smart metering services for residential (and SME) consumers in the Netherlands. The trials are also expected to help shed light on the relative attractiveness of various media, functional and design options for specific metering service concepts.

All trials in the national monitoring program will be performed by, or in cooperation with the largest Dutch network operators Liander, Enexis and Stedin (representing approximately 90% of all meter connections in the Netherlands). This takes place under the supervision of independent academic advisors who will statistically analyze the consumption data gathered from the trials to determine the customer response to the smart metering enabled measures tested in terms of the impact on their overall electricity and gas usage. Pre-trial and post-trial surveys will also be conducted to draw demographic, behavioural and experiential conclusions from the trials.

The monitoring program results will deliver input for parliamentary evaluation of the small-scale rollout towards the end of 2013. The statistical evidence from the trials will also provide relevant consumer information for the commercializing and/or the deployment of smart metering services by free market players.

Conclusions and learnings

The Netherlands is the first EU Member State to opt for a voluntary-based rollout of smart meters, after fierce opposition from consumers' organizations and privacy campaigners. Taking into account that government mandated rollouts are generally considered to be the preferential method to reap the benefits of smart metering, the question arises about the significance of the developments in the Netherlands for future rollout decisions in other Member States. How would a trend towards voluntary-based rollout schemes affect the economic and environmental advantages of widespread smart metering, as foreseen by the 3rd Energy package and EED?

This question is hard to answer at the moment, although similar discussions take place in other Member States. The occurrences in the Netherlands highlight the importance of a well-considered regulatory introduction of smart meters. Although more challenging, the Dutch pioneering route towards a voluntary rollout offers equally good prospects for a widespread rollout of smart meters and promising energy savings. However, a crucial factor for success in the first place will be close contact and collaboration with important stakeholders and opinion leaders in society to better meet end-user needs and agree on joint prospects for a widespread rollout of smart meters. Another factor of success is to provide evidence-based information related to actual, behavioural and attitude effects on household electricity and gas consumption following the simultaneous installation of smart meters and accompanying energy management services. Overall, it must be realized that a mandated rollout only ensures a full penetration of smart meters but does not guarantee successful consumer involvement and widespread energy savings.

Detailed end-use metering of domestic appliances in Japan

Takahiro TSURUSAKI, Tatsunori TSUJIMARU, Chiharu MURAKOSHI, Hidetoshi NAKAGAMI

Jyukankyo Research Institute, Inc., Japan

Abstract

Since the March 2011 Great East Japan Earthquake, nearly all Japan's nuclear power plants are shut down, making electricity saving measures urgent. However, there are not yet databases for evaluation of measures to decrease household appliance electricity demand. In 2012, the Ministry of Environment of Japan began both a questionnaire survey and an end-use metering survey. In this paper the breakdown of household electricity consumption in 56 households in the Tokyo area and in Hokkaido (a cold climate) is shown, based on results of the end-use metering survey over a 7-month period and a questionnaire about lighting usage. On average, for the metering period, understand 79% of overall usage in Tokyo can be accounted for and 87% in Hokkaido, including estimates for lighting.

For peak grid demand, for Tokyo summer daytime peak, air conditioning consumes the most, at 38%. Together with refrigerators and TVs, these three make up 70% of total demand. The Hokkaido winter daytime peak occurs in early evening, with no single appliance dominating the demand. For the six specified household electrical appliances with standard indicators for annual electricity consumption, metered results were compared with labeled values. Actual refrigerator unit electricity consumption (UEC) was 1.6 times the labeled value. For models after the 2006 revision of standard measurement conditions this difference shrunk, and both UEC and UEC per unit of internal volume tended to decrease. TVs and DVDs also exceeded their labeled UEC, while microwaves, rice cookers, and electric toilet seats consumed less than their labeled UEC.

Introduction

The Great East Japan Earthquake of March 2011 damaged many power plants in eastern Japan, leading to serious electricity shortages. In the summer of 2011, the Government of Japan, empowered by law, called for a 15% reduction in peak power demand by all large customers of Tokyo Electric Power Company (TEPCO) and Tohoku Electric Power Company. After that, due to concerns over the safety of nuclear power, nearly all Japan's nuclear power plants that shut down for scheduled maintenance were not restarted, so electricity saving measures expanded to all of Japan (except for Okinawa, where there are no nuclear power plants).

As of June 2013, unexpected or planned power outages have successfully been avoided through electricity saving measures. In planning electricity savings, it is vital to understand the structure of electricity demand. However, in Japan, while there were surveys for residential sector energy consumption (for example, see [1],[2]), existing data were insufficient to understand the structure of electricity demand. In particular, no database had been compiled for electricity demand by appliance type, and change in demand for each appliance by time of day (load curves), although results from past studies have been published sporadically in research reports and academic papers [3],[4]. For this reason, the electricity saving effects of measures sought by government and electric utility companies and implemented by businesses and residents could not be adequately predicted. In summer of 2011, measures with large impacts on service but relatively small saving effects (such as reducing the number of elevators in use) were widely carried out, causing a great burden on users. Of course, there were also businesses that could use effective monitoring data from building energy management systems (BEMS) already installed.

From before the Great East Japan Earthquake, opinion solidified that Japan should develop statistics similar to other countries, related to energy use for measures implemented as energy efficiency and climate change countermeasures. In the basic plan concerning the development of official statistics agreed on in 2009, it was specified to develop statistics that accurately grasp the CO_2 emission quantities of each sector. Therefore, from the fall of 2012, the Ministry of Environment began a test survey with the goal to develop statistics for the residential sector. The test survey is a questionnaire survey that provides an understanding of monthly energy consumption by energy source, but it cannot provide load information by type of appliance and time of use.

As shown in Figure 1, the proportion of household energy use held by lighting and appliances is high, so the need to understand its internal structure is significant. In order to do so, independently of the above mentioned questionnaire survey, the Ministry of Environment carried out an end-use metering survey relating to residential electricity demand, and for lighting equipment (for which it is difficult to measure electricity consumption) carried out a questionnaire survey about types of lights owned and conditions of their use.

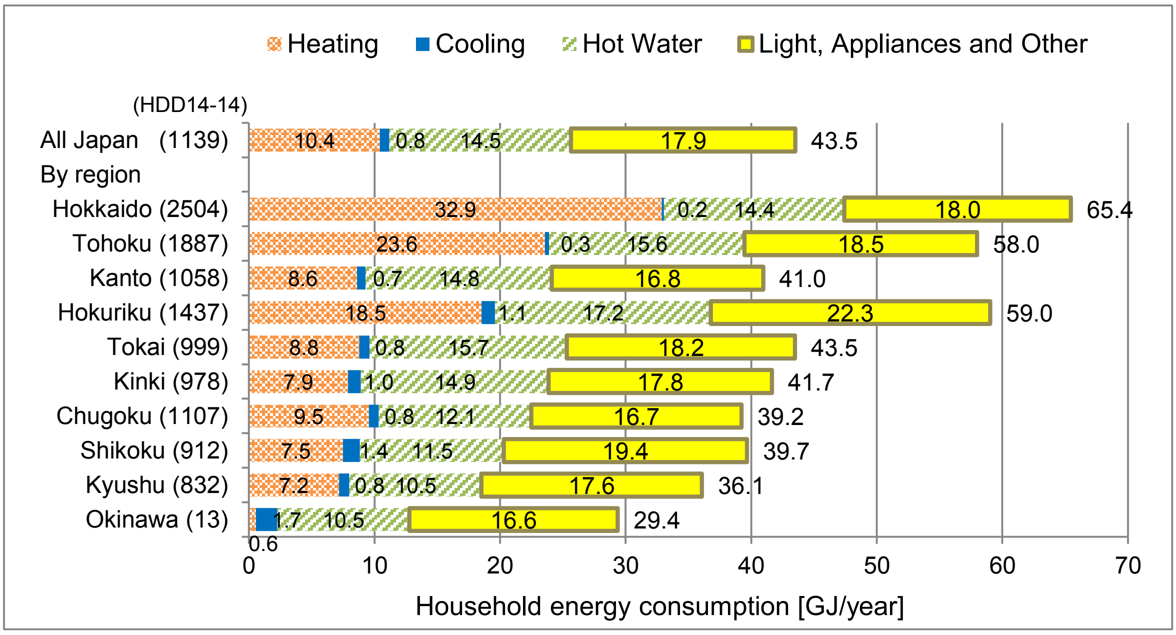

Figure 1: Household energy consumption by end-use in 2011

Source: Estimation by Jyukankyo Research Institute from Family Income and Expenditure Survey and other resources. Note 1: Value in parenthesis shows heating degree days (HDD14-14) of the region. Note 2: The heat conversion factor for electricity is 3.6MJ/kWh.

In this paper, we present breakdowns of residential electricity demand by appliance, based on results of the end-use metering survey and the lighting questionnaire survey. Results are shown for both overall electricity use, and for times when electricity savings are especially needed (times of grid peak demand). We also compare the label values for annual electricity consumption (based on energy efficiency standards) with the metered results.

Methodology

Profile of monitored households

Two regions were chosen for this study. One is Japan's most populous region, the Tokyo metropolitan area. The other is Hokkaido, which has a cold climate and different patterns of energy use than Tokyo.

The number of households studied by region, household type, and house type are shown in Table 1. In Tokyo, 36, and in Hokkaido 20 households were monitored. Targets for the distribution of house type were equal numbers of single-family detached houses and apartments. Targets for household type were singles and couples each at 20%, couples with children at 50%, and three-generation families at 10%. Participating households were chosen from those that applied via an online survey company's internet research panel, met the conditions for inclusion, and showed their intent to cooperate with the study. Excluded from consideration were the few households living in all electric houses, as well as those generating their own power (for example, by solar cells) due to concerns that the monitoring system could not be used correctly. Also, we note that the average number of personal computers per household was 1.9, which exceeds the average value in the March 2012 Monthly Consumer Confidence Survey of 1.1 by more than 70%.

Table 1: Number of monitored households

Household type	Tokyo metropolitan area		Hokkaido		Total
	Single-family detached house	Apartment house	Single-family detached house	Apartment house	
Single-person	2	5	0	4	11
Couple	4	3	2	2	11
Couple and children	10	9	5	5	29
Three-generation	3	0	2	0	5
Total	19	17	9	11	56

Note: This includes one replacement household for a family in the Tokyo area who quit the survey in December 2012.

Basic attributes of the monitored households are shown in Table 2. The average number of people per household is 2.64 in the Tokyo area and 2.85 in Hokkaido. This exceeds the average from the 2010 National Census of 2.26 for the Tokyo metropolitan area (for Tokyo, Kanagawa, Chiba, and Saitama) and 2.21 for Hokkaido. Similarly, the average floor areas of the monitored houses exceeded those from the 2010 Census (75 m^2 for the Tokyo area and 86 m^2 for Hokkaido). The average house age was 22 years for Tokyo and 16 years for Hokkaido. When compared to the 2008 Housing and Land Survey average age (21 years for Tokyo, 22 years for Hokkaido) we see that, on average, the houses in our Hokkaido study population are somewhat newer.

Table 2: Basic attributes of monitored households

Item	Tokyo metropolitan area	Hokkaido	Total
Average size of household [persons]	2.64	2.85	2.71
Average floor space [square meters]	82.0 (n=35)	97.2 (n=18)	87.2 (n=53)
Average of age of house [years]	22 (n=35)	16 (n=18)	20 (n=53)
Number of households	36	20	56

End-use metering survey

The monitoring study is planned for the one-year period from July 2012 to June 2013. The research in this paper describes an analysis performed using metering data through 17 February 2013. The targets of metering were electricity consumption of the whole house and of electrical appliances. Data other than electricity, such as room temperature, outdoor temperature, gas consumption, water consumption, were not collected.

Two types of power consumption meters were used. First, to measure power consumption for the whole house, a sensor was installed at the main circuit breaker at the house power distribution board. If a certain appliance had a dedicated distribution circuit (e.g. air conditioner) a sensor would also be installed in that circuit. Second, for appliances that could not be metered at the power distribution board, a small electric meter was installed between the power cord and the outlet. A total of 12 small meters were prepared for each household, and these were distributed according to numbers of appliances in the household, obtained from a preliminary questionnaire. The metering interval was 30 minutes. Metered data were automatically collected and transmitted over cell phone network or the internet.

Electricity use of the metering system is high enough that it cannot be ignored, so a fixed value is subtracted from the whole house value for each 30-minute measurement. Furthermore, although corrections due to air temperature were generally not made, to compare appliance label values from energy efficiency standards to metered results, temperature corrections were made in some cases.

Table 3 shows numbers of each appliance monitored in August 2012. All air conditioners in all participating households were metered. For other main appliances, such as refrigerators and TVs, more than 80% of units were metered. Appliances not metered included those with (1) no space in which to put the meter (for appliances like refrigerators and washers) or (2) in cases constrained by the number of meters per household, appliances expected to have low consumption (such as a TV in a bedroom, a router, a fan in Hokkaido). In winter, electricity used by heating appliances increases. Therefore, in autumn 2012, appliances chosen for metering were adjusted, from those only used in summer (e.g., electric fans) or those with small consumption, to heating appliances, not only including electric heaters and electric carpets, but also boilers and heaters mainly fueled by kerosene or gas.

Table 3: Quantity of metered appliances in August 2012

Appliance	Quantity of metered appliance [units]			Proportion of metered appliances to appliances in use	
	Tokyo metropolitan area	Hokkaido	Total	Tokyo metropolitan area	Hokkaido
Air conditioner	87	6	93	100%	100%
TV set	54	31	85	84%	82%
Refrigerator	37	20	57	97%	91%
Laundry machine	33	19	52	94%	90%
Microwave oven	34	18	52	92%	90%
Rice cooker	30	19	49	91%	95%
Electric toilet seats	32	16	48	89%	100%
Desktop PC	28	15	43	85%	100%
Notebook PC	24	17	41	62%	89%
DVD / Blu-ray recorder	26	12	38	63%	41%
Modem / Router	16	6	22	40%	30%
Electric fan	22	0	22	35%	0%
Air cleaner	11	4	15	69%	40%
Electric pot	8	6	14	40%	60%
Dishwasher	8	5	13	73%	71%
Other	32	39	71	-	-
Total	482	233	715	-	-

Note: There were 35 Tokyo area and 20 Hokkaido households participating in August 2012.

Questionnaire survey on lighting

Direct measurement of electricity consumption of lighting equipment was outside the scope of the end-use metering survey, but lighting was expected to use a high percentage of overall electricity. There are various methods to understand lighting electricity usage. Besides direct measurement, other methods involve measuring lighting intensity or lamp temperature and estimating electricity consumption. All these methods are expensive and difficult for occupants to cooperate. For this work, we investigated essentially all lighting equipment in use, using a questionnaire survey regarding kinds of lighting (incandescent, fluorescent, LED), lamp wattage, and average hours of illumination. From those results values for lighting electricity usage were estimated. The questionnaire period was October 2012. For future research, it would be good to validate the accuracy of this method.

Results

Breakdown of residential electricity consumption

Results of the lighting questionnaire survey and estimated values of electricity consumption are shown in Tables 4 and 5. Average consumption per lighting appliance of a Tokyo area household was 0.11 kWh/day. With an average of 13.9 lights, the average household was estimated to use 1.5 kWh/day for lighting. The average Hokkaido household used 1.6 kWh/day for lighting. Electricity consumption by incandescent lamps made up 22% and 16% of total lighting electricity usage in the Tokyo area and Hokkaido, respectively.

Table 4: Lighting appliance power consumption, hours used, and estimated daily UEC

Area	Type of lamp	Consumed power [W/unit]	Hour of use [h/day/unit]	Unit electricity consumption [kWh/unit/day]	N [unit]
Tokyo metropolitan area	Incandescent lamp	52	1.4	0.08	114
	Fluorescent lamp	43	2.5	0.12	200
	LED lamp	15	3.6	0.07	35
	Complex or unknown	89	2.7	0.19	7
	average, total	44	2.3	0.11	356
Hokkaido area	Incandescent lamp	51	1.0	0.06	83
	Fluorescent lamp	49	2.6	0.13	168
	LED lamp	11	2.4	0.03	15
	Complex or unknown	48	4.8	0.29	3
	average, total	47	2.1	0.10	269

Note: Results of the questionnaire survey, including valid responses only.

Table 5: Numbers of lighting appliances used and estimated daily electricity consumption

	Number of units		Daily electricity consumption	
	Tokyo metropolitan area	Hokkaido area	Tokyo metropolitan area	Hokkaido area
Type of lamp	[units/household]		[kWh/day/household]	
Incandescent lamp	4.2	4.6	0.32	0.26
Fluorescent lamp	7.0	9.3	0.87	1.21
LED lamp	1.9	1.0	0.14	0.02
Complex or unknown	0.8	0.4	0.14	0.10
total	13.9	15.2	1.47	1.57
Number of households	36	20	36	20

Note: These results are estimated from the lighting questionnaire survey.

Figure 2 shows the average electricity consumption per household from August 2012 to January 2013 for Tokyo metropolitan area households. In summer, electricity consumption rose, mainly due to air conditioning, while in winter it rose due to air conditioners (in heating mode) and other heating appliances, electric toilet seats, etc. Refrigerator electricity consumption was nearly twice as high in August as in January. TV electricity consumption showed essentially no seasonal change. Lighting electricity consumption based on the questionnaire survey was estimated at 1.5 kWh/day per household in October 2012. While lighting electricity consumption is expected to have seasonal changes, these were not measured as part of this study. Note that the category, "Other", includes consumption by unmetered refrigerators, TVs and lighting (except for October and for the annual average, when the estimated value for lighting is subtracted based on the October 2012 estimated values). "Other" consumption increased in winter, which may be due to some heating appliances and lighting not being metered.

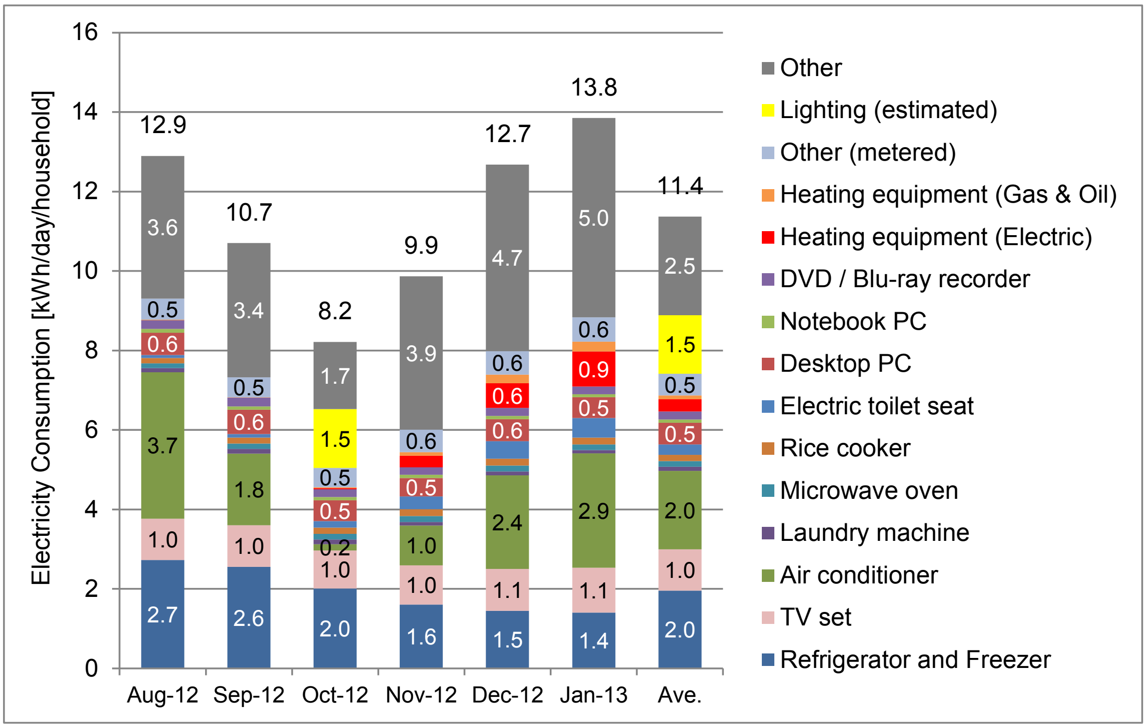

Figure 2: Monthly electricity consumption by appliance in the Tokyo metropolitan area

Figure 3 shows the average electricity consumption per household over the same period for households in Hokkaido. There is hardly any demand for cooling so summer and fall consumption is nearly the same. Compared to the Tokyo area, heating demand in Hokkaido is very high, but kerosene heating appliances are predominant, so the increase in electricity consumption is not as great as that of Tokyo. Electricity consumption to operate gas and oil heating appliances exceeds electricity consumption by electric heating appliances.

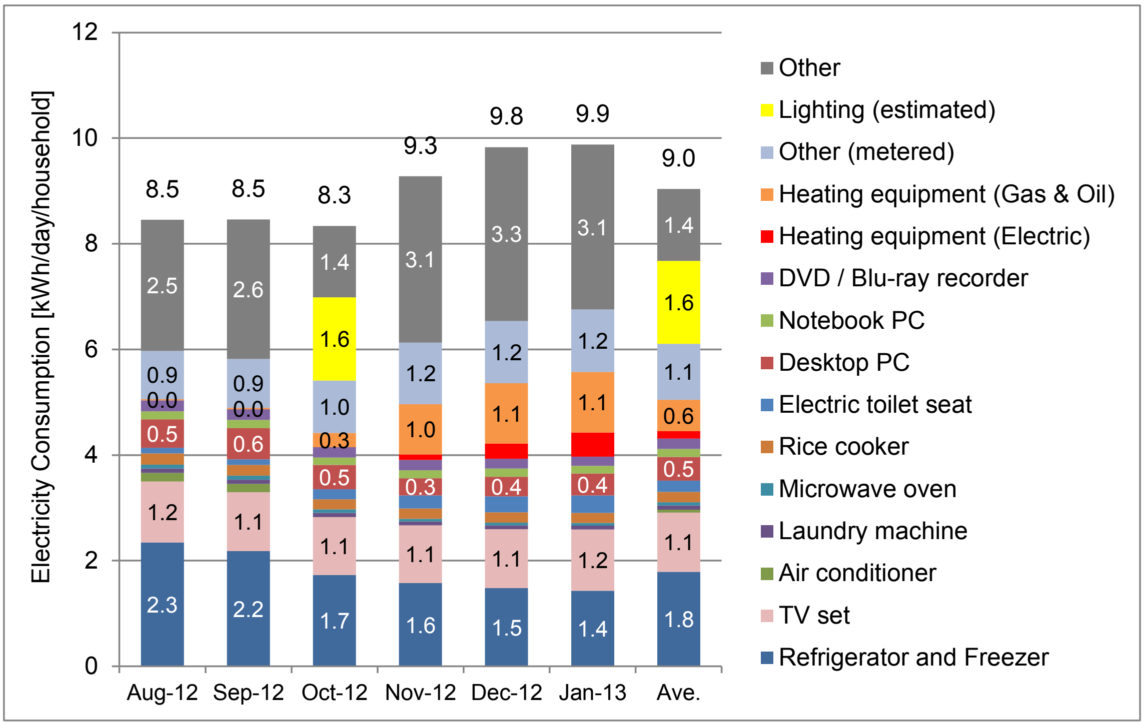

Figure 3: Monthly electricity consumption by appliance in Hokkaido

Figure 4 shows the relative contribution of each electrical appliance to total household electrical consumption for both regions. The breakdown of consumption that can be understood from the end-use metering survey is on average 65% for the Tokyo metropolitan area and 68% for Hokkaido. On average during the measurement period, for Tokyo, refrigerators and AC both used 17%, lighting was estimated at 13%, and TVs used 9%. For Hokkaido, refrigerators used 20%, lighting was estimated at 17%, TVs and electric components of gas and oil heating appliances each used 12%. The remainder ("Other"), which was not sub-metered and not estimated as lighting use, made up 22% for Tokyo and 15% for Hokkaido.

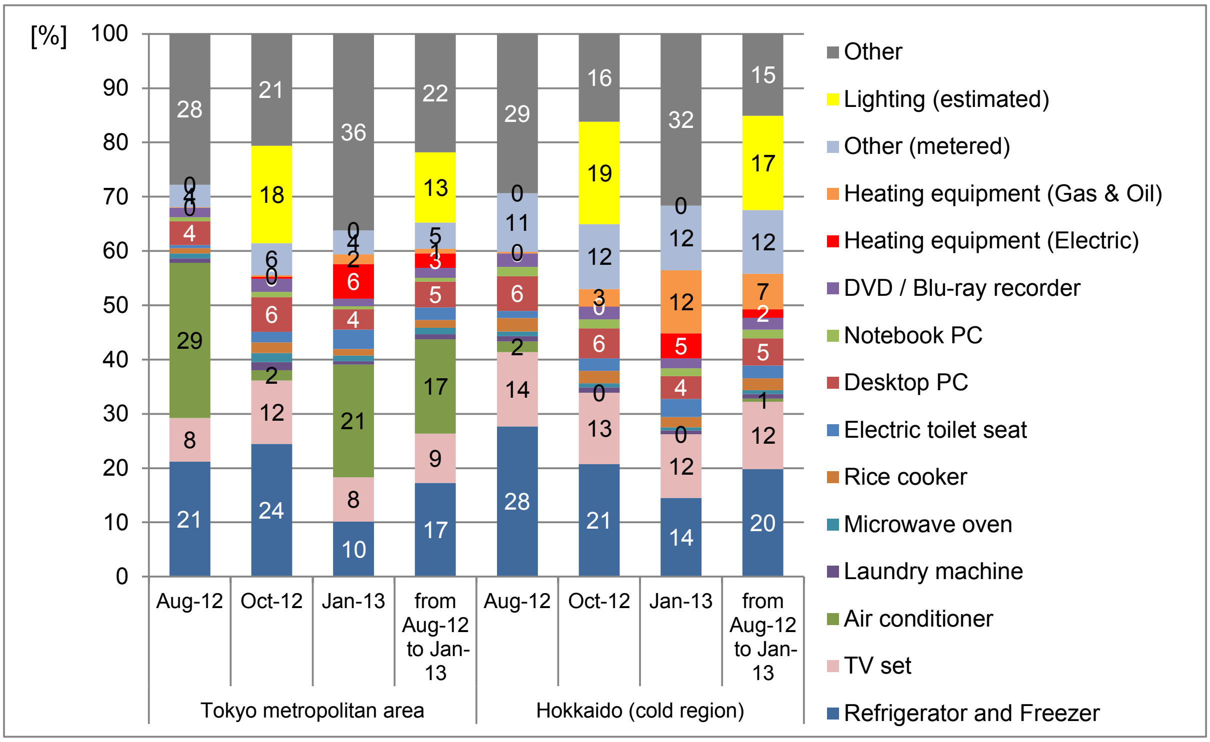

Figure 4: Composition of electricity consumption by appliance

Note: As explained in the text, lighting was estimated only for October 2012.

Breakdown of residential electricity consumption in grid peak hours

Based on the half-hourly metered values, the electricity consumption breakdown for each appliance for the survey households during grid peak hours was investigated. For the Tokyo area, TEPCO's top three daily peak demand days during summer 2012 were considered. For Hokkaido, Hokkaido Electric Power Company's (HEPCO) top three daily peak demand days during the winter of 2012-2013 were considered. There is a direct relation between grid power demand and outdoor temperature, so these peak demand days were extremely hot in the Tokyo metropolitan area and extremely cold in Hokkaido.

Figures 5 and 6 show the electricity consumption averaged over the three peak days by appliance for each half hour period, in both regions. On very hot days in the Tokyo area, air conditioner electricity consumption is high, can be seen throughout the day, and is particularly high between 8 pm and midnight. Refrigerator electricity consumption stays roughly constant at about 0.12 to 0.13 kWh/h. On very cold days in Hokkaido, daily electricity consumption of heating appliances (gas and kerosene, mostly kerosene) is about the same as that of refrigerators and TVs. During the grid peak hours of 17:00 to 19:00 they hold the third largest share of consumption, behind refrigerators and TVs. Refrigerator consumption is roughly constant at about 0.06 kWh/h.

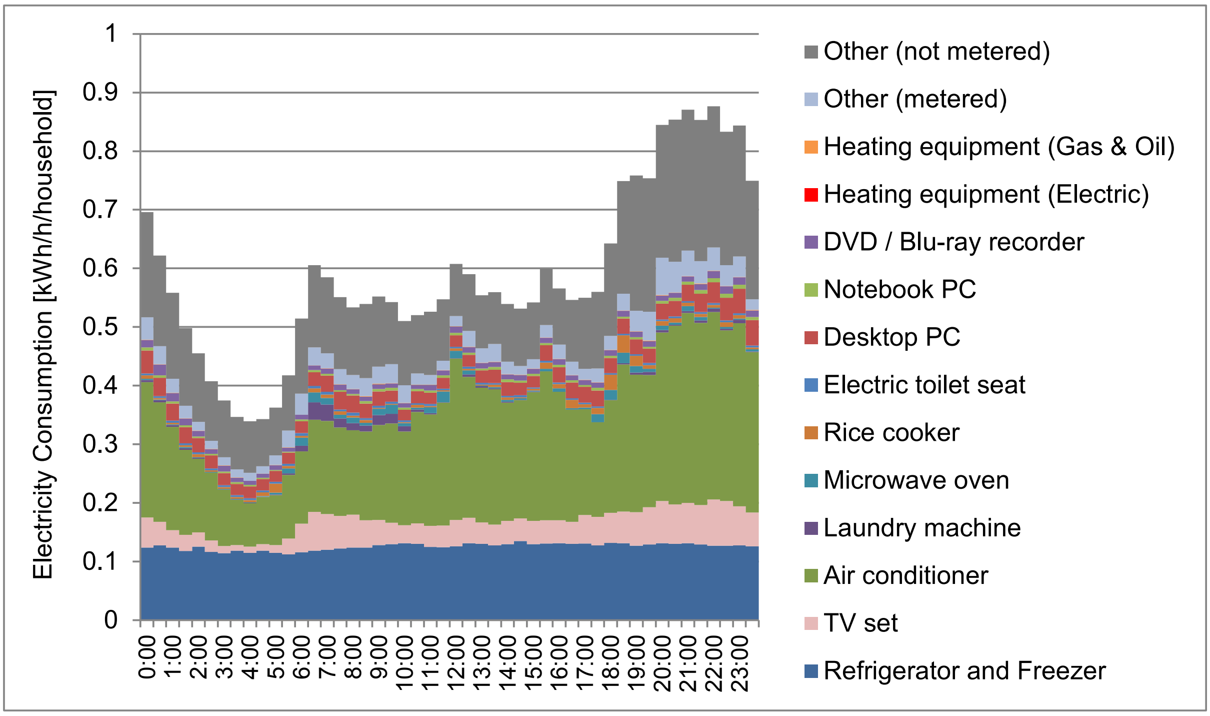

Figure 5: Half hourly electricity consumption by appliance on hot days in the Tokyo metropolitan area

Note: The days aggregated are TEPCO's top three daily peak demand days for summer 2012 (7/27/2012, 8/23/2012, 8/30/2012).

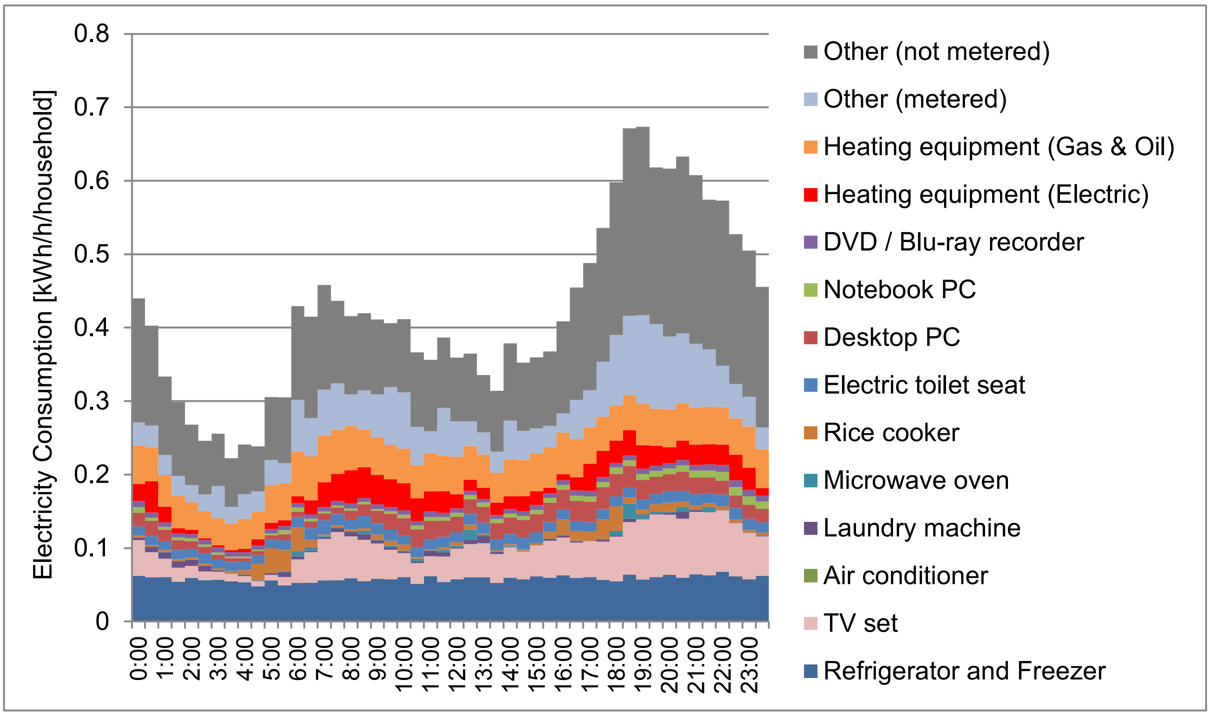

Figure 6: Half hourly electricity consumption by appliance on cold days in Hokkaido

Note: The days aggregated are HEPCO's top three daily peak demand days for winter 2012-2013 (12/26/2012, 12/27/2012, 1/18/2013).

Figure 7 shows the composition of household electricity consumption during grid peak hours for the two regions. Peak hours in the Tokyo metropolitan area are 14:00-15:00. At this time, the breakdown of electricity consumption is AC 38%, refrigerator 25%, and TV 7%. These three appliances make up 70% of consumption. Therefore, AC and refrigerator control measures are important for curbing peak demand. Peak hours in Hokkaido are 17:00-19:00, and compared to Tokyo's summer peak, the composition of electricity usage is diverse. "Other" is a significant 36%, which is probably due to the overlap of lighting hours with peak hours. Also, HEPCO's power demand on extremely cold days stays at a high level all day, with demand during the early morning (3 to 4 am) and morning (9 to 10 am) varying only about 1% from the peak demand. This is influenced by the demand of electric thermal storage heaters, electric tank water heaters, and also electric snow melting systems, operating in early morning hours. Note that households with such appliances were excluded from this study. Overnight, refrigerators and gas and oil heating equipment make up 38% of total electricity consumption (Table 6, so control of these appliances would be effective in reducing peak demand.

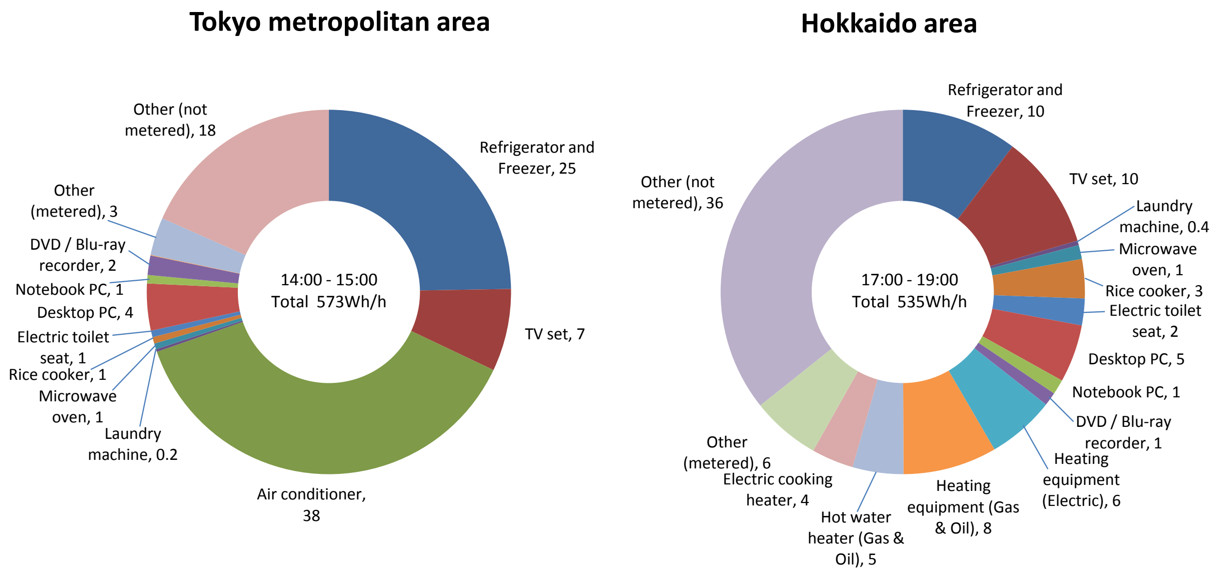

Figure 7: Composition of electricity consumption in grid peak hours

Note: Days aggregated are the same as those in Figures 5 and 6.

Table 6: Composition of electricity consumption in grid peak hours in Hokkaido

	Refrigerator and Freezer	TV set	Heating equipment (Gas & Oil)	Grid Demand [MW]
3:00-4:00	23%	5%	15%	5377
9:00-10:00	14%	11%	12%	5401
17:00-19:00	10%	10%	8%	5445

Note: Days aggregated are the same as those in Figure 6.

Comparison with labeled unit energy consumption (UEC)

In Japan there are energy efficiency standards for major household appliances. For air conditioners the energy efficiency indicator is the annual performance factor (APF), which compounds the coefficient of performance (COP) for heating and cooling, but it is very difficult to measure the APF under conditions of actual use. In contrast, for appliances such as refrigerators, for which the energy efficiency indicator is set as annual electricity consumption, through the end-use metering survey it is possible to understand the efficiency of appliances under conditions of actual use, and examine the validity of the labeled UEC.

The standard, JIS C 9801, specifying measurement conditions for determining refrigerator energy efficiency (annual electricity consumption) was revised in 2006. The catalyst for the revision was that a large difference had been seen between the labeled values and the results of metering under conditions of actual use [5]. End-use metering can be effective in validating measurement conditions related to energy efficiency standards.

Besides refrigerators (including freezers), other appliances in Japan with standard energy efficiency indicator of annual electricity consumption are TVs, DVD recorders (including Blu-ray), microwave ovens, rice cookers, and electric toilet seats. Below, the results from this end-use metering survey are compared with the labeled values based on energy efficiency standards.

Refrigerators and freezers

Refrigerator electricity consumption is highly correlated with ambient temperature, but temperature was not measured in this study. Figure 8 shows a comparison of the temperature at the regional Local Meteorological Observatory and refrigerator electricity consumption. The inflection point in the vicinity of 15°C for Hokkaido is due to the room temperature not decreasing as much as with outdoor temperature past that point. Also, the observation that at temperatures below about 20°C refrigerators in Hokkaido use more electricity than those in Tokyo can be explained since the temperatures in rooms with refrigerators (mainly kitchens) are lower in Tokyo than in Hokkaido.

For this analysis data from 1 July 2012 to 17 February 2013 were used, which includes metered results for three seasons. Although this is acceptable for obtaining an average value, for each refrigerator a piecewise linear function for electricity consumption as a function of temperature was generated, and then temperature data for a normal year were used to calculate temperature-adjusted annual electricity consumption.

Table 7 shows the temperature-adjusted actual unit electricity consumption (UEC) and the labeled UEC. The overall average actual UEC is 613 kWh/year, which is 1.6 times the labeled UEC. When broken down according to refrigerator model year, the ratio of actual to labeled UEC was 3.0 for products from 2003 to 2005--a bigger difference than for other years. This result is consistent with previous research [5]. After the 2006 revision of JIS C 9801 governing test measurement conditions for refrigerators, the ratio for units made in 2006 to 2008 decreased to 1.2, and for units made in 2009 or later the ratio stayed at 1.4. The actual UEC for units made in 2009 or later was 443 kWh/year, which is 37% lower than that of the 2003 to 2005 group. Also, the actual UEC per unit rated volume was lower for newer refrigerator models at 1.2 kWh/L-year for units made in 2009 or later, a decrease to about half the level of pre-1999 refrigerators. Therefore, it is evident that refrigerator energy efficiency has greatly improved in recent years.

Table 7: Comparison of actual and labeled electricity consumption of refrigerators and freezers

Year of production	Actual UEC (temperature adjusted) [kWh/year] [a]	Labeled UEC [kWh/year] [b]	Rated volume [L] [c]	Ratio of actual to labeled [a]/[b]	Actual UEC per rated volume [kWh/L/year] [a]/[c]	N
until 1998	704	445	284	1.6	2.5	12
1999-2002	644	406	347	1.6	1.9	10
2003-2005	704	233	394	3.0	1.8	10
2006-2008	590	487	357	1.2	1.7	13
since 2009	443	316	382	1.4	1.2	12
All	613	383	352	1.6	1.7	57

Note 1: UEC is unit electricity consumption. Note 2: Actual UEC (temperature adjusted) is calculated for each refrigerator using the observed relationship between outdoor temperature and that refrigerator's electricity consumption, using temperature data for a normal climate year to calculate temperature-adjusted annual electricity consumption. Note 3: Labeled UEC standard measurement conditions were revised in 1994, 1999, and 2006.

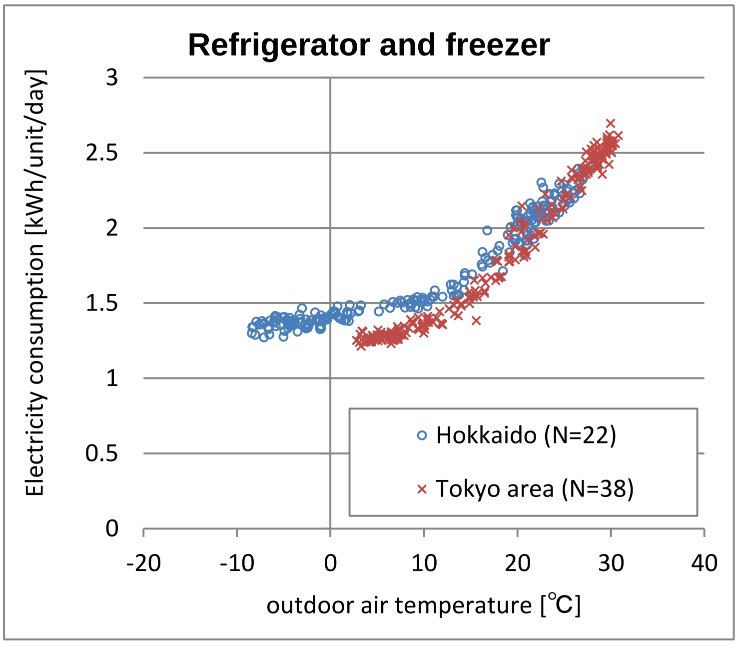

Figure 8: Daily electricity consumption of refrigerator and freezer versus outdoor air temperature

Note1: The metering period is from 1 July 2012 to 17 February 2013. N varies, depending on the day. Note 2: Outdoor air temperature is the Meteorological Observatory's observed value. For the Tokyo metropolitan area it is Tokyo and for Hokkaido, it is Sapporo.

TV sets

Table 6 shows the comparison results for TV sets. The TV labeled UEC assumes 4.5 h/day of use. Because TVs in living rooms were used a lengthy 7.3 h/day, the actual UEC exceeded the labeled UEC by a factor of 2.3. TVs in other places, such as bedrooms, were used relatively briefly, so the ratio of actual to labeled UEC was lower, at 1.3. For each TV set, a usage adjusted UEC was calculated by multiplying the actual UEC by the ratio of standard (4.5 h) to actual usage hours. The average usage adjusted actual UEC was 182 kWh/year, exceeding the labeled UEC by a factor of 1.5. A detailed examination of the reasons for this gap is needed, but it is possible that it arises due to differences in modes of use, such as screen brightness.

Table 8: Comparison of actual and labeled electricity consumption of TV sets

Place	Actual UEC [kWh/year] [a]	Actual UEC (usage adjusted) [kWh/year] [b]	Labeled UEC [kWh/year] [c]	Hour of use [h/day]	Display size [inch]	Ratio of actual to labeled [a]/[c]	Ratio of actual (adjusted) to labeled [b]/[c]	N
Living room	314	197	137	7.3	36	2.3	1.4	48
Other	124	146	94	4.2	26	1.3	1.6	20
All	258	182	124	6.4	33	2.1	1.5	68

Note 1: UEC is unit electricity consumption. Note 2: Actual UEC (usage adjusted) is calculated for each TV set, adjusting its usage to the standard (4.5 h/day) used for the labeled UEC.

DVD recorders

As shown in Table 7, the ratio of actual UEC to labeled UEC for DVD recorders (including Blu-ray) was 2.7 on average. To identify the time of use from the electricity consumption level is more difficult than for TV sets, so time in use was not added up. For recorders that had particularly big differences between actual and labeled UEC, a trend to exceed 10 W of minimum power consumption was seen.

The labeled UEC is calculated using the mode in which standby power is small, but it is likely that in these households, occupants set their recorders for the mode in which standby power is more significant, in order to shorten the wait time during start-up.

Table 9: Comparison of actual and labeled electricity consumption of DVD/Blu-ray recorders

Average of daily minimum power	Actual UEC [kWh/year] [a]	Labeled UEC [kWh/year] [b]	Ratio of actual to labeled [a]/[b]	N
Above 10 Watt	255	54	4.7	6
10 Watt or below	87	44	2.0	20
All	125	46	2.7	26

Note 1: UEC is unit electricity consumption.

Other

Results of comparisons for microwave ovens, rice cookers and electric toilet seats, together with the other three appliances are summarized in Table 8. The actual UEC was less than the labeled UEC for microwave ovens, rice cookers and electric toilet seats. However, the difference was not statistically significant for rice cookers. The standard measurement conditions for these three appliances have been set in detail based on survey results of actual conditions of use (such as environmental conditions and frequency of use), and it is possible that the circumstances of use of these microwave ovens and electric toilet seats differed from the standard assumptions.

Table 10: Comparison of actual and labeled electricity consumption of appliances

	Actual UEC [kWh/year] [a]	Labeled UEC [kWh/year] [b]	Ratio of actual to labeled [a]/[b]	N	Significant difference
Refrigerator and freezer	613	383	1.6	57	***
TV set	182	124	1.5	68	***
DVD / Blu-ray recorder	125	46	2.7	26	***
Microwave oven	46	71	0.66	21	***
Rice cooker	80	96	0.83	33	-
Electric toilet seat	115	210	0.55	28	***

Note 1: UEC is unit electricity consumption. Note 2: Refrigerator and electric toilet seat are temperature adjusted UEC, and TV is usage adjusted UEC. Note 3: Except for rice cookers, all appliances have actual UEC that are significantly different from the Labeled UEC at the 0.01 significance level. For rice cookers, the difference is not statistically significant even at the 0.1 level.

Conclusion

In Japan, in addition to their relevance as climate change countermeasures, electricity saving measures have become an urgent topic in their own right, but existing data were insufficient to understand the structure of electricity demand of household appliances. With the objective to understand in detail the breakdown of household contributions to CO_2 emissions, the Ministry of Environment carried out a questionnaire survey and an end-use metering survey.

In this paper the composition of household electricity use has been presented, from results of an end-use metering survey (over about a 7-month period) and a questionnaire survey about lighting equipment and usage, conducted in 56 households in the Tokyo metropolitan area and in Hokkaido (a cold climate region). Over the measurement period, on average, it was possible to account for 79% of total household electricity use in the Tokyo metropolitan area and 87% in Hokkaido, including estimated values for lighting.

Additionally, the composition of electricity consumption during grid peak demand hours was also shown. During the Tokyo metropolitan area's summer grid peak hours, electricity consumption in the metered households could be broken down into AC with 38%, refrigerators with 25%, and TV sets with 7% of total household consumption. In other words, these three appliances accounted for a 70% share. The winter peak hours in the cold climate region of Hokkaido occur in the early evening, and various appliances contribute to household electricity consumption. However, it is noted that on very cold days in Hokkaido, electricity demand in the late night and the morning is also very high.

For appliances with energy efficiency standards that specify annual electricity consumption as an energy efficiency indicator, the metered results were compared with the labeled values. For refrigerators and freezers, the actual UEC was 1.6 times the labeled value. However, for units made in or after 2006, when the standard measurement conditions were revised, this difference was smaller, and both the UEC and the UEC per rated volume tended to decrease. TV sets and DVD recorders also exceeded their labeled UEC, probably due to being used in a different mode than that specified in the standard measurement conditions. Microwave ovens, rice cookers, and electric toilet seats used less than their labeled UEC, but the difference was not statistically significant for rice cookers.

Abstract

In South Africa and elsewhere, electricity supply exigencies and a need to promote the sustainable use of resources have prompted an emphasis on affordable, rapidly scalable solutions in the form of Demand Side Management and Energy Efficiency. The improvement of end-use energy efficiency is generally accepted as an obvious, simple and inexpensive measure to manage a consumer's energy demand. Residential electrical end-use has been identified as an area where the potential for change exists and the research documented in this paper is aimed at a residential end-user. The ability of an interventionist strategy to harness this potential determines its effectiveness in delivering desired results. The paper describes the development of an interactive web application for residential end-users as an intuitive, dynamic tool to improve energy efficiency through modified consumption behaviour and the adoption of energy efficient habits. Emphasis has been placed on the education of end-users through exposure to energy efficient guidelines and consumption analysis. Current web technology was evaluated and the resulting format is a Rich Internet Application favouring an interactive, minimalistic design with graphic content. "At-a-glance" feedback is presented by means of data visualization to resemble a dashboard. With extendibility and ease of maintenance in mind, the desired functionality and dynamic content have been achieved through a relational database-driven design structured around electric end-use categories and associated household appliance types.

Introduction

The vulnerability of energy systems impacts energy security on economic, technical and social levels. At a micro-economic level, this vulnerability determines how exposed consumers are to possible interruption of supply as well as an increase in price [1]. In 2008, supply-related issues culminated in a large-scale power crisis in South Africa. Insufficient coal supplies, infrastructure requirements and supply disruption had depleted the country's electricity reserves and caused immense pressure on the state-owned electrical supply utility, Eskom. The course of events underlined the pressing need for affordable, rapidly scalable solutions in the form of Demand Side Management (DSM)/Energy Efficiency (EE) initiatives to reduce disruptive measures such as load shedding [2].

Eskom's ability to deliver sustained energy security is routinely beleaguered with bureaucratic issues and concerns. South African consumers must adjust to a steep electricity price increase to compensate for a lack in investment in generation capacity and a historically too low electricity price. In the beginning of 2010, the National Energy Regulator of South Africa (NERSA) approved the implementation of a sliding-scale tariff-based structure for the residential customer base in the form of an Inclining Block Tariff (IBT). A Time Of Use (TOU) pricing scheme correlates electricity price with time of consumption and according to the tariff structure, higher consumption customers will be charged more based on their electricity usage. The time-based pricing scheme for the suburban residential sector with relatively high consumption, will be phased in once advanced smart metering infrastructure is in place. The IBT roll-out by Eskom commenced in the first half of 2010 [3].

The category of households whose fuel expenditure is in excess of 10% of the household income is deemed vulnerable to fuel poverty [1]. However, as electricity consumers are demanding higher levels of reliability, efficiency and environmental performance [4], coupled with the need to promote the sustainable use of resources, the introduction of simple interventionist measures to manage consumer energy demand can significantly benefit most households. This research paper documents a number of key aspects of the development of a tool to educate residential end-users on energy efficiency and improve end-use energy efficiency by means of an interactive, web-based application. The provision of consumption analysis feedback in the form of appliance usage profiles, can assist a consumer in realizing the cost benefits associated with appliance scheduling based on a TOU framework.

Energy Efficiency (EE) and Demand-Side Management (DSM)

The cumulative residential load on a power system or part thereof, is determined according to different residential customer types whose household activities are unique yet in accordance with certain predictable usage patterns. In order to establish energy security within the energy provision-consumption context, DSM involves all interventions that occur on the demand side (as opposed to the supply side) where the end-user resides. Consumer participation within the residential sector can minimize peak hour consumption through the implementation of measures such as appliance scheduling and a more judicious use of electricity. Demand in most households can be directly correlated with family activity peak times and is simultaneously linked to affordability, lifestyle and preferences [5]. Knowledge of household consumer loads is considered essential in order to both forecast demand at utility level and to predict potential savings through DSM schemes. In recent years, an extensive body of research knowledge has been collected on interaction between members of a household and their appliances and how consumption is defined by non-technological factors such as price, convenience and habit.

End-use analysis is proposed to be the best way to study load usage in order to fully grasp and model customer usage and is defined as the study of basic causes of electric demand by customer type, time, end-use category, and type of appliance [5]. Disaggregation of residential consumption has been applied in research studies as a means of distinguishing between different energy consuming appliances to reveal consumption trends. As noted by Paatero and Lund, unless exposed, "(t)he fluctuation of electricity consumption concerning an individual household remains unrevealed as well as the division of consumption between different types of household appliances." [6]

Findings from a study on the effectiveness of feedback on energy consumption indicate that, domestic energy use is largely invisible to the user and most consumers are ignorant of their consumption behaviour, i.e. how much energy they use towards various ends [7]. Consequently, consumers are also ignorant of the effect of modified behaviour through an investment in efficiency measures. The case for feedback is put forward as a measure to "make energy more visible and more amenable to understanding and control" [7]. The author recommends a user-friendly display to show "instantaneous usage, expenditure and historic feedback as a minimum, with the potential for displaying information on microgeneration, tariffs and carbon emissions" for optimal usefulness [7].

Overview of end-user feedback

The research documented in this paper underwrites the proposition that, through readily accessible real-time feedback, consumers can adjust usage patterns in accordance with energy efficiency principles. The utilisation of instantaneous direct feedback can serve as means to devolve and transfer both control and ownership to the end-user. Feedback should enable the consumer to immediately see the effect of switching on an appliance and realise the benefits of a reduction in consumption.

Feedback is associated with a learning process through its contribution to the end-user's implicit knowledge repository. Through the exercise of interpreting feedback on energy supply and usage, end-users assimilate information concerning their energy use which in turn prompts them to act and modify their behaviour in some way [7]. The combination of a home energy audit and "disaggregated" feedback, made available as at-a-glance displays, can reveal to the end-user which end-uses consume most energy. The rationale for this type of feedback is based on the educational value in raising awareness of the relative demand from different appliances. Disaggregated feedback can be included in billing in a format such as a pie-chart to display a typical breakdown of main domestic end-uses [7].

The feedback system in this research is conceptualized as a virtual residence which the end-user can construct and populate with appliances to observe the effects of various end-use scenarios. A web application was used to accomplish this and channel feedback to the user by means of a dashboard interface. A dashboard is nowadays commonly associated with a real-time user interface to convey an organization's Key Performance Indicators (KPIs).

Efforts in recent years have been made to develop residential energy management systems to intelligently manage and raise awareness about residential energy consumption [8]. This has given rise to the development of both commercial projects such as Microsoft's System Hohm, and freely available energy monitoring tools such as Google's PowerMeter [9]. Nevertheless, the GoogleMeter service was retired in September 2011 and similarly Microsoft's Hohm has been halted [9]. A number of conjectures are put forward as to why the big Internet companies' online energy monitoring tools have failed [10]. One reason considers the American market for home energy management to be still too immature and that the online energy tools were prematurely introduced.

In comparison with the American market, there is a far greater financial incentive for South Africans to utilise energy saving tools. When measured in real terms, the cost of residential electricity in the US decreased by an annual average of 0.8 percent in both 2012 and 2013 [11]. In terms of disposable income, an average American household spends far less on electricity compared to a South African household.

To date there is no market research available from the Human Sciences Research Council (HSRC) in South Africa on how the South African market may respond to online energy metering tools. In February 2012, the European Utilities Telecom Council (EUTC) and Eskom held a conference on the Smart Grid in Africa in view of planning for the development and deployment of smart metering [12]. Eskom's spokesperson noted that the commercial viability of smart metering still needs to be demonstrated since it is key to be able to deploy and interface with existing systems [13].

South Africa's diverse demographic make-up poses a challenge in identifying the target market and the average end-user with whom to engage during the design process. An honest review is required of what can be most effectively accomplished, yet presented and communicated in a simple, intuitive way. Although income levels are indicative of end-user energy consumption, a high earning household does not necessarily waste energy. Similarly, an indigent household does not necessarily consume energy prudently. Despite the marked differences in literacy levels amongst South Africans, the technological dexterity of the youth, forming a large portion of the South African society, and the ubiquitous presence of smart phones set the stage for a high adoption rate of a web-based application. With many metropolitan schools in South Africa providing computers with Internet access and with increased access to wireless (Wi-Fi) network points, the channels to modify energy consumption behaviour and cultivate awareness of EE habits are more readily available.

Profiling residential electrical energy demand

Domestic demand can be qualified by means of end-use energy models by considering particular end-uses. The accuracy of end-use models is dependent on grass-root level consumption details such as appliance inventories and associated usage profiles [6]. Demand is determined as a load-average for a given time period referred to as the "demand interval", for example measured for 15 minute intervals, 30 minute intervals, or on an hourly, daily, monthly or annual basis [5]. Demand which is measured and recorded on an hourly or half-hourly basis for one day yields a load curve. If measured half-hourly, there are 48 intervals and each of the values is an indication of the average demand for that interval. The domestic load profile fluctuates on an hourly, daily and seasonal basis [5]. Demand for lighting, for example, is characterized by a daily pattern, varying according to the time of day, i.e. usually highest in the early morning and after dusk. End-uses such as cooling and heating exhibit seasonal variations as accompanying weather conditions impact daylight hours and ambient temperatures.

An energy profile associated with an appliance depicts its usage over a designated period of time, such as a half-hourly energy consumption profile. For DSM interventions and EE initiatives, conventions that apply in the field of Measurement and Verification (M&V) are used to consolidate consumption into half-hour intervals associated with applicable TOU tariffs [15]. Indicators such as Half-hourly Energy Consumption profiles and Cumulative Energy Consumption are typically included in feedback information. Cumulative Energy Consumption, as the sum of the half-hourly energy consumption profile values for a specified period, is reported as kW demand.

Instead of directly measuring demand, daily half-hourly energy consumption profiles can be calculated from knowledge of the appliance's kilowatt (kW) rated value and a user-defined period. Based on the user's choice of appliance, a database query can extract the appropriate kW value and, together with the user's input of start- and end-timestamps, the appliance's energy consumption can be calculated. Proceeding in this way, a daily energy consumption profile over 48 half-hour intervals 00:00, 00:30, 01:00 etc., can be constructed for one or more appliances.

It is conventional to utilize one of two time-stamping formats in M&V, namely forward filling and backward filling timestamps [15]. In the case of forward filling timestamps the associated energy consumption value designates the value for the half-hour starting at the time-stamp value. In the case of backward filling timestamps the associated energy consumption value designates the value for the half-hour ending at the timestamp value [15]. Forward-filling timestamps are used in the application.

Appliance duty cycles

Unlike resistive loads such as lights, toasters and kettles, a number of appliances' operation exhibit cyclic on and off temporal patterns. These cycles are referred to as duty cycles and are features of appliances that typically have an embedded controller such as a temperature control system. Appliances that have duty cycles are for example hot water geysers, air conditioning units, heaters, refrigerators and freezers as well as dishwashers and washing machines. Most of these appliances have, as part of their control system, a thermostat to control temperature. For example, in the case of an air conditioning unit, during the hottest part of the day the unit will remain on for longer and off for shorter periods in order to achieve and maintain a required set ambient temperature [5].

It is important to differentiate between an appliance duty cycle, which is intrinsically part of the operation of some appliances, and a user-initiated usage cycle, as illustrated in Figure 1. When a user switches on an appliance such as a washing machine at 06:15 on a weekday morning in summer, the user has initiated a usage cycle. If that is the usual time that the user uses the appliance on a weekday in summer, a usage pattern or profile can be identified for the particular appliance. On the other hand, once the washing machine is switched on, and depending on its setting, the appliance itself runs through an appliance specific pattern of on and off cycles of variable duration. These duty cycles will vary based on the particular machine's washing, rinsing or spinning cycles.

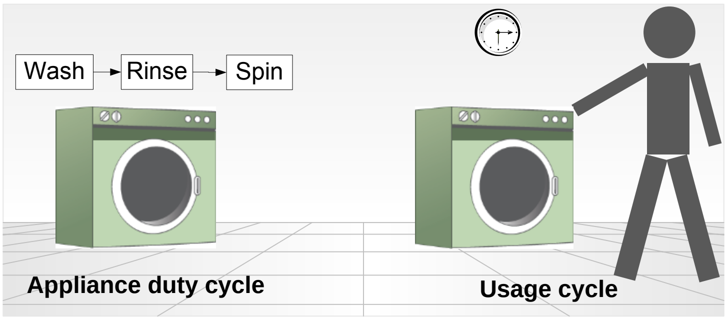

Figure 1: Appliance duty cycle versus usage cycle

To avoid compromising accuracy, the software application makes provision for controlled appliances through the inclusion of duty cycle data in the background as shown in the diagram in Figure 2. Duty cycle data was obtained and stored in a database during a case study in which household appliances were logged to generate event log data.

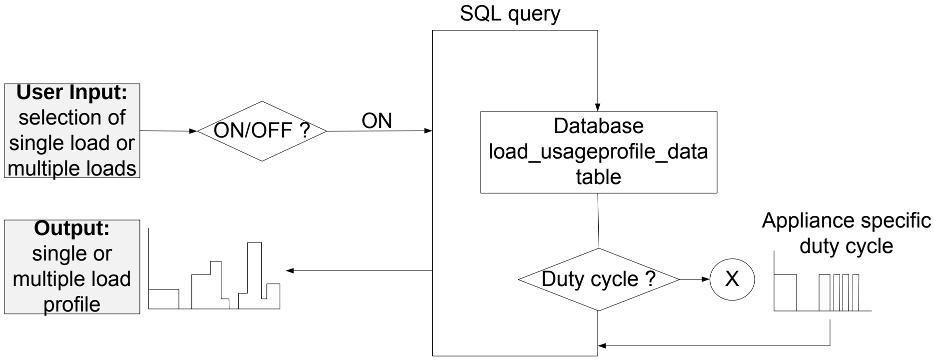

Figure 2: Incorporation of duty cycle data in profiling consumption

Since appliances, such as washing machines and their settings, vary greatly, it is not feasible to establish a universal duty cycle pattern per appliance. Extensive research would be required in order to accumulate such data for all household appliances whose operation display cyclic on and off patterns. However, for a more accurate representation, duty cycle data should be incorporated during the creation of usage profiles of relevant appliances/loads.

Application Development Methodology

Design

The research was aimed at creating a tool to educate an end-user on the benefits of improved energy efficiency through changed attitudes and behaviour. The design philosophy has therefore been focused on the need to extend both information and control to the user by means of a real-time feedback system. System inputs are tailored around the user's specific end-use scenarios with associated load types and energy-consuming activities.

A dynamic application ensures extendibility and ease of maintenance. To achieve a dynamic application, the design is divided into a server side, to provide dynamic content by means of a relational database, and an interactive user interface on the client side, as demonstrated in Figure 3.

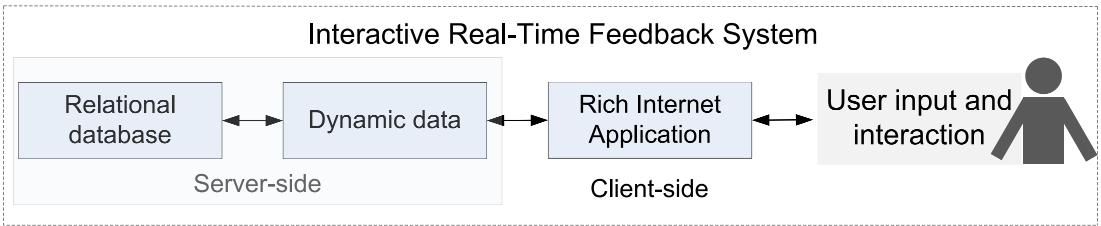

Figure 3: Interaction between the client and server sides

The relational database is structured around end-use categories and appliance types. The database is a data repository associating certain end-uses with certain areas or venues. Accordingly, only those appliances which are grouped within certain end-use categories would be available choices for the user. This logical grouping constrains the number of scenarios which a user can create, as illustrated by the intersection shown in the Venn diagram in Figure 4.

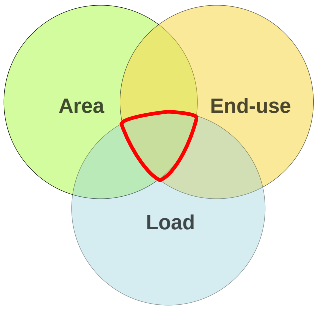

Figure 4: Intersection between area, end-use category and load type

Under normal circumstances, a user will not have a washing machine in a dining room or a microwave in a bathroom. The application caters for the general case, whereby an activity is associated with the most likely venue choice. An end-use category such as laundry is therefore associated with areas such as a kitchen, scullery, garage or bathroom.

Two platforms were used during the development and testing of the application, namely Microsoft Windows and the UNIX/Linux platform with their respective open-source stacks, i.e. WAMP (Windows, Apache, MySQL and PHP) and LAMP (Linux, Apache, MySQL and PHP).

Extensive research was conducted to collect data on common household appliances and their electrical power ratings for inclusion in the MySQL database. For the client side, current web technology was evaluated and the resulting format is a Rich Internet Application (RIA) favouring an interactive, minimalistic design with graphic content. An RIA provides more seamless data exchange and interactive features resulting in a richer user experience than traditional page-based HyperText Markup Language (HTML) applications. The following considerations were taken into account:

- Ease and speed with which to achieve a complex level of interactivity.
- Cross-browser compatibility.
- Full integration with a MySQL database where Hypertext Preprocessor (PHP) can be used as the scripting language to facilitate the data exchange between the client and the server side.

At the time of the application’s development, Flash technology, using the Flex framework, was best suited to achieve the desired functionality, although HTML5 is now making similar features more available. A Flash Player plug-in (downloadable for free) is required, however, the adoption rate is high and if a user’s computer does not have a current enough version, a prompt to upgrade will follow. With regard to future deployment alternatives, Flash content is, however, not supported on all mobile devices. To date, Apple is famously resistant meaning that iPhone and iPad users cannot view Flash content.

Emphasis was placed on designing for the user, otherwise referred to as "User Experience Design", which relies on the implementation of three primary aspects, i.e. Content Strategy, Interaction Design and Visual Design [16]. A number of principles for effective user interface design was originally developed by Molich and Nielsen [17] and since distilled by Nielsen to a set of "Usability Heuristics" [18]. The following four have been considered most significant during the application’s development:

- *Conformation between the system and the real world:* The system design should adopt familiar conventions with which the user can relate. The presentation and ordering of information should appear natural and logical. The design and terminology should be user-oriented as opposed to system-oriented.
- *Consistency and standards:* Ambiguity should be avoided so that users do not have to wonder about the meanings of different words, situations or actions.
- *Enhanced visibility:* Visibility should be promoted in favour of reliance on the user's ability to recall objects, actions and selections. Dialogue and program flow should demonstrate a sense of continuity. Instructions for system-use should be easily perceptible and retrievable as needed.
- *Clear and minimalist design:* Essential and relevant information must be conveyed, since a focus on one particular area or dialogue inadvertently reduces the relative visibility of other areas.

Usability engineer, Donald Norman, cautions against the tendency to increase complexity through the addition of features which in turn leads to a decrease in usability and comprehension [19]. According to Wood and Newborough, a design should establish preferred or optimal display arrangements by restricting features which are not absolutely necessary and organizing and grouping features to broadcast a message of simplicity [20].

Implementation

Interactive features such as drag-and-drop functionality as well as data visualization were implemented to create the concept of a virtual residence that is designed to combine simplicity with a user-friendly, intuitive approach. The development of the application and its Graphical User Interface (GUI) was accomplished by implementing the four usability features within the framework of Content Strategy, Interaction Design and Visual Design as follows:

- Content Strategy:
  - Logical layout and navigation.
  - Graphic content in the form of generic icons.
  - Dashboard presentation with panels and charts.
  - Dropdown boxes with filtered choices based on dynamic database-driven content to reduce typed data input and dialogue.
  - Preserved data integrity and avoidance of SQL injections by keeping user input to the minimum.
- Interaction Design:
  - Rich Internet Application technology with event-driven features such as click events and interactive charts.
  - Drag-and-drop functionality.
  - Dynamic client-server data exchange.
  - Intuitive navigation.
- Visual Design:
  - Use of graphic icons to minimize text and dialogue.
  - Watermarked areas to support recognition rather than recall.
  - Dashboard "at-a-glance" presentation.
  - Data visualization using Flex native charts and 3rd party charting solutions.

The application combines the above design features with the following functionality in a three-tier arrangement whereby the user can perform certain tasks:

- Survey:
  - Create a virtual residence.
  - Conduct an appliance audit in order to identify electrical loads within the residence.
- Analysis:
  - Analyse installed capacity based on different end-use categories.
  - Analyse appliance usage through division of consumption.
  - Select an appliance and assign a daily usage profile to it by determining the times during the day when the appliance is in use. The user can thereby characterize and create a load profile based on appliance-specific usage.
  - View a resultant daily usage profile generated from the accumulated usage profiles of a number of appliances.
  - View a cost analysis by combining the time of appliance operation depicted in the usage profile with a Time Of Use (TOU) tariff structure.
- Educational guidelines:
  - Raise awareness and educate the user through exposure to practical energy efficient guidelines.
  - Educate the user on the load characteristics of common household appliances.

This functionality is summarised in Figure 5:

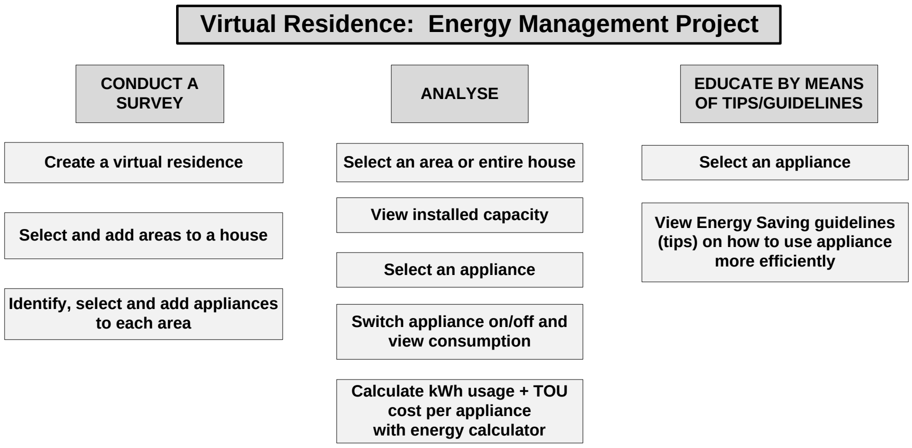

Figure 5: Three-tier functionality of the web application

Figure 6 and Figure 7 present some features of the GUI. Implementation of the concept of "recognition rather than recall" was accomplished by means of a watermarked area within the virtual residence, as illustrated in Figure 6:

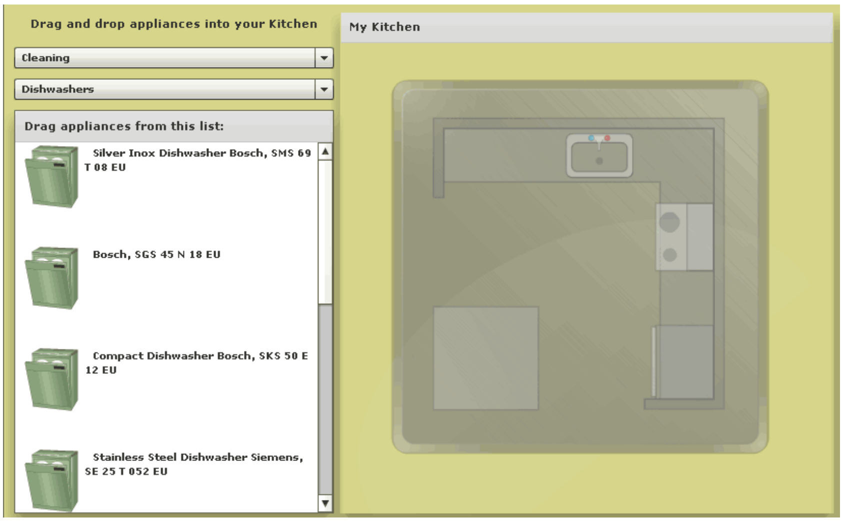

Figure 6: Virtual residence with watermarked area

Figure 7 provides an example of logical grouping for simplicity and disaggregated guided feedback from which the end-user can view installed capacity for a specific virtual venue and for a specific end-use category.

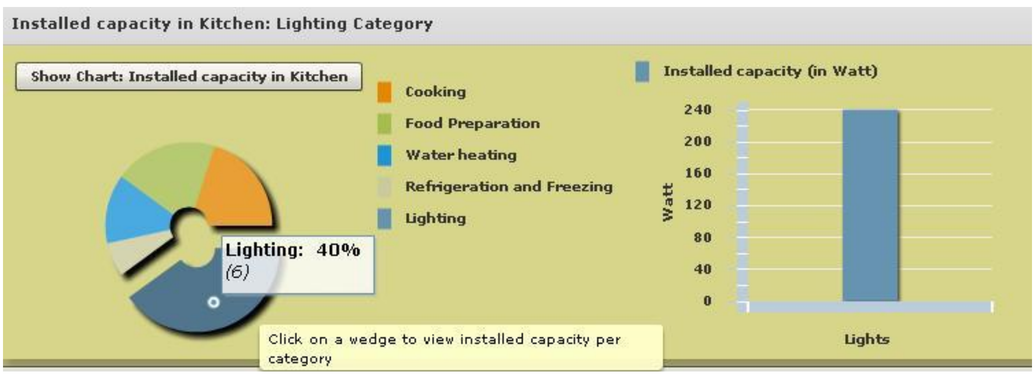

Figure 7: Disaggregated feedback showing installed capacity per venue and per end-use category

User-defined daily usage profiles

Various types of feedback of varying complexity and detail can be utilised by means of data visualisation objects such as charts. The following end-user feedback regarding appliance usage is incorporated in the application:

- ON/OFF daily profile for a specific appliance or load.
- Daily average ON time (as %) per half-hour interval for a specific appliance or load.
- Cumulative daily kW demand for a user-defined selection of appliances.
- Comparative/relative daily kW demand for a user-defined range of appliances over a defined period.
- A daily TOU cost profile per appliance.

The conceptualization of a user-defined ON/OFF profile is shown in Figure 8, whereby a user can define a specific usage pattern per appliance:

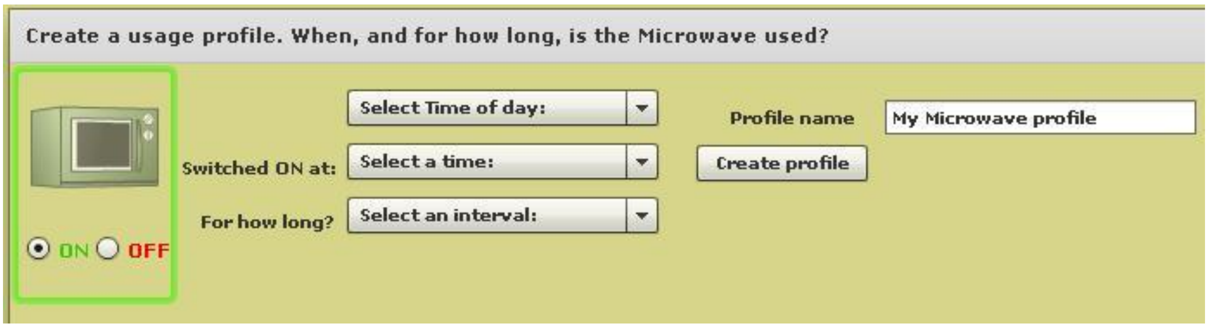

Figure 8: Conceptualization of a user-defined ON/OFF profile

An example of an ON/OFF profile for an individual load is shown in Figure 9 where the ON/OFF cycle is portrayed by switching between 1 and 0. Depending on the choice of appliance/load by the user, duty cycle information would automatically be incorporated into a profile.

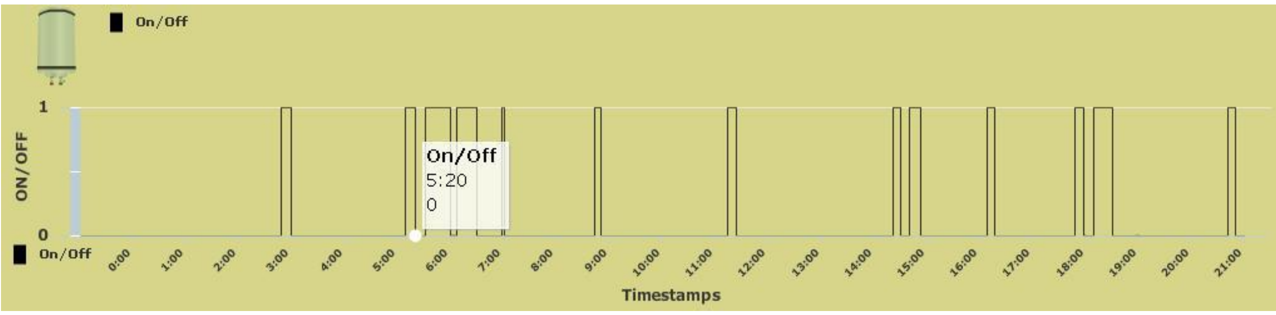

Figure 9: User-defined ON/OFF profile for a geyser with duty cycle information incorporated

As shown in Figure 10, the user can be provided with feedback on the average daily ON time (as a percentage) for one or more user-selected appliances.

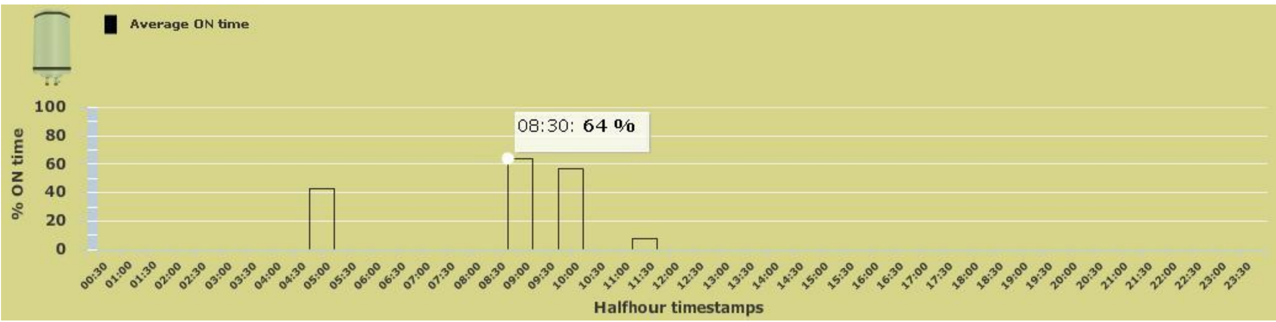

Figure 10: Daily average ON time (%) per half-hourly intervals for a geyser

Figure 11 shows feedback in the form of cumulative kW demand for one day for a selection of loads:

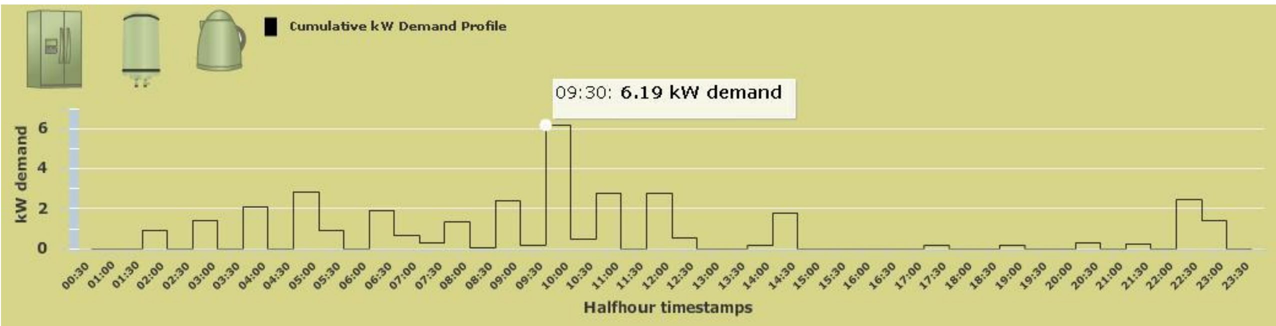

Figure 11: Cumulative daily kW demand for three user-selected appliances

Figure 12 portrays feedback in the form of a grouping for three consecutive days so that the user can compare relative demand for a user-defined set of appliances/loads.

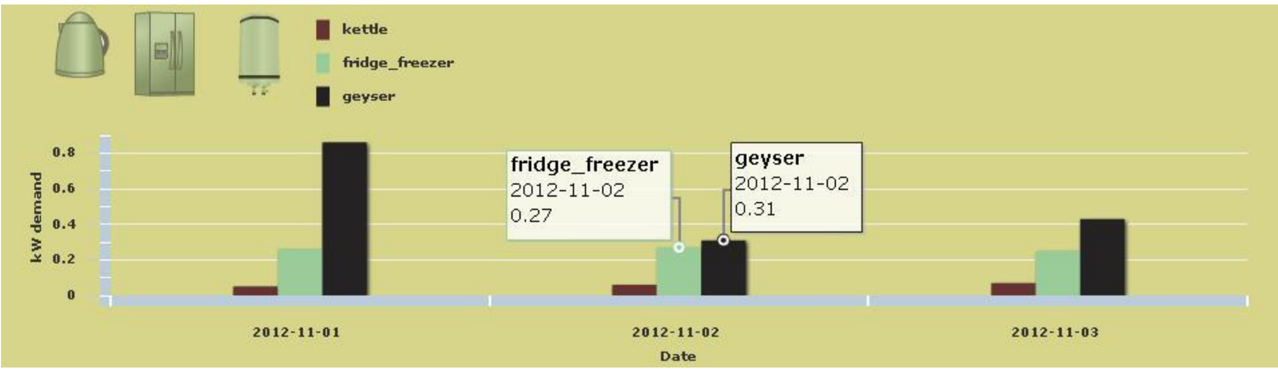

Figure 12: Three-day comparative kW demand for a user-defined set of appliances

The TOU pricing scheme applicable for suburban South African residential consumers will be phased in once advanced metering infrastructure is in place [3]. Based on the TOU pricing scheme, the following functionality, shown in Figure 13, is included in the application tool to provide user feedback in the form of a cost analysis and encourage appliance scheduling.

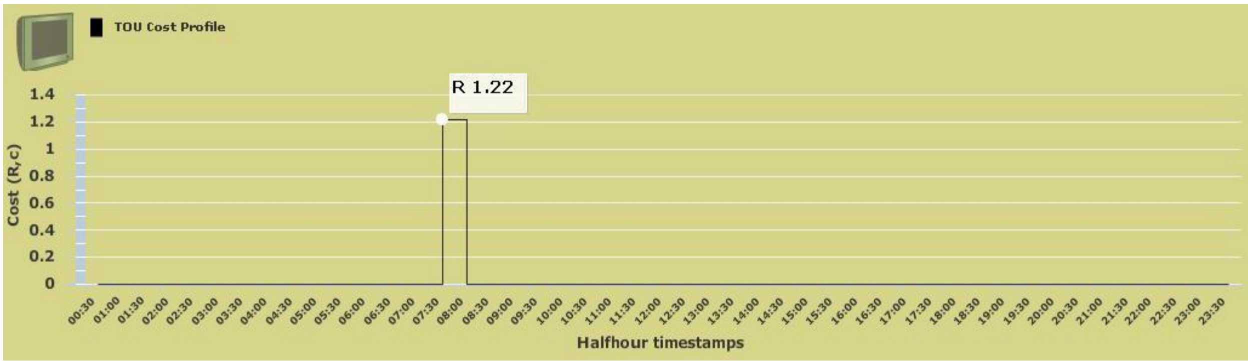

Figure 13: User-defined TV usage and TOU cost profile for one day

Test case

The web application was applied to a middle-income residence within the Stellenbosch municipal area in the Western Cape. The household consists of four members, namely two adults and two children. A virtual residence was created followed by an appliance audit per area/venue in order to establish both an area inventory and a loads inventory. The analysis features were tested and usage profiles were generated for a number of the appliances. As recommended in the next section, assessment on two different levels is required, i.e. testing of the technical features and market research.

Conclusion and recommendations

Active participation by consumers to improve EE requires some form of intervention to educate and raise awareness. The paper has promoted the use of a feedback system as a tool to transfer knowledge and control to the end-user to reduce energy consumption and improve efficiency. The research outcomes have been the product of an investigation into various technology and display options in order to ensure the presentation of fairly complex functionality in the simplest, most intuitive fashion. The resultant feedback interface has been a web application in the form of an RIA to present the end-user with relevant information. Dynamic interactivity has been achieved through the development of a relational database on the server-side.

Recommendations

Further development and ongoing research would be required in terms of the database to ensure up-to-date, comprehensive content with regards to common household appliances.

It is proposed that the application's technical features are reviewed by releasing a beta version of the application to a selected focus group. Based on the outcome, an iterative software development process will follow to prepare a version for the next phase of testing.

A test group, representative of the South African population, would need to be identified to use the application as part of a survey in order to evaluate aspects such as:

- How is the application received by a varied group of end-users?
- Is the application's design and layout user-friendly and intuitive?
- How effective are the educational guidelines and real-time feedback for end-users to make sensible consumption decisions?
- Can the application meet the overall objective of encouraging consumers to reduce consumption and adjust their usage patterns by, for example, scheduling appliances?

Evaluation of adjusted consumption patterns can be accomplished by comparing the test group to a control group who have had no exposure to the application.

Based on the outcomes of the evaluation stages, it may be worthwhile to investigate the creation of a mobile application or "app" in order to migrate to a mobile platform in addition to the web platform. Incorporating the application with technology employed in smart metering could also become a consideration in order to interface with smart systems.

The impact of home energy feedback displays and load management devices in a low energy housing development

D.M. Whaley, S.R. Berry, W.Y. Saman

Barbara Hardy Institute, University of South Australia

Abstract

Home energy feedback display and monitoring systems are a key feature of Australia's leading eco-friendly housing development at Lochiel Park in South Australia. The displays comprehensively measure electricity, gas and water usage in real-time, and can manage loads during periods of peak electricity demand. The houses are designed to be near net zero energy homes and incorporate a high performance building envelope, roof-mounted photovoltaic panels, solar water heaters and energy efficient appliances.

The paper describes the display and monitoring systems, summarises samples of delivered energy results for selected households, and the average for Lochiel Park. The results show that despite living in similarly constructed houses, often with the same number of occupants, there are significant monthly and annual variations in net delivered energy.

In addition, this paper draws on a series of in-depth interviews to discuss the residents' attitudes towards, and experiences interacting with, the in-home feedback display and associated energy systems, and describes how feedback displays may assist residents understand their end-use energy behaviour, reduce their net energy use, and assess whether household appliances and energy systems are operating correctly.

The interview responses reveal a mostly positive attitude to the energy feedback displays, but a generally negative attitude towards the load management system. This negative response may be due to the lack of perceived benefits from such a device, and a poor understanding of how to operate this feature. Finally, this paper outlines the residents' suggestions for improving the energy feedback monitoring systems.

Background

Evidence presented by world leading climate scientists is showing that anthropogenic greenhouse gas emissions has reached the level which is altering the global climate, and continued high use of carbon based fuels will further exacerbate the problem [1, 2]. Leading economists have suggested that human impact on the global climate is one of the greatest economic, social, political and environmental challenges facing this generation and our immediate future generations [3, 4].

In most developed nations housing has evolved to the degree that households expect high levels of thermal comfort, the convenience of an almost endless supply of electricity available at the flick of a switch, and hot water on demand, irrespective of the environmental impact of making that energy available [5]. Increasing demand for thermal comfort and other energy services around the world, combined with factors such as increasing population, all contribute to a continuing upward trend in energy demand [6]. Housing expectations and cultural norms, embedded institutional construction practices, regulatory standards and dominant technologies have evolved without due consideration of the resultant ecological footprint [7]. What we build, the appliances we install, and the way we operate our buildings is the result of many social, economic and technical influences, such as the cultural institutions that shape communities, the technology norms applied by industry, the education and training of actors that meet market demand for new housing, and the experience of households that demand and use new residential products [8]. This interaction of actors, institutions, rules and technologies over many years has brought us to the point where housing in many nations has a significant negative impact on the local environment and the global climate [9].

Concern for anthropogenic greenhouse gas emissions has prompted individuals, communities and governments in many countries to consider reducing building energy use and thus lowering the carbon impact of the building sector [6, 10]. Researchers and government agencies alike have suggested that improving the energy and carbon performance of residential buildings will play a key role in delivering substantial and sustainable greenhouse gas emission reductions in developed economies [11-14]. This energy and carbon emission reduction will likely be the result of changes in the technology applied to buildings, changes to the design of buildings, and changes to the way we operate our buildings and appliances [15].

Responding to concern over building energy use and residential greenhouse gas emissions, the South Australian Government chose to showcase the cutting edge of climate relevant sustainable urban development by creating Lochiel Park, a model green village of national and international significance [16].

Creation of Lochiel Park

The Lochiel Park Green Village is a planned estate of 106 residential dwellings, created though the policy initiative of the State Government of South Australia, with estate design and management by a government agency, infrastructure and housing constructed by the private sector, and the majority of dwellings sold to the general public through the local real estate industry.

Located on 15 hectares of surplus government land, approximately eight kilometres North-East of the Adelaide central business district [17], the development was originally intended to be disposed to the property market as a standard broad-acre land sale of 150 residential allotments, but a change of state government introduced new policy objectives including an increased interest in environmental outcomes [18]. This resulted in the Premier of South Australia declaring in 2004 of the project's new intent [18]:

> "I want South Australia to become a world leader in a new green approach to the way we all live. The Lochiel Park Development will become the nation's model 'Green Village' incorporating Ecologically Sustainable Development (ESD) technologies."

Given explicit direction from the State Premier to develop a niche green urban estate of world standing, an advisory panel of state and local government officials and community representatives was established to define high level objectives across a relatively broad range of areas including environmental sustainability, social sustainability, urban form, transport, industry development and economics [17]. By benchmarking against major international and national niche green residential developments, performance targets were set covering potable water, open space, water recycling, energy technologies, revegetation, solar passive design, waste reduction and management, designed building life span, local transport use, community interaction, and many other impacts. These detailed targets were refined in consultation with the various expert groups [18], with final design overarching targets set at a reduction of:

- 66% energy used
- 74% greenhouse gas emissions
- 78% potable water use

Expert consultative groups for energy and water were used to translate the original targets into rules and guidance materials that could communicate the desired sustainability principles to be applied to each house. These were published in the Urban Design Guidelines [19], with minimum requirements including:

- 7.5 NatHERS Stars thermal comfort[1]
- Solar water heating, gas boosted
- 1.0kWp photovoltaic system for each 100m^2 of habitable floor area
- High star rated (highly efficient) household appliances
- Low energy lighting (CFLs & LEDs)
- Ceiling fans in all bedrooms and living spaces (to promote air movement)
- Rainwater harvesting feeding the hot water system
- Treated storm water feeding toilets, cold laundry taps and irrigation
- An in-home energy use feedback display (in a location that encourages resident interaction)

The Guidelines established a new set of rules, calling for practices outside existing institutional and professional norms, requiring the application of technologies and systems uncommon to the mainstream building industry, and the consideration of new performance indicators bringing new concepts to building design and construction practices. These Guidelines meant that households were exposed to different technologies and styles of house design compared to new dwellings commonly available in South Australia.

Upon the release of the Guidelines, housing product was offered to the open market in 2007 with construction of the first homes beginning in 2008. The majority of the housing allotments had been sold by mid 2011, and the majority of the homes completed and occupied by late 2012.

[1] The star rating indicates the dwelling's predicted annual heating and cooling requirement to maintain human thermal comfort, which is determined by a computer program that considers the dwelling's fabric and form, and assumed user behavioural patterns for a nominated climate year (see www.nathers.gov.au). A star rating of 10 means that that no external heating or cooling is required, whilst a star rating of 0 means that the building shell does practically nothing to reduce the discomfort of hot or cold weather.

This paper provides an insight into the energy performance of this green village, and in particular examines the effectiveness of in-home energy feedback displays in encouraging behaviour change. The paper is structured to provide a short review of the academic literature on the use and effectiveness of energy feedback displays, discuss the methodology and monitoring systems used in Lochiel Park, explore the energy performance of the development, and examine the findings from the in-depth household interviews.

Literature Review

Energy use feedback typically exists in the form of periodic energy bills or through the need to gather and prepare fuel for cooking, heating and cooling or lighting. In developed and many developing countries, energy use feedback is often provided by regular bills based on metered consumption or predicted consumption of electricity, gas or liquid fuels. This feedback process is temporally removed from the day to day energy services that are responsible for the energy use, with billing intervals often monthly, bimonthly or quarterly. Metered bills typically show cumulative consumption over the billing period and are very unlikely to disaggregate consumption by end-use or time, while bills based on estimated consumption prevent households from recognising any relationship between energy services and energy use [20]. More recently, complex real-time of use information, even disaggregated to typical end-use, has become possible via computers, mobile phones, and other portable devices [21].

Readily accessible energy use information for households has been found to facilitate experimentation, encourage learning and support good energy management practices, but while feedback is necessary for the learning process, feedback on its own may not be sufficient to bring about behaviour change [20, 22]. Darby [20] notes that energy use feedback has an educational impact as well as directly impacting behaviour, facilitating a greater consumer understanding of the relationship between energy services and energy use.

Energy feedback is not limited to the provision of energy use information. The recent acceleration in the uptake of domestic rooftop solar photovoltaic panels by the general public has meant a more widespread distribution of electricity generation and household tracking of energy generation data. Evidence is available demonstrating that building-integrated electricity generation with feedback displays can lead to energy demand reduction [23, 24].

A number of studies have identified energy savings associated with the use of in-house energy feedback displays [20, 25-28], with the energy saving impact of feedback technologies varying modestly across the literature. Ueno et al. [27] monitored the energy use of 8 households in Japan pre and post the installation of an in-home interactive feedback display, finding an average 9 per cent energy saving in the first two months after installation. Darby [20] summarised the results of various feedback studies and noted that savings of between 5 to 15 per cent were associated with direct feedback displays. Faruqui et al. [25] examined a dozen North American and international pilot programs and found that energy savings range from 3 to 13 per cent, with an average of 7 per cent. Ehrhardt-Martinez et al. [26] reviewed 23 mostly North American programs and found that energy savings associated with real-time aggregate feedback typically fall somewhere between 0.5 and 18 per cent. Stromback et al. [28] investigated 74 energy feedback trials in Europe, North America, Australia and Japan reporting average savings of 8.68 per cent for in-home displays.

The amount and type of displayed information are important factors in the success of achieving energy savings [22, 26, 29]. Darby [22] and Ehrhardt-Martinez et al. [26] have found that ‘direct’ feedback, such as real-time energy use data, has a significantly larger impact than ‘indirect’ feedback, such as billing data provided after consumption has occurred. Ehrhardt-Martinez et al. [26] and Fischer [29] argue that greater savings occur when information is more frequent (current) and more detailed (disaggregated).

Ehrhardt-Martinez et al. [26] also noted a relationship between the energy savings impact of the study and the period of householder interaction with feedback information, finding that average energy savings tend to be higher for shorter studies (average 10.1 per cent) than for longer studies (average 7.7 per cent). This raises the issue of sustainability for energy use behaviour change due to direct feedback systems. Ueno et al. [27] found that energy saving behaviour extended beyond the technology associated with the direct feedback information, demonstrating that in-home feedback displays help householders become more energy literate and develop new behaviour patterns. For the small sample of houses in their research, Ueno et al. [27] found that total energy use of the appliances displayed on the feedback system was reduced by about 12 per cent whilst the total consumption of the not-displayed appliances was reduced by about 5 per cent.

The literature also identifies different levels and types of energy savings. Ehrhardt-Martinez et al. [26] found three categories of action: 1) simple changes in routines and habits, 2) infrequent and low-cost energy stocktaking behaviours (i.e. replacing incandescent bulbs with CFLs), and 3) investments in new energy-efficient appliances, devices, and materials. The study noted that most of the energy savings achieved through feedback programs resulted from changes in behaviour rather than investments, although greater savings were achieved by those households that invested in new technology.

The literature shows that households can react quite differently to the availability of energy use feedback data [30]. In a study of various in-home feedback display devices in Sweden, Vassileva et al. [30] found that 47 per cent of the participants interacted with the display quite often, while 19 per cent of the participants never consulted it. This study also found that the use of energy feedback displays with low-energy use households might, in some cases, cause an increase in energy use.

The Australian specific research into the effectiveness of in-home energy feedback displays is reasonably limited with results available from only two small-scale surveys, both of which are limited because the sample households were in the early stages of interaction or had virtually no experience interacting with the newly installed technology [31, 32]. This paper provides an opportunity to survey a larger group of households, most with multi-year experience interacting with in-home energy feedback displays.

Methodology

This research was based on the analysis of quantitative data collected from installed monitoring systems, and the analysis of qualitative data collected from interviewing 10 resident households living in Lochiel Park.

Resident Interviews

To understand the experience and perceptions of residents, primary qualitative data was gathered through a set of 10 in-depth interviews, with residents selected at random from a field of over 60 candidate households who had lived at Lochiel Park for a period not less than 12 months. All volunteer households were owner-occupiers, who represent the largest resident type at Lochiel Park. Where possible all adult owners of the same household were interviewed together, but where this was not possible prompts were used to enquire into any differences likely between the adult residents. For households with children, additional prompts were used to enquire into their likely usage of the energy feedback display.

The semi-structured interviews [33], conducted ‘face-to-face’ in their home, utilised open-ended questions to provide a replicable focus on the research questions, and were designed to explore the experiences and perceptions of households.

The questions probed the experience of residents during the home buying and construction phases, their perception of thermal comfort and ease of operating a passive solar home, and their experience interacting with new energy technologies such as solar photovoltaics, solar thermal water heaters and the energy feedback displays.

To protect the confidentiality of the interviews, anonymous verbatim quotes are used to illustrate points. Elsewhere the original language used by interviewees has been incorporated into the paper, or paraphrased with a light touch to facilitate the clarity of the message.

The information collected from the interviews was triangulated through a comparison with the experience of the principal authors, who have interacted with almost all potential candidate households at Lochiel Park on related energy use research. The researchers have informally discussed the use of the feedback displays with residents separately, sometimes on multiple occasions. These interactions have been used to test whether the sample survey results are representative of the experiences of the total potential population. Comparisons are also made with the findings of the 2010/2011 series of Lochiel Park residents’ interviews and an associated survey [32]. This series of interviews was conducted during the early stages of the development of Lochiel Park when only around a quarter of the homes were occupied, and during a period when many residents were still establishing their household routines and behaviours, but nevertheless these interviews provide a valuable comparison with the more recent series of interviews.

Overview of Lochiel Park Monitoring Systems

The data presented in this study is based on monthly analysis of one minute interval data collected from the in-home displays installed in each Lochiel Park dwelling. Although the systems collect electricity, gas and water use, and electricity generation information, the focus of this paper is on individual household delivered energy, i.e. the difference between the onsite energy consumption and that generated onsite.

Each home is fitted with an ‘EcoVision’ brand monitoring system, which incorporates an in-home display, a programmable logic controller, and an array of intelligent meters and sensors [34, 35]. This monitoring system measures and displays the residents’ electricity, water and gas use, plus solar photovoltaic electricity generation, in real-time. This level of monitoring is referred to as *general* in the data reported in this paper. In addition, other information are monitored in 10 of the houses, such as the indoor air temperature and relative humidity, the electrical consumption of up to eleven energy services (including heating and cooling, lighting, laundry, etc). This is referred to as *detailed* monitoring. Table 1 summarises the data measured by each monitoring system. Detailed information is available in [34].

Table.1: EcoVision measured and calculated parameters for the general and detailed monitoring systems. Note (D) indicates digital, (A) represents analogue (4-20mA) sensors [35].

	Electricity (kWh)						Water (L)					Tank Level (%)	Gas (L)		GHG (kg)	Temp / RH
System	Solar (D)	Import (D)	Export (D)	Total*	Net*	Individual appliances (D)	Mains (D)	Recycled (D)	Hot Usage (D)	Mains Hot (D)	Rain*	Volume (A)	Mains (D)	Hot Water (D)	Greenhouse Gas Emissions*	Living , Lounge, Bed rooms (6 A)
General	✓	✓	✓	✓	✓	×	✓	✓	✓	✓	✓	×	✓	×	✓	×
Detailed	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓

A detailed monitoring system schematic is shown in Figure 1. The figure identifies the EcoVision touch screen, the programmable logic controller (PLC), the optical network terminal (ONT), the contactors, the interconnecting cables, and the various analogue and digital sensors. Note that an overview of the general monitoring system can also be seen in the figure, due to the common components (i.e. the 8 digital sensors surrounded by the dashed box). Raw data from each system is collected remotely each month.

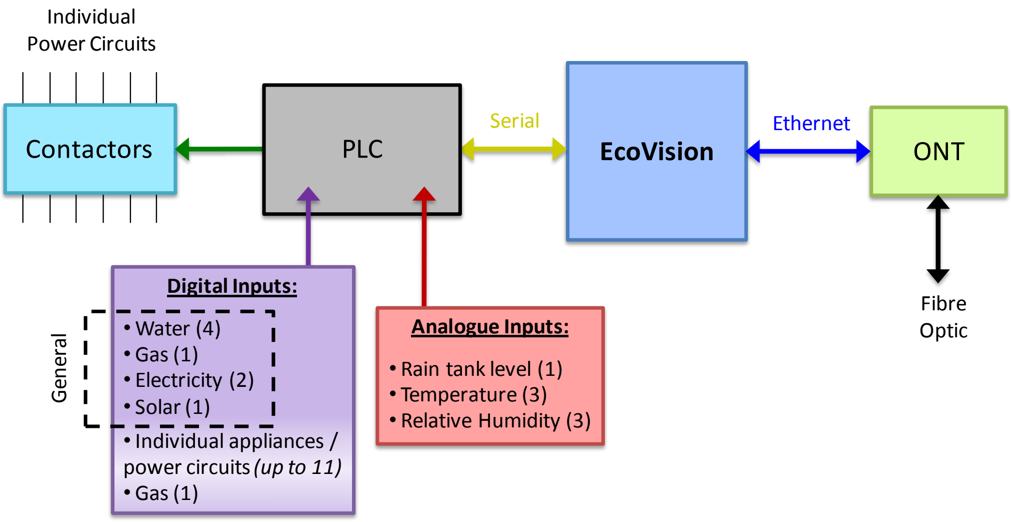

Figure 1: Overview of the detailed monitoring systems, showing various components. The dashed box represents the sensors used in the general monitoring system [35].

The system can also control the peak power demand by limiting it to a preset value. A feature of the EcoVision monitoring system allows peak energy demand events to be managed by interrupting the power supply to up to 6 individual power circuits or appliances by controlling specific contactors. The contactors are typically wired to appliances such as reverse-cycle air conditioners; pool or spa pumps; ovens and dishwashers, and power circuits such as laundry and kitchen, but not systems important to health and safety such as lighting and refrigeration. The load limit and the order in which appliances are deactivated are customised by the resident. The feature shuts down nominated appliances until the electricity load falls below the preset limit. Due to safety reasons, deactivated appliances are not automatically re-energised; this must be done by the resident manually. The Load Management feature is voluntary, and to encourage initial uptake the electrical retailer offered a small financial incentive to residents who maintained a 3kW limit at all times, however, this incentive is no longer available.

The heart of the EcoVision system is the in-home display which offers residents direct feedback, and real-time monitoring. The touch screen allows users to quickly summarise their consumption by time period and type of fuel / water, for any desired hour, day, week or month. Data is displayed numerically as well as in bar charts. The *detailed* monitored systems also offer a small degree of electrical energy consumption disaggregation, by breaking down how much energy is consumed by specific appliances or power circuits. Figure 2 shows a summary of electricity consumption and generation for one day.

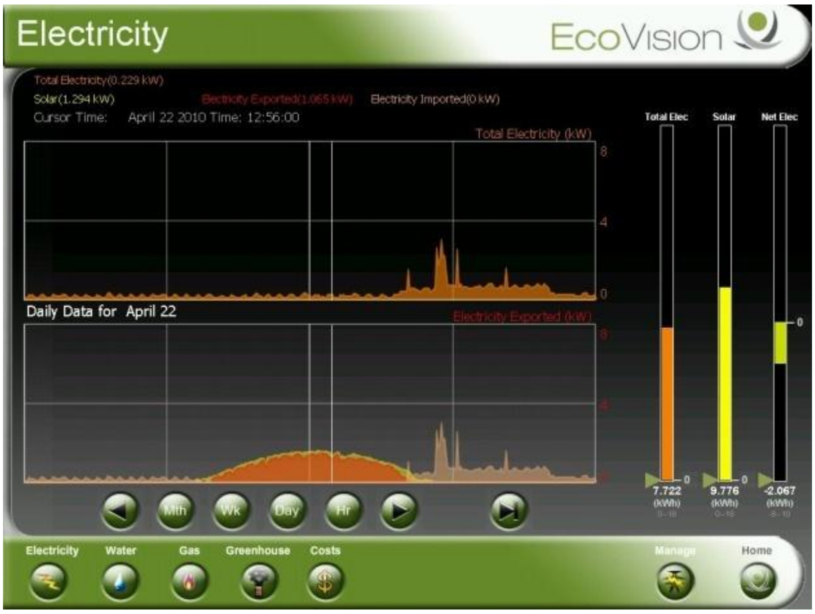

Figure 2: EcoVision screen, showing electricity consumption and generation for a period of one day.

The EcoVision system not only provides real-time information, it also allows users to compare their energy use and generation historically by month, week, day or hour. It also has the capability of converting the energy consumption to associated greenhouse gas emissions. Currently the system does not allow residents to directly compare results against other residents' usage or estate averages.

The EcoVision system consumes about 38W continuously (0.92kWh per day). This means that an amount of behaviour change is required before the system is of net energy and economic benefit to households.

Energy Performance of Lochiel Park Homes

Figure 3 shows the average delivered energy for the entire estate over a 12 month period. The dashed blue line represents the estate's average, and shows the monthly standard deviation as vertical bars, whilst the red dots represent the average of the households interviewed in this study. The close agreement between the two averages indicates that the interviewed households are broadly representative of the estate as a whole. Note the number within the round brackets of the x-axis represents the number of households within the estate for which data is available to calculate the average. This number generally increases over the monitoring period as newly constructed houses are connected to the monitoring system, however, in some instances the number slightly decreases due to intermittent data collection system problems.

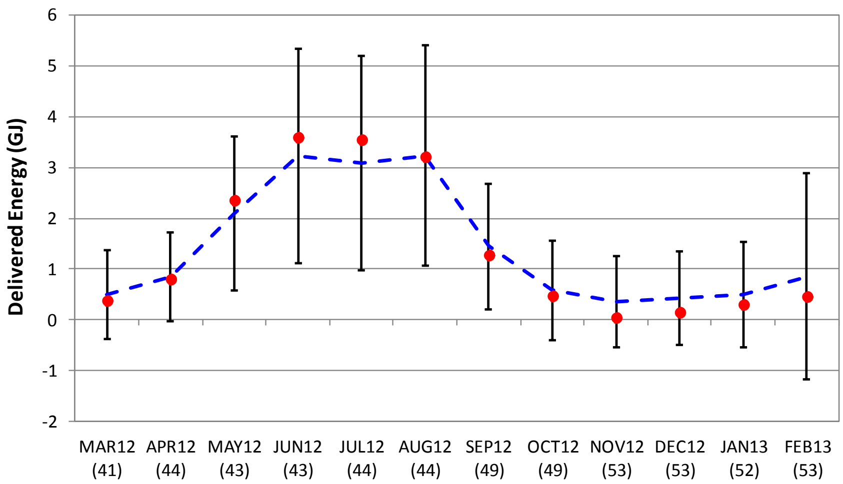

Figure 3: Average monthly delivered energy for Lochiel Park households (blue dashes), and for the subset of interviewed households (red dots).

Figure 3 also highlights three key features. Firstly, some Lochiel Park households are operationally net zero or below zero energy for summer months and those months immediately pre and post summer. Such a result demonstrates the successful application of low energy house design and fitout for temperate Australian conditions. Secondly, the average of the interviewed households is similarly zero or near net zero energy for those months. Thirdly, the large standard deviation span, particularly for winter months and late summer (February), indicates that there is a significant spread in net delivered energy for some households. This is despite the many common design and resident characteristics and energy system fitouts.

Figure 4 below shows the net delivered energy per month per resident for each of the interviewed households. After normalising for the number of residents in each household, the monthly delivered energy varies significantly between households, possibly indicating different energy consumption behaviours and/or the impact of differences in patterns of use and efficiency for particular appliances and equipment. In general, each house follows the same trend of higher delivered energy in winter months, most likely due to a combination of significantly lower solar photovoltaic electricity generation, higher artificial lighting use, and higher heating demand. Note that some of the interviewed households are missing data points, due to intermittent monitoring system faults.

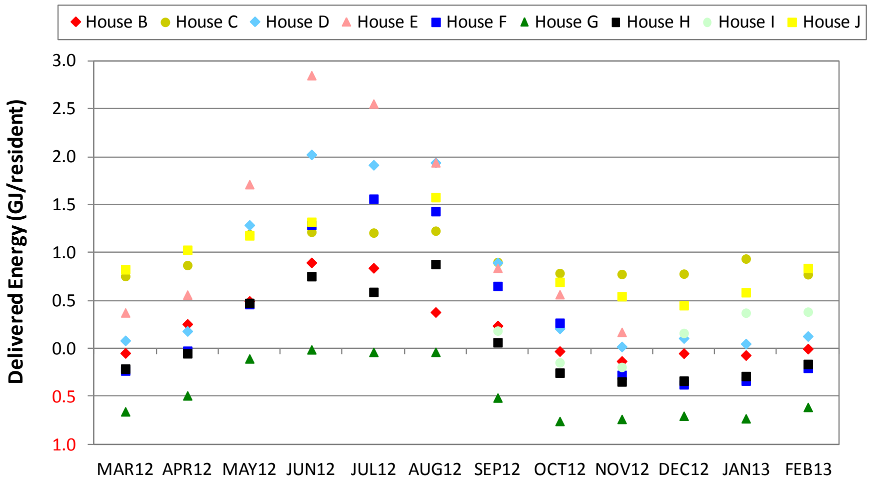

Figure 4: Normalised average monthly delivered energy per resident of the interviewed households.

Figure 4 shows that three of the interviewed households achieve below zero delivered energy for six months of the year, whilst another achieves this for five months. In addition, the figure highlights two key features: firstly, Households D and E require higher amounts of delivered energy in the winter months. This is probably due to use of gas space or underfloor hydronic heating, whilst the remaining households utilise reverse-cycle air conditioners with a high coefficient of performance. Secondly, Household G consistently achieves operationally net or below zero energy performance. This is probably due to the combination of frugal energy use, an all-electric house with high efficiency appliances, and a relatively large solar photovoltaic system to offset expected electrical loads.

Comparison with other Households

Although the results from Figures 3 and 4 demonstrate that some Lochiel Park households require near zero delivered energy for either part or full year periods, the performance of these households should be compared with other existing data sets for similar homes and similar climates to properly gauge their performance. Figure 5 compares the delivered energy of the interviewed houses per habitable floor area, with existing data collected by the research team for a nearby new housing estate (Mawson Lakes, MLK) in 2002/03, and with current state (SA AVG) and Australian (AUS AVG) national averages [34]. Note that the total delivered energy for Houses E, I and J has been extrapolated to correct for incomplete data sets.

Figure 5 demonstrates that Lochiel Park households require significantly less delivered energy compared with the monitored sample of new homes from the Mawson Lakes estate, and compared to both the state and national averages for all households (including apartments, units and holiday homes).

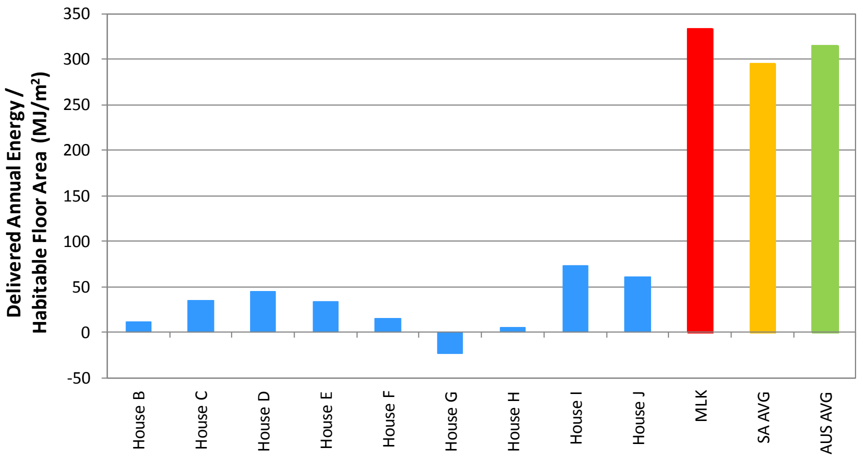

Figure 5: Delivered annual energy per habitable floor area for the interviewed households, a sample of Mawson Lakes households, and both state and national averages.

Interview Findings and Discussions

The level of interaction between the households and their in-home energy feedback display varies widely from no engagement, to occasional use, to multiple daily interactions. Differences can be observed across gender and age, with females less likely to use the display, and older (retired persons) less likely to have high frequency (daily) interaction with the feedback system.

The majority of households (6/10) had daily interaction with the feedback display, 3/10 households had occasional interaction and one household never interacted with the display. These figures hide differences between genders, whereby almost all male adults (9/10) interacted with the feedback display, yet 4/10 female adults stated they had no regular interaction with the display. The response from Household E characterises a reasonably typical level of interaction with the feedback system:

> *I think it's useful, I value having it there, I look at it most days.*

The frequency of interaction is slightly lower than that noted in the previous study [32], which found 80 per cent had daily interaction, but this may be explained by the novelty of the system wearing off with residents. Our research found a perception that use patterns have changed since the initial period of interaction, with half of the households suggesting they use the display less now than in the first 12 months of having the system available. One household felt that they have increased their usage of the display as they have grown more comfortable and confident using the system and the information provided. Household H represents the majority perception of usage changes, stating:

> *Less, a lot of it's the curiosity and learning the patterns of our usage.*

The Edwards and Pocock [32] research was conducted during the first months of occupation for the first tranche of Lochiel Park households, and changes to interaction frequency have most probably occurred as households settle into their new home, lose some of the initial curiosity with the display, and become more familiar and comfortable with the various energy technologies and the pattern of their use.

Very few households (2/10) keep detailed tracking of daily energy use and electricity generation, manually transferring data from the feedback display to separate spreadsheets. Other users more casually track energy use and electricity generation. Household J used the monitored energy data to help predict the size of their next energy bill. Household B represents a high frequency user, revealing:

> *'I love the touch panel. I keep an ongoing spreadsheet of all our daily solar generation and electricity usage.'*

Most higher frequency users asked for wireless local area network or Bluetooth compatibility to allow data downloads to other devices. Almost all households (9/10) considered some value in having the feedback information available on other devices such as mobile phones, tablet or laptop computers, particularly so data could be checked when residents are away from the house (i.e. at work or on holidays). Some households suggested greater value could be gained from the feedback displays if they could facilitate other activities such as linking to the internet, or allow settings for their solar water heater to be altered. Some users expressed frustration that variables such as energy prices and the time-clock could not be altered by residents, reducing the accuracy and usefulness of the output information.

The feedback displays were most often used for checking electricity usage, electricity generation from the solar photovoltaic system, and to a lesser extent, water usage. The residents of a detailed monitored house also monitored the amount of water available in the rainwater tank, using their display. One household found the gas data confusing. Household B expressed a desire to use the data to track the deterioration of photovoltaic panels over time. The monitored data was also used for fault identification, with five of the households mentioning how the in-home feedback display was helpful in identifying system failures or underperformance. For example: Household F checks the solar generation data on a regular basis to ascertain whether their DC/AC inverter is still operating, as a response to the original inverter burning out.

Several households thought that comparing their energy and water use with others in the Lochiel Park estate would be useful. Household C suggested a creative competition to encourage behaviour change by having an energy use challenge across the estate, with households able to see the energy use patterns of other Lochiel Park households.

Most households (7/10) felt that the system was easy to use, although comments were made from some who felt the software was not intuitive. This finding is similar to that of Edwards and Pocock [32] who found 80 per cent of households perceived the feedback displays to be easy to use. Household C provides a typical response to the question of ease of use:

> *Yeh, not a lot to it really.*

Several households suggested that some of the information provided was confusing, particularly the time axis information which doesn't show the actual time of use. This may limit the user's ability to recognise the relationship between specific technology use and energy use. Household H stated:

> *On the timescale it's not registering the time of day, so I can guess when the graph timescale is. I can see the beginning of the day and end of the day …*

Few (3/10) households had attended a training session, with 6/10 suggesting that either more guide material or training would be useful.

The Load Management feature of the system was not being used by any of the households. Many households thought that feature was no longer operating, others thought the feature was of little value to them for they were already very energy efficient. Household B did not use this feature because they wanted to maintain control of all electrical appliances and equipment. Household E had used the feature but found it 'useless' after it turned the washing machine off when they needed the clothes washed. Household G attempted to use the feature without success. Household I thought it was 'conceptually fantastic, but not a good feature at the moment', and referred to a negative experience of another Lochiel Park household that was not interviewed in this study. Household F was typical of responses to this feature:

> *[person's name] did mention that and explained it somewhat, but we haven't sort of run into that territory where we've been motivated to need to do it, …*

The majority of households (7/10) believe they have modified their behaviour due to their interaction with the feedback system. And although the quantum of behaviour change could not be determined with any confidence through the interview process, two of the households suggested their behaviour changes were relatively small, but others have achieved larger savings. Household D noted that they disposed of an old second refrigerator because it used too much electricity for the pleasure of providing cold drinks. When asked about behaviour change Household J felt the feedback system had been instrumental in helping them alter their energy use behaviour:

> *Yeh, definitely; the last two billing periods we have really examined what we using and how we are using it and have made some significant changes.*

Other households were not as positive about the affect of the feedback display of their energy use behaviour. Similarly Edwards and Pocock [32] found that some households considered their behaviour to be reasonably energy efficient and suggested that their behaviour would not be greatly affected by the feedback display. This type of response was identified in our interview series, with Householder I stating:

> *'We're here because we already were wary of our behaviours, we had already taught ourselves to conserve power .... Our behaviours had already changed, and they go on changing as we read more and we live in our house, but the screen is not part of that.*

The displays provided a variety of other benefits. Several households noted they use the feedback data to maximize their economic return from the local solar feed-in tariff, by reducing electricity use during photovoltaic generation hours and maximising export to the grid when electricity is at its highest value. Household C has used the feedback display to determine the energy use change associated with installing standby-load reduction technology.

The display was also being used as an educational tool, both to other members of the household and to visitors. Both Households D and G noted the value of showing the display to visitors.

An issue expressed by many households was the importance of service to maintain and repair the in-house feedback system. Several households talked about sensor faults, poor levels of response from the display provider, the slow process for software upgrades, and the lack of technical support. Household J raised the question of whether the system will be maintained for the life of the house.

Overall the value of the in-home energy feedback system is reflected in the number of households that wish to have a system in their next home. Six out of ten households suggested they would like a feedback system in their next home, although not all wanted the same brand of monitoring system, and one household qualified the response with concern about the system's affordability. On the whole there was sufficient interest to suggest the majority of households valued having live energy use and electricity generation monitoring in their home.

A larger sample of Lochiel Park households will be interviewed or surveyed to gain further understanding and insight into the experiences of residents and their in-home energy feedback displays. The larger sample size will facilitate a broader range of both quantitative and qualitative analysis investigating relationships between energy usage and other factors, such as demographics, frequency of interaction with displays, perceived need for energy services, and perceived energy use behaviour change.

Conclusions

The paper has provided integrated technical and social research on the outcomes of a world class model green village which demonstrates how building design and practices, energy efficient appliances, renewable energy technologies, and household behaviours may lead to a more environmentally sustainable lifestyle. The Lochiel Park development includes the first large-scale residential development in South Australia with in-home energy feedback displays.

Detailed energy use and electricity generation monitoring has demonstrated that households in the Lochiel Park Green Village use substantially less delivered energy than others residing in new homes in the same climate.

A series of ten household interviews, backed by informal discussions with over fifty households, provides a new insight into the interaction of residents with in-home energy feedback displays. This new research is compared with data collected from the first tranche of households arriving at the same housing estate.

The research has found that the majority of households interact regularly with the feedback displays to examine their energy use and solar generation, but a small number of households have little or no interest in drawing on the available energy use information. Most households, even some who rarely use the displays, find the system easy to use.

Households perceive that the frequency of use has lessened over time as the curiosity wanes and they establish more regular patterns of energy technology use, but many households maintain daily interaction.

The load management feature of the system is not being used by any interviewed household, and few considered the feature useful. This is not surprising as there is no current financial incentive for limiting the peak demand.

The evidence from the interviewee perceptions is that the energy feedback displays assist households to reduce their energy use and identify energy system faults, although the quantum of energy saving is difficult to ascertain. Most households considered the feedback displays to be valuable tools and indicated they would most likely install similar technology in a future home.

The response of interviewees indicates that further research should be conducted by the feedback display system developers to ensure the information provided is easy to understand, provides useful comparisons, and the software navigation is user-friendly. Feedback display system developers should also consider minimising the system's energy demand, which would reduce the amount of behaviour change that is required before the system is of net energy and economic benefit to households.

The research has found that in-home energy feedback displays may play a useful role in supporting and encouraging energy use behaviour change, leading to lower energy use.

Acknowledgements

The authors wish to acknowledge the funding and support provided by the CSIRO's Intelligent Grid Cluster. They would also like to thank the support and information provided by Renewal SA, in particular Andrew Bishop and Phil Donaldson. Finally, the authors wish to thank Dr Anne Sharp for her valuable advice and assistance in shaping the Lochiel Park residents' interview design.

Abstract

This paper presents a model of a detached house in which home automation has been progressively introduced into the building. The model integrates different factors related to end-user behaviour and decision-making regarding the management of electrical energy consumption, and integrates a gradual end-user response to home automation measures. The presented model aims to show the potential economic benefits obtained by the modelled changes of end-users' behaviours within a smart energy network based energy system. Matlab/Simulink is used as a simulation tool for representing the model in which a 10 year database of Nordic climatic data has been built in, on an hourly and half hourly basis. The modelled building environment comprises twenty-one appliances and two lighting systems with different power rates. Each appliance and light bulb is individually measured. The feedback methods assessed were self-comparison, inter-comparison, and a target based system. The effect of home automation on energy consumption at the building level is assessed, and the importance of end-users in energy reduction is highlighted. The model categorises "green" and "brown" energy users and integrates their behavioural profiles within the end-user response. As part of a smarter electricity management system, the home automation system is able to interact with other buildings, either in terms of geographic or building infrastructure similarities. This will enable taking or modifying decisions at any given time, thus contributing to the local flattening of power demand. Such systems must work hand-in-hand with the grid operator.

1. Introduction

With the massive deployment of smart meters across Europe allowing digital measurements, energy companies and Public Institutions have access to a consequent database of energy consumption data throughout a country. European Union (EU) Member States have the obligation of implementing smart meters covering 80 % of consumers by 2020 at the latest [1]. In contrast to European Directive 2012/27/EU [1], Finnish legislation (18.1.2013/50) sets a deadline of 2014. The deployment of smart meters also brings up the issue of data security and use of the collected information, in particular in relation to the role of energy utilities and Public Institutions [2]. Legal obligations to increase energy efficiency also provide a motivation to the deployment of renewable energy sources, as a vector for energy production, and an increase in the energy efficiency of buildings. Home energy management can have a significant role in contributing to energy efficiency and cutting down peak load. This can be achieved through an active collaboration of energy consuming systems and the information network e.g. at the local level [3], [4]. Putting together the different factors mentioned involves the development of a smart energy network (SEN), capable of managing the energy system through constant monitoring.

SEN can be seen as a multi-layered configuration of the energy infrastructure, within which smart buildings are at its foundation [5]. Within a SEN architecture, the energy network is split into multiple complexes, forming a set of networks that communicate between each other [6]. Each horizontal area belongs to the same layer and vertical area to different layers. Energy and data may travel horizontally and vertically but not in diagonal. The main objective in this context lays in an increase of energy efficiency along with an economically viable reduction of environmental impacts where home automation has an important role. The effect of energy efficiency on the decrease of energy consumption at the local level is often offset by the rebound effect. The direct rebound effect, which is affected by the variation of the home energy budget, shares a responsibility in the success of energy efficiency measures [7]. Analyses of energy end-use at the home level become necessary for structuring a bottom-up system.

For the past fifteen years, surveys of energy consumption habits have been carried out across European households. Most of the surveys were looking at the effect of energy feedback to end-users' behaviour ([8-11]). Earlier work [6] showed that retrieving feedback regarding end-users' energy consumption could affect positively the overall impact on energy efficiency. An average decrease from 4 to 20 % of energy consumption has been found in the literature [12].

Modelling daily energy demand has been tackled from different angles in a top-down and bottom-up approach. A non-exhaustive list of these models have been described in [13] showing details of the different ways for representing the energy consumption in households. The timescale represented in previous models goes from hours to minutes [14-16]. In order to have a detailed energy profile, the bottom-up approach appears to be the most suitable method, compared to a top-down approach, where the overall energy consumption is broken down to individual appliances [16]. Modelling the energy consumption profile generally uses measured data from field tests as input data [13], [17]. Depending on the method used, energy consumption may be simulated from a human perspective by creating occupancy scenarios that will enhance the use of appliances. Grandjean et al. [13] pointed out the difficulties of such a technique, as it requires an extensive database on human behaviour and the activities undertaken. It is preferable to find a solution via the pattern of appliances' usage and deduce from it the human activity within the household. A comparable approach has been carried by Borg and Kelly [18] for evaluating the impact of appliances on energy efficiency in the future. They have not considered either the probability of an event or action occurring in the eventuality that home automation through smart metering would be applied in dwellings.

Modelling an energy system from the bottom up, more appropriately takes into account distributed energy systems [19] as an alternative to centralized energy production systems. Such energy architecture is being developed in parallel with the development of micro- and small-scale energy production systems [20]. Currently, Finland is considered to be a centralized system but has a considerable potential for having a decentralized system.

This paper investigates a bottom-up approach model centred on the use of appliances. The first part highlights the model description and its architecture. The second part details the data collection involved in order to run the model. The third part illustrates the model with the results obtained. Validation of the model puts in perspective the obtained results with real time energy consumption data of typical Finnish detached houses from the Oulu region.

2. Model

Structuring a model with a bottom-up approach requires detailed information regarding the studied living environment. Stokes [21] introduced a widely used system taking into account specific information related to the appliances, the socioeconomic status of the occupants, and a large panel of measured data as the basis for a statistical analysis of the energy profile. The energy system built with the bottom-up approach thus requires a precise, pre-defined system that creates a consequent database.

The model presented in this paper is based on an hourly scenario of appliance and lighting use. Based on a pre-selected number of users, their housing types, and the corresponding number of rooms, the model describes the usage of twenty-one pre-defined appliances. The lighting system presents two technological alternatives (incandescent and low consumption bulbs) in order to describe the energy consumption related to a lighting system. The model associates pre-determined energy consumption with the usage of different appliances (Figure 1). This is based on the assumption that, in order to use some of the appliances, a given number of persons are expected to be in the house, therefore consuming a statistically pre-defined amount of energy.

The user behaviour is evaluated depending on the feedback strategy chosen for the simulation. Feedbacks are dependent on the controller side of the model, which is used as a statistical tool. In this model, feedbacks are based on the self-consumption, the inter-comparison and the target based system.

The controller allows the piloting of certain appliances that are flexible over time, such as the washing machine and the dishwasher. The controller crosschecks information with the grid and between appliances in order to electrically decrease the power demand of relevant appliances during peak load hours.

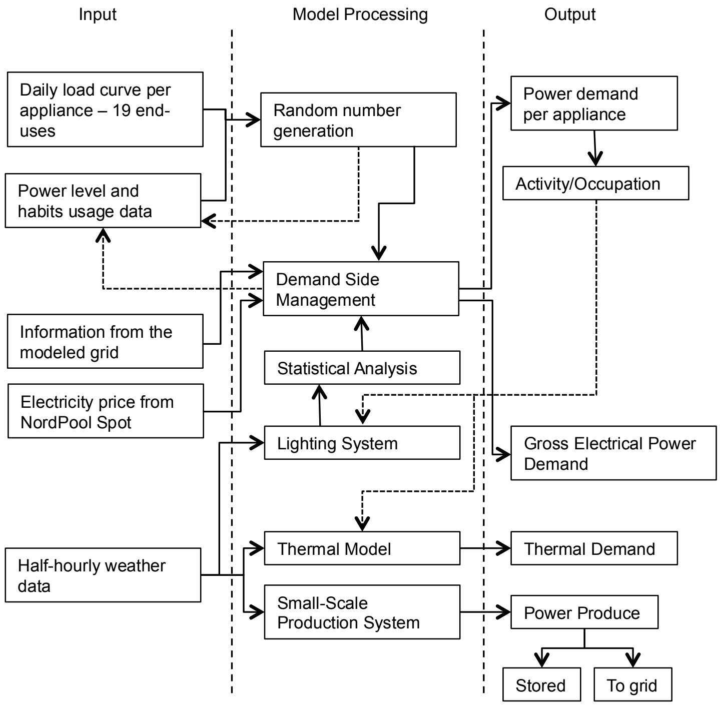

Figure 1. Block diagram of the model developed (based on [13])

2.1 Scenario Architecture

The model is built on an hourly basis using statistical results from earlier research [6].Firstly, the user behaviour regarding the use of appliances follows results coming from the Energy-using Product (EuP) [17] surveys on energy efficiency and use. These large-scale surveys intended to pattern the use of appliances in order to settle the energy efficiency rating scale under the European Energy Efficiency Directive. An example of data that can be extracted from these studies is shown in Table 1 which shows the different number of washing machine cycles that occur during the week per inhabitant. In the case of a washing machine, the type of program as well as the mean time for carrying out the action is given. Other information such as the average energy use per year or information that belong to specific appliances (e.g. mean recharging time of a mobile phone) is provided. These data set the model boundaries.

Table 1. Time of use and probability of activity occurrence for a washing machine

	Nbr of wash/week
1 person	2.1
2 persons	3.4
3 persons	4.9
4 persons	6.4
5 persons	6.3
6 persons	7.0

Temperature	Distribution	Time [min]
Cold	02 %	35
30°C	09 %	40
40°C	49 %	45
50°C	07 %	50
60°C	27 %	60
90°C	06 %	70

The second part of the model consists of tracking the daily energy profile of each appliance. In order to understand how an appliance is used, results from the REDMODECE [3] European Project have been processed to give mean daily energy profiles for the twenty-one appliances used in this model. To create these vectors, empirical values from multiple surveyed houses have been extracted from comparable Nordic countries (Norway and Denmark). In addition, it seemed relevant to integrate in the model the use of a sauna, considering that, in Finland, there is an average of 0.38 electric sauna stoves per capita [22]. Therefore, field data and/or assumptions for sauna stove use were added.

Figure 2 indicates the daily usage of the abovementioned electric appliances. Each plot represents the probability function for an appliance to be used over the course of a day. This explains the very high occurrence for some appliances such as a hair dryer in certain periods, due to the low probability of use another time of the day. Note that the hairdryer and iron peak at 56 % and 33 % respectively.

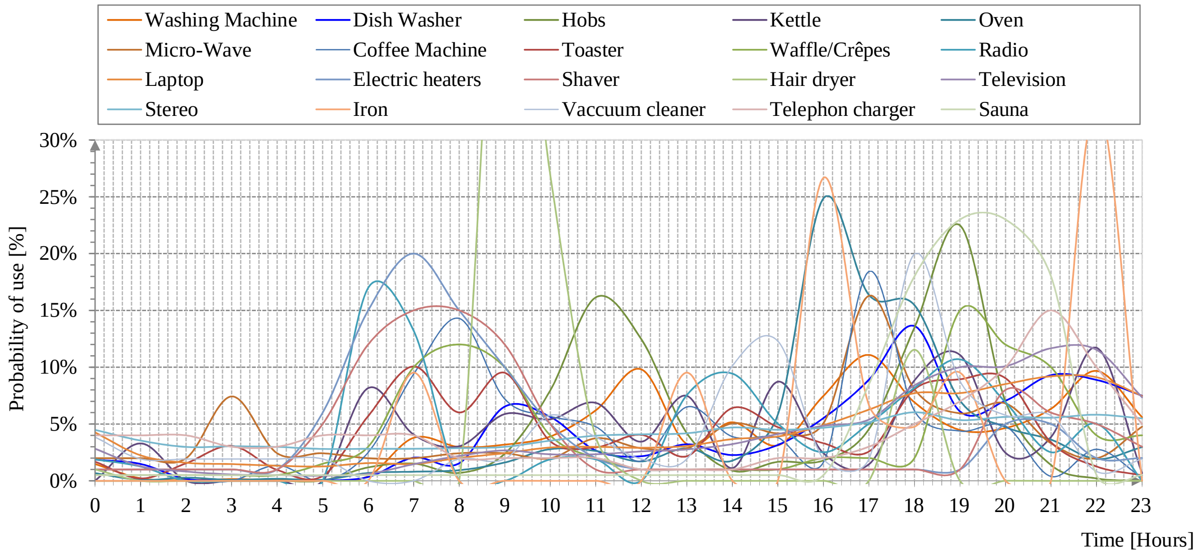

Figure 2. Daily energy profile for twenty-one appliances extracted from electric measurement

Once the profiles have been drawn out, daily and weekly safeguards are defined limiting the usage of an appliance [6]. Equations (1-4) express the conditions to be verified in order to have a confirmed action at t = n.

$$\overline{A}_{d-1} < \frac{2}{7} A_{w-max} \quad (1)$$

$$\text{and } \overline{A}_{w-1} < 1.1 A_{w-max} \quad (2)$$

$$\text{and } C_{h\,n} < R_h \sim U(0,1) < C_{h\,n+1} \quad (3)$$

$$\text{and } R_d \sim U(0,1) < C_w \quad (4)$$

Where $\overline{A}_{d-1}$ is the mean activity of the previous day, $\overline{A}_{w-1}$ is the mean activity of the previous week, $A_{w\text{-}max}$ is the maximum weekly activity as defined in Table 1, C_{hn} is the probability of use at t = n and $C_{h\,n+1}$ is the probability of use at t = n+1, C_w is the probability that an action will occur over the week or the weekend, R_h~U(0,1) and R_d~U(0,1) are uniform random numbers generated for the hourly and daily activities respectively.

The usage model of appliances allows the occupation within the detached house to be defined, which is also used for the lighting model. The available luminosity is calculated following solar irradiation. The relationship between solar irradiation and luminosity has been empirically established by Yokoya and Shimizu [23]. The lighting model is built using three components; namely the activity/occupation scenario, the available natural luminosity, and the luminosity required to carry out a certain task. Combining these three factors establishes the probability of use of light between 10% and 100%, where 10% is the probability of using artificial light on a very clear day and 100% is the probability of using light when the natural light is non-existent.

2.2 Demand Side Management

Including the user response within the model required the use of a demand side management (DSM) model. Consumption data are used for statistical purposes, monitoring the average appliance usage with reference values [17] on daily, weekly, monthly, and yearly levels.

These average consumption data are used for self-comparison and giving information to the end-users if they have over-consumed compared to the four reference levels. Independently from the user type, the fact that the end-user does not reach the level of consumption from the previous reference period (weekday, week, month or year) increases the acceptance of consuming energy at t = n [6].

The target-based system uses the previous data to build up the target for each dwelling (in case of multiple dwelling in the simulation). The tolerance for energy consumption increases or decreases depending on how well the end-user has performed at each iteration.

For both the self-comparison and the target-based system, the user response follows three trends, depending on the nature of response to the advice coming from the DSM system. A “green” user is considered to have a high positive response to the advice due to his/her personal background. In this context, such user is considered to have a standard positive response of 70 %. Similarly, an “orange” user will have a 50 % positive response, and a “brown” user a 30 % positive response. It is considered that a user would not have a 100 % positive response to any of the advice coming from the DSM system. The DSM ponders the standard response. Depending on the electrical consumption and the advice that the DSM may give, the standard response varies by up to +10 %. The user response will affect three variables related to use of the appliances: reducing the time of use of an appliance by integrating low-cost energy efficiency measures i.e. e.g. covering the pot, reducing the use of light; shifting the use of an appliance to an alternative time in case of peak load hours e.g. the use of the dishwasher during the night. In this case, the shifting requires the consent of the end-user but the time of the action is controlled by the automation system; and shifting the use of the sauna up to 1 hour in case of peak load. In the case of shifting the sauna use, the agreement of the end-user on actually agreeing on offsetting the use of the sauna from the traditional hour to another one is required. Therefore, it has been assumed that the end-users will not agree on taking a sauna in the middle of the night but would rather change the traditional sauna time by 30 minutes up to 1 hour.

The control system integrated in the model is capable of automatically postponing an action for specific appliances such as the washing machine or the dishwasher to any given time. It is highly unlikely that a control system would ever automate the use of all appliances in a household, thus a restriction to these two appliances has been made. Furthermore, in case of peak load time detected on the grid, the household control system is capable of reducing the power demand of appliances that require high power e.g. kettle, and iron. In these ways, the household power demand is reduced and a decrease in the peak load at the grid level is expected. Decision-making by the control system is currently based on the price information that it is receiving from the grid. In the case of a fixed-price system, critical hours are perceived during the high price period. In case of real-time pricing based on the electric spot price system, a combination of the real-time pricing and the price forecast is made in order to define the peak load time and thus apply a reduced power demand from the appliances.

3. Data collection

Running the model requires the use of reliable data, including the price of electricity on the energy market, the power levels for each appliance that defines the quality and the age of the appliances, and the weather conditions on a regular basis. Each dataset was combined together into two monotonic increasing vectors of half an hour and an hour.

3.1 Climatic Data

In order to create a dynamic model, data on temperature, solar irradiation, wind speed, wind direction, relative humidity, sky condition, atmospheric pressure, wind chill, dew point temperature and visibility were retrieved from an online weather database [24]. Raw data were given for 30 minutes samples on average, meaning that data processing was a necessary step to have a uniform vector of data. The Finnish Meteorological Institute issued the global horizontal irradiation data on an hourly basis for the years 2004 to 2012.

For the years 2000 to 2002, large amounts of data were found to be missing. In these few cases, artificial data was calculated from the mean variation of a variable for the previous and the following year, with the reference value of the previous hour. In the case of most recent years, smaller amounts of data were found missing for up to 6 hours in a row. In this case, a linear interpolation between the two existing values was created. The full processed dataset can be found in [6].

3.2 Appliances Data

The power demand required for each appliance was defined following the Best Available Technology (BAT) defined in the EuP research tasks [17]. As long as the information was given in terms of kWh per year, the total working hours per year for each appliance were taken. The ratio between the total energy consumption per year and the total number of working hours gave an average power demand in expressed in kW. Furthermore, seven categories (from A to G) were defined in the EuP report, “A” being the most efficient appliances and “G” the least efficient appliances. In order to select a certain category of appliance to be implemented within the model, each appliance was divided into three categories: A/B, C/D, and E/F. Each category was assigned a median value of the power demand calculated using the previous method as summarised in Table 2.

Table 2. Rated power for each appliance used in the simulation

Based on the European Energy Label

House zone	Appliance	A/B Category [kW]	C/D Category [kW]	E/F Category [kW]	Standby power [kW]
Kitchen	Washing machine	0.306	0.410	0.520	N/A
	Dish Washer	0.929	1.250	1.600	N/A
	Electric Cooktop		4.000		N/A
	Kettle	2.000	3.000	4.000	N/A
	Electric Oven	4.000	5.000	6.000	0.005
	Micro-wave	0.950	1.200	1.400	0.005
	Coffee Machine	0.600	0.800	1.000	N/A
	Toaster	0.800	1.300	1.600	N/A
	Waffle/Crêpes	0.900	1.200	1.500	N/A
	Fridge	0.300	0.400	0.600	N/A
Bedroom	Radio	0.005	0.008	0.010	0.001
	Laptop Active	0.060	0.080	0.120	N/A
	Laptop Sleeping	0.003	0.005	0.010	N/A
	Laptop off mode	0.002	0.003	0.006	N/A
	Telephone charger	0.010	0.015	0.020	N/A

Living Room	Television	0.125	0.150	0.200	0.005
	Stereo/Hi-Fi	0.080	0.100	0.120	0.001
Cleaning Tools	Iron	1.000	1.300	1.500	N/A
	Vacuum cleaner	0.700	1.200	1.400	N/A

3.3 Electricity price data

In order to integrate the price variation of electricity in the model, the public prices from the main energy retailer from the Finnish Oulu region (Oulun Energia Oy) have been compiled. Three contracts, offered from the same company, have been included. Each contract allows the end-user to choose what type of energy production system their energy comes from i.e. biofuel, wind energy or mixed energy. A fourth option was given to the end-user by selecting the real-time pricing system. A more complex system could be built in order to take into account the variation of energy demand on the network [25]. In this model, a method for creating the real-time pricing based on historical data has been developed. This approach requires the hourly price of electricity on the spot price market on one hand, and the average retailed electricity price to the end-user for the same period on the other hand. Both datasets are publicly available from the Energy Market Authority [26]. Using Equation (5) allowed the establishment of an hourly purchasing price for the end-user by correcting the spot price from its extreme incentive values, which can reach thousands of €/MWh on the positive side for some specific hours in order to increase energy production, and may be a negative price to reduce energy production.

$$P_h = \overline{P}_m \times \frac{P_{h-Network}}{\overline{P}_{m-Network}} \quad (5)$$

Where P_h is the hourly price of electricity for the modelled dwelling [€cent/kWh], $\overline{P}_m$ is the monthly average price of electricity for dwelling [€cent/kWh], $P_{h\text{-}Network}$ is the hourly electricity price on the spot price market [€/MWh], and $\overline{P}_{m\text{-}Network}$ is the monthly average price of electricity on the spot price market [€/MWh].

4. Results and Discussion

The model presented above aimed to draw daily energy demand profiles coming from the appliances plus lighting systems. Moreover, the implementation of home automation is included in the model with the aim of increasing the effectiveness and efficiency of the household's energy consumption.

The model used measured data in order to build up the scenario of energy demand. The modelled data were contrasted with real-time energy consumption measurements carried out in 16 households in the Oulu region in 2012 [27]. The mean daily energy demand profiles have been drawn for the entire year in the case of the modelled dwellings and a typical four-person family house in Oulu (Figure 3). General electricity consumption as well as the electricity price was taken every six seconds for each phase (in the case of three-phase houses). These houses had dynamic pricing following the spot price market. The electricity consumption recorded varied from 5 929 kWh/y up to 13 706 kWh/y for the period of January 2012 to January 2013. The mean daily energy profiles aim to recognize a tendency in the energy production for each dwelling. A common pattern in a Finnish home sees a peak of consumption in the evening due to the use of the sauna stove, which levels out the other peaks occurring during the day e.g. the morning peak.

The modelled house was set for the twenty-one appliances named earlier and all of the appliances were classified as being A/B labelled. As an indicator, the sauna stove used for the modelled house was set to 6 kW as mentioned in Table 2. The overall electricity consumption coming from the appliances has been found to be around 4 501 kWh/y which is correlated with the findings in the European ODYSSEE MURE project and by the Sähkötohtori Analysis [28]. The measured data were carried out in a four-family detached house (in Oulu, Finland), which is equipped with a 10 kW sauna stove.

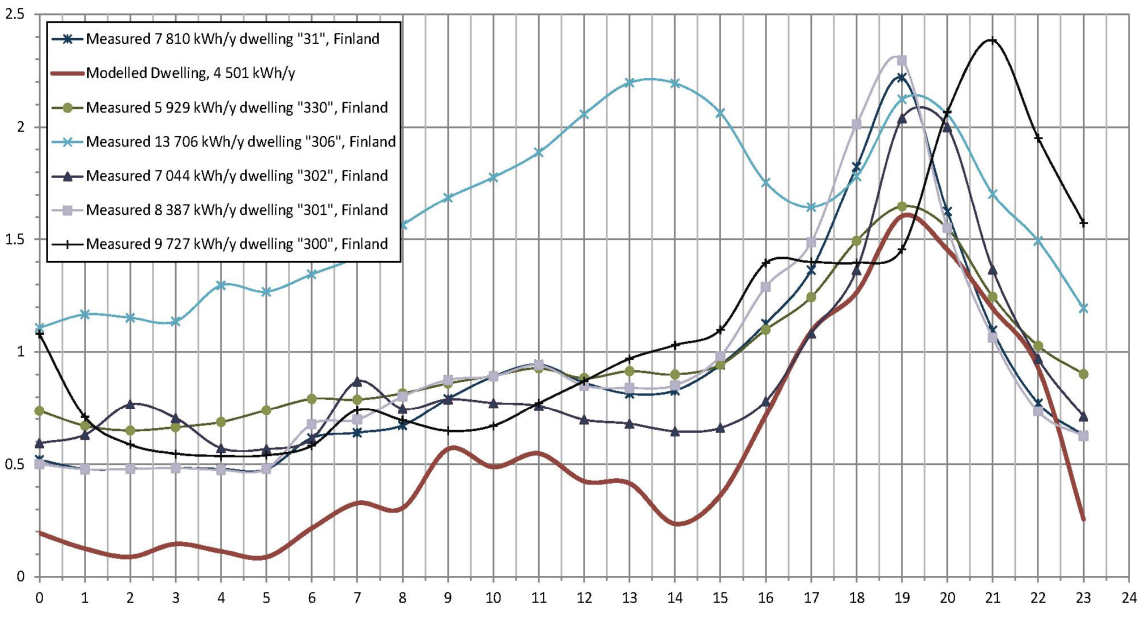

Figure 3. Comparison of a dwelling modelled with real time data measured in a four-person detached house in Oulu, Finland

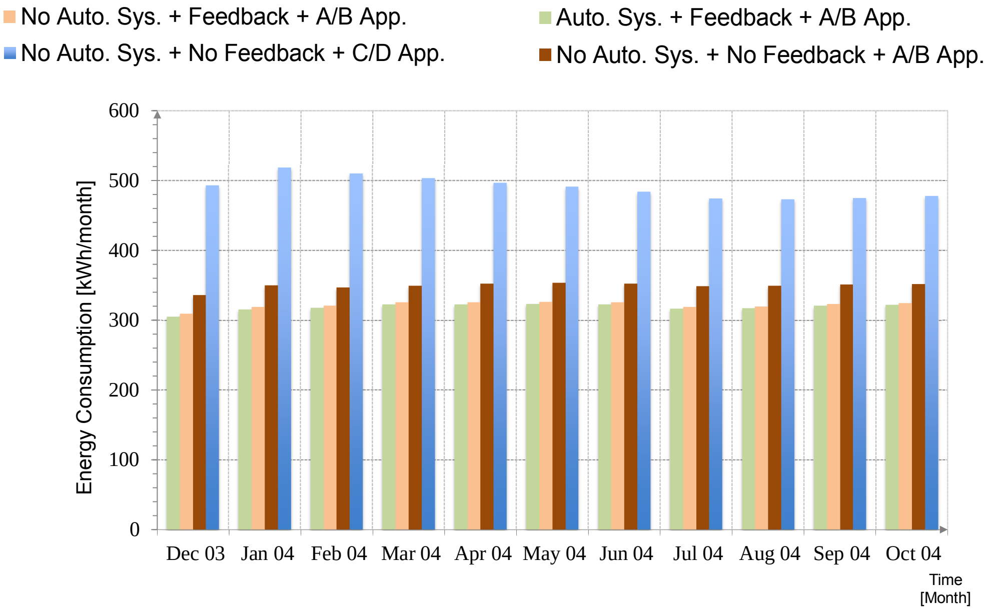
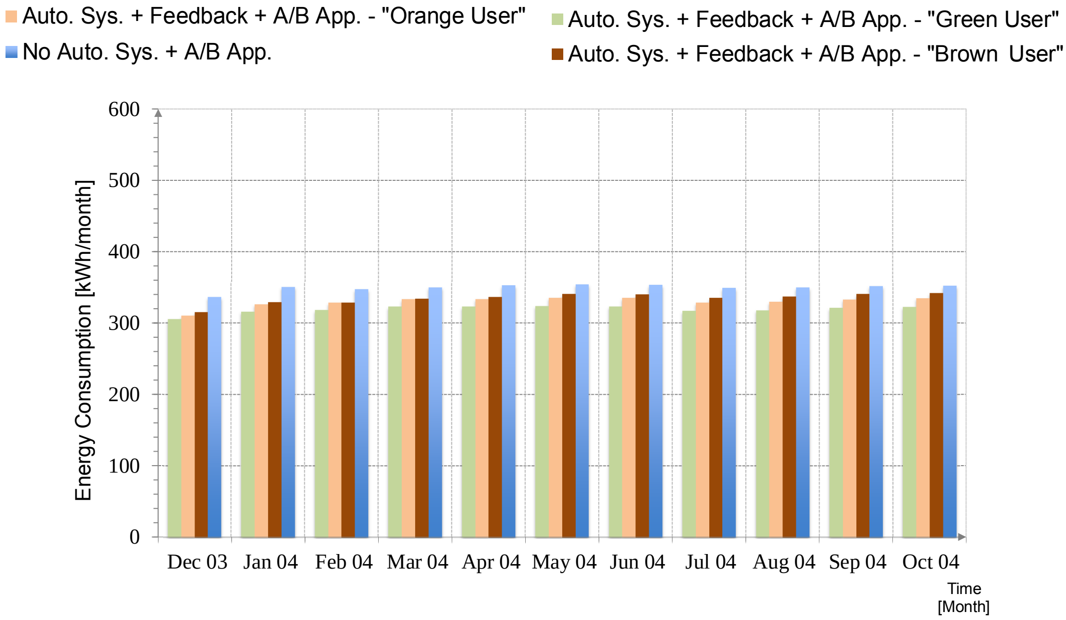
It is not yet clear how the offset (of approximately 400 W of average power demand) shown in Figure 3 appeared. Our assumption is that it could be an electric under-floor heating in wet rooms, as is common in Finnish homes. This would be on constantly during certain periods of the year and it was not included in our model of the detached house. Earlier research has shown [6], [28] that the share of electricity demand for a secondary heating system may be considered as the highest proportion of electricity demand, reaching up to 50 % of electricity consumption of detached houses in Finland. Nevertheless, it can be pointed out that the trend of modelled mean power demand follows the trend of data collected in real houses, giving confidence in the model.

We focused on the change in energy consumption due to the introduction of energy efficient appliances (Figure 4 a.), and on the impact of user response on final electricity consumption (Figure 4 b.). The simulation showed a decrease in energy consumption of 30% using the same scenarios when all C/D labelled appliances were replaced by A/B labelled appliances. In the second stage, a feedback system was introduced in the model in order to simulate the effect of providing data information to people using self-comparison or a target based system. The simulation presented a decrease of the overall electricity consumption by 8 %, which is coherent with the findings from Ehrhard-Martinez [12]. In the last stage, the automation system allowing the direct control on the washing appliances managed to decrease the energy consumption by 1 %.



a.



b.

Figure 4. a. Consumption level by upgrading the technology installed in the dwelling, b. Monthly energy consumption level by user category.

Figure 4 b. indicates the importance of user response on energy consumption. The difference of decrease in energy consumption between the two extreme categories varies from 3.3 % up to 7 % depending on the month. Compared to the base scenario where no feedback system is installed within the home (the brown bar on Figure 4 a. and the blue bar on Figure 4 b.), the difference in electricity consumption between the base scenario and the scenario that considers a high positive response from the end-user may reach as high as 10.9 %.

In the context of flattening the daily energy demand profile, the model looked at the consequences of consumer feedback and home automation on the mean daily electric demand. The shifting of electricity from one particular hour to another one can be seen in Figure 5. On one hand, the electric consumption from 12am to 6am increased by 50 %. On the other hand, the electric demand from 7am to 12pm slightly shifted down from their original level. This longer period of negative shift supports the decrease of energy consumption over the day. This is explained by the feedback effect that influences the way appliances are used and offers up to 10 % reduction of energy consumption, compared to the original demand profile.

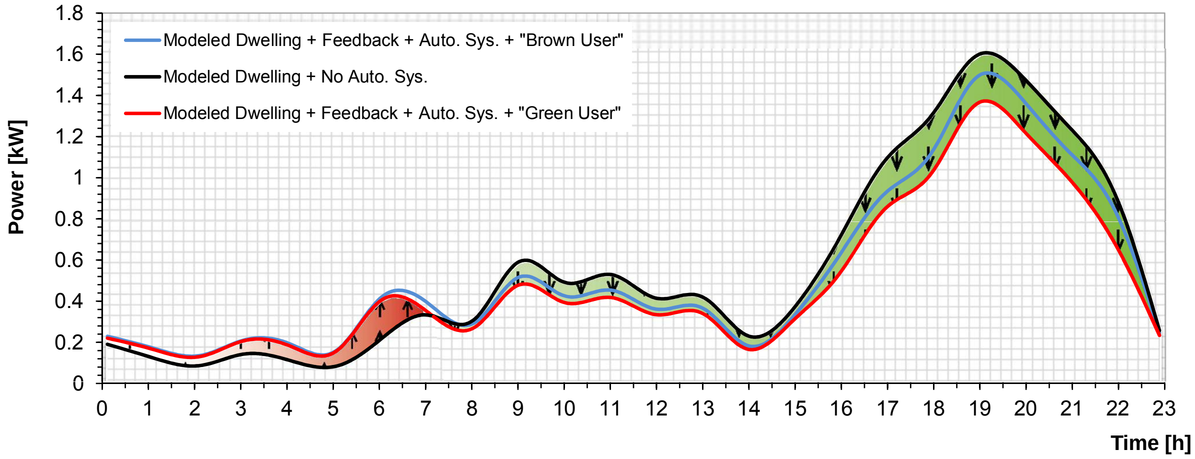


Figure 5. Effect of feedback strategies on demand profile and home automation in a detached house

The shift of energy demand seen in Figure 5 has to be balanced between the shift due to the automatic controller, and the one due to human behaviour. The latter is directly linked to user response and the way that end-users are utilizing their appliances at home. Thus, the “Brown User”, with its lower response and more frequent use of certain appliances may have a higher consumption than an end-user with a higher positive response when the system is asking to reduce the demand (see the Blue plot and the Red plot between 5 and 6 in the morning on Figure 5).

5. Conclusions, Recommendations and Future work

In this paper, a model of daily energy demand in a detached house in Finland has been set out. The model showed concordance with real data measured in a Finnish household. The model also integrated three types of user-responses as well as home automation, in order to control the use of programmable appliances. In terms of feedback impact, the model showed similar results to those found in the literature i.e. an average reduction of household electrical consumption by 8%. The automation system controlling the dishwasher and washing machine was able to decrease overall energy consumption by 1 %. In order to flatten the mean daily electricity consumption profile, some peak loads were shifted from the evening to the night period.

In order to fully use this model, it should be combined with a layered-grid model in charge of the energy management of multiple micro-grids. Such architecture should support a bottom-up approach of the electric infrastructure for creating dynamic pricing and managing the energy by geographical sectors. This model represents a starting point for evaluating the possibility to switch the mostly centralized energy system to a hybrid, mostly decentralized energy system. In this sense, the limitation of the model presented in this paper challenges to build up of viable scenarios involving dynamic pricing that would take into account the energy demand for building in the same geographical area.

Further work needs to be done in order to improve the model and get a better profile for each dwelling. Development should firstly focus on a minute-based electricity demand simulation, assuming that the output function would still be flexible enough to simulate a meter communicating hourly or daily data to the grid. Linked to the model, the daily energy demand profile per appliance will be varying in time, meaning that each appliance will follow the pre-defined energy profile and will evolve with the simulation time in order to integrate the end-user response and its effort for shifting the use of appliances in time. For integrating each aspect of energy efficiency, the direct- and micro- rebound effect should be integrated for each appliance and for the household. Finally, defining the appliances present in the households should depend on the end-user's definition within which appliances may be recurrent e.g. multiple TVs, video games and so on. In the future, the model should assess the impact of real-time pricing (hour-to-hour or minute-to-minute) on the peak load hours, and, its consequences on the electricity consumption by the end-users.

Benchmark results towards energy efficiency in residential care homes for the elderly

Abstract

The Energy Performance of Buildings Directive has been the driver for the establishment of energy performance ratings and certification in buildings. The development of benchmarks to compare the energy performance of similar buildings across different countries has been an important method to promote energy efficiency in buildings. While energy consumption benchmarks for office buildings have been already studied in several countries, no energy benchmarks are available for Residential Care Homes for the Elderly (RCHE). However, this sector is becoming more and more important as the population is ageing at an increasing rate. Estimates indicate that in 2050 the European elderly population will have doubled, reaching 60 million people. Moreover a recent research (Intelligent Energy Europe SAVE AGE project) found Care Homes lack knowledge and awareness on energy efficiency, and they are generally quite reluctant to adopt new technologies, since their main concern is to provide the best quality care possible. Therefore, there is a significant potential for energy savings in this area. The benchmark indicators presented in this paper are based on data collected from monitoring 10 RCHE in each of 10 different Member States (MS) participating in the study. The monitoring was based on a detailed survey assessment, followed by a computer modeling that used a multivariate linear-regression approach to model the energy consumption data and correlate different energy usage indicators. Heating Degree Days (HDD), net area, year of construction, number of residents, and number of employees are selected as the factors that may influence the energy consumption of a building. User behavior has also been analyzed but was not considered for the benchmark. The results show that HDD was not the most important factor influencing the energy use intensity but rather total conditioned area and number of residents. However, energy consumption used for heating purposes per resident per year has a positive correlation with the HDD.

Introduction

The European Council of March 2007 emphasized the need to increase energy efficiency in the European Union (EU) and to reduce the EU’s energy consumption by 20% by 2020 compared to projections. Therefore, an energy efficiency action plan was created and MS have identified significant potential for cost-effective energy savings in the buildings sector. The Energy Performance of Buildings Directive (EPBD 2002/91/EC) has been the driver for the establishment of energy performance ratings and certification in buildings by MS. Shortcomings in that Directive led to a recast to improve its effectiveness and set things more clearly. On 19 May 2010, the EU adopted the new Energy Performance of Buildings Directive 2010/31/EU (EPBD) which is the main legislative instrument in place to reduce the energy consumption of buildings. Under this Directive, MS must establish and apply minimum energy performance requirements for new and existing buildings, ensure the certification of building energy performance and require the regular inspection of boilers and air conditioning systems in buildings. The Directive requires MS to ensure that by 2021 all new buildings are so-called 'nearly zero-energy buildings'. However, a recent report by the Buildings Performance Institute Europe (BPIE) identifies the need for further guidance since weak rules put building efficiency off track [1]. The report says that EU countries may mismanage their energy efficiency commitments and risk missing their energy savings' target without further guidance. The report also said: *“The building sector is responsible for the largest share of energy consumption and greenhouse gas emissions and therefore they are a key sector to reach the long-term climate and energy targets".* The building sector accounts for 40% of the EU’s energy consumption and 36% of total CO_2 emissions. Therefore, building energy efficiency is key to achieving the reduction targets established by EU Policies.

Benchmarking is an important tool to promote energy efficiency in buildings and for influencing energy policy within building management [2]. Energy use in RCHE is becoming an important concern, because the population is aging at an increasing rate and because these centers operate 24 hours a day, 365 days a year, usually with full occupancy. Driven by falling fertility rates and increases in life expectancy, the elderly population will continue to increase. The findings of this study potentially have much broader applicability than the EU. The number of people aged 65 or older is projected to grow from an estimated 524 million in 2010 to nearly 1.5 billion in 2050, with most increase in developing countries [3]. In Europe, according to the European Association for Directors of RCHE (EDE), nearly 14% of the population is over 65 years old and 1.5 million people live in more than 24,000 RCHEs. Estimates indicate that in 2050 European elderly population will double, reaching about 60 million people [4]. The rising life expectancy within the older population increases the need for long term care services, since age also brings many health problems and disabilities (dementia, Alzheimer, several dependencies, etc.) which require specific care and continuous surveillance. The demand for professional care for elderly will inevitably increase because traditional living arrangements are changing: family size is getting smaller and the prevalence of co-residence by multiple generations is declining. The global trend toward having fewer children assures that there will be less potential care and support for older people from their families in the future [3]. Building experts and policy makers should definitely pay attention to the energy efficiency of this sector, since the increasing aging population will likely lead to an increase in energy use in this sector.

There have been many European projects regarding energy efficiency in buildings, namely REMODECE, ManagEnergy, Build Health, ASIEPI etc. Nevertheless, no one has dealt specifically with this particular niche of buildings. SAVE AGE is the first European project to restrict its scope to RCHE, having analyzed the current situation and sought out technical, behavioral, knowledge and financial obstacles and solutions towards energy efficiency. The development of benchmarks that enable the comparison of the energy performance of similar RCHE, across different countries, can have a large impact on the energy use within this sector.

Energy consumption benchmarks for office buildings have been already studied in several countries [5, 6, 7, 8, 9]. These benchmarks are based on statistical analysis, of data collected through forms and include all type of energy consumption used in the buildings.

Benchmarking in buildings has been established using several approaches, depending on the degree of detail of data collection and on how informative the benchmark should be. Sharp [10] used averages, medians, simple ranking and normalized ranking to benchmark commercial office buildings. The collection of a list of potential drivers for increasing the energy consumption of buildings and apply regression techniques to identify the statistically significant factors for normalization is also an usual practice [11]. Xuchao [9] concluded that ranking buildings based on their energy use intensity (EUI) provides a more informative benchmark. However, simple ranking can mask the results and can unfairly penalize some buildings (for example, hotels with high occupancy will be penalized compared to hotels with much lower occupancy). These factors that influence energy consumption, such as HDD, occupancy rate, number of employees, floor area, operation schedule, and building age, need to be normalized in order to make comparisons between buildings more equitable.

Our extensive literature search found that energy benchmarks have not yet been studied for RCHE. Moreover, RCHE lack knowledge and awareness on energy efficiency and they are generally quite reluctant to new technologies. Their main concern is to provide the best quality care they are able to, and they often neglect technical energy issues. The development of cross country comparisons of energy efficiency within RCHE will raise their awareness and drive decision making towards energy efficiency.

This paper presents the methodology to develop energy performance benchmarks for RCHE in order to compare the performance of similar institutions within the 10 European countries involved in the SAVE AGE[1] Project.

---

[1] http://www.saveage.eu

In the first phase of the SAVE AGE project, an analysis of the total energy consumption in 100 RCHE (10 in each 10 countries) and building characteristics such as net area, year of construction, number of residents and employees, type of insulation, envelope materials, etc. was carried out. Energy consumption data and relevant information collected from the RCHE were subject to statistical analysis, and a multivariate regression based benchmarking model approach was established to correlate different EUI with factors that may influence the energy consumption of a building, namely heating degree days (X1), net area (X2), year of construction of the building (X3), number of residents (X4) and number of employees (X5) and year of retrofit (X6). This approach would allow comparing performances of different RCHEs, so that RCHE managers can assess European consumption levels and evaluate their own efficiency, acknowledging where they stand within a National and European sample. In order to compare the efficiency of RCHE, the following Energy Use Intensity (EUI) performance indicators were considered:

- EUI1 (kWh/m^2/year) – provides information on total consumption per square meter of the building;
- EUI2 (kWh/residents/year) – provides information on total consumption per residents;
- EUI3 ($kWh_{heating}$/m^2/year) – provides information on heating consumption per square meter;
- EUI4 ($kWh_{heating}$/residents/year) – provides information on heating consumption per residents.

Figure 1 summarizes the SAVE AGE benchmarking approach.

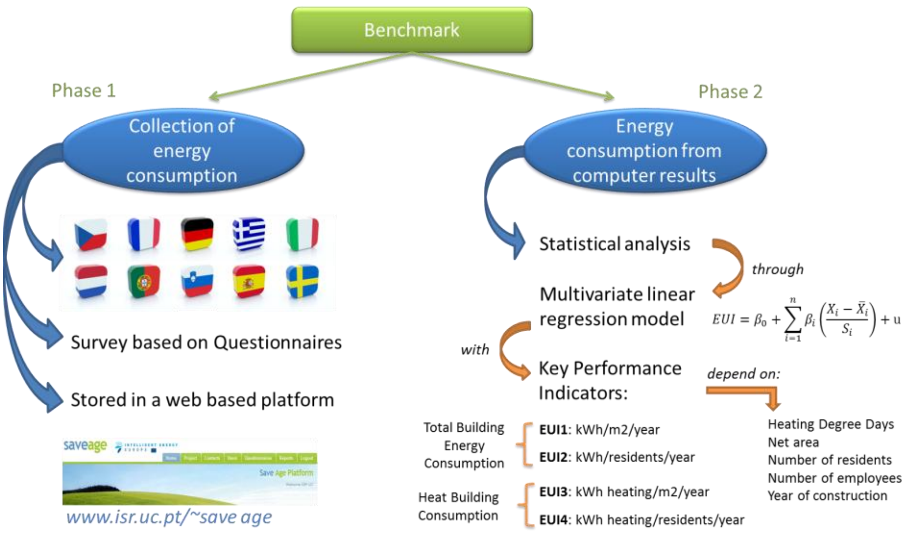

Figure 1 – Methodology of SAVE AGE Benchmarking

Methodology

To establish the energy efficiency benchmark, a literature survey assessment was carried out to collect information about energy efficiency benchmarks all over the world, in similar buildings. This survey enabled the collection of data related to performance indicators for assessing energy efficiency. In addition, a research on recent monitoring projects took place, in particular the Tertiary and REMODECE[2] projects, as well as older projects such as the SAVEII project DSM in Health-Care facilities, which aided decisions about on site data collection. Based on these assessments, it was possible to develop a detailed questionnaire used to monitor 10 RCHE in each of the 10 EU participating countries: Germany (DE), Greece (GR), Italy (IT), Portugal (PT), Slovenia (SI), Sweden

[2] http://www.eu.fhg.de/el-tertiary and http://remodece.isr.uc.pt

(SE), Spain (SP), France (FR), The Netherlands (NL) and the Czech Republic (CZ), hence a total of 100 RCHE.

The following phase of the project dealt with monitoring the RCHE. This monitoring was based on a detailed survey assessment which was based on the collection of the questionnaire filled in through interviews with the RCHE managers, technical staff, maintenance staff, nursery, etc. The advantage is that the energy consumption benchmark is more practical, because it uses statistical analysis of the data collected from the survey form. However, there is a limitation of this approach. As the benchmark relies on the number of RCHE of the sample, if the entire population is energy inefficient the result of the benchmark can be poor confident. Moreover, the only requirement imposed to the sample was to collect data from 10 RCHE in each country, located in different locations. Although no other requirement was considered in order to guarantee a statistically representative sample and assuming that the houses were randomly selected, the final set of 100 RCHE spread throughout Europe is believed to contain a representative sample of this type of facilities.

All collected questionnaires were stored in a specific database which was developed to store the huge amount of collected data in an effective way. A web based platform[3] enabled each partner to feed in the database with the information collected from the field surveys regarding general information of the RCHE such as number of residents, number of employees, number of rooms, etc.; construction details such as type of building, net area, type of terrain, etc.; heating/cooling; equipment; type of lighting; and building´s energy bills (electricity, natural gas, oil, etc.) for the three last years (whenever possible). In addition, climate factors have also been considered, since there are RCHE from countries with different climatic conditions and therefore climate adjustment of the energy data was considered in the analysis. Field collection of data is a huge task that is very time consuming, and it took longer than foreseen to collect enough data that could be useful to model the benchmark. This was a worthy effort, since data on energy supply and end-use are a pre-requisite for developing policies and initiating a change towards increased sustainability [11].

Climate factors

When applied to real-world buildings, common degree-day-based methods suffer from a number of problems that can easily lead to inaccurate, misleading results. Degree days should thus be handled with care and the most appropriate degree-day data should be used.[4] However, the degree-day data freely available is unlikely to be entirely appropriate for calculations relating to any specific buildings. Ideally, degree-day data should be obtained for an appropriate base temperature[5] and covering just the hours over which the building is heated. Heating degree days have been collected, but it was not possible to obtain degree-day data with an appropriate base temperature for all partners. However, it was possible to access mean-air-temperature data (e.g. monthly readings of mean air temperature), so the following methodology was used to obtain approximate degree-days, with a specified base temperature. The degree day value was defined as the difference between the daily mean temperature and the defined base temperature [11, 24].

Heating Degree-Days (HDD) are used for calculations relative to buildings' heating requirements. If considering a base temperature (T_baseH), and the daily average temperature T_out[i] for each day i in a period of N days[6], the HDD provides a measure of how many degrees and for how long the average outside air temperature was below the base temperature. Similarly, Cooling Degree-Days (CDD) are commonly used for calculations that relate the cooling of buildings - especially those using air conditioning. If considering a base temperature (T_baseC), and the daily average temperature

---

[3] http://www.isr.uc.pt/~saveage

[4] http://www.energylens.com/articles/degree-days

[5] The base temperature is a reference temperature used to calculate the Degree Days and allowing comparing thermal performance among buildings located in different climates.

[6] Typically one year.

T_out[i] for each day i in a period of N days[6], the CDD provides a measure of how many degrees, and for how long the average outside air temperature was above the base temperature [23].[7]

Establishing the Energy Efficiency Benchmark for RCHE

Energy benchmarking is an assessment approach in which energy-related metrics measured or estimated at one building are compared to those from other buildings and/or specific performance targets. These metrics can be specified at the level of the building, a functional area within a building or specific systems and operations. Benchmarks can be derived from distributions of metric values obtained from buildings that have a similar functionality or characteristics. Consequently, improvements in benchmarking methods can have a large impact on the energy use within the building.

To compare the energy performance of the RCHE, benchmarking energy indicators have been developed. These indicators should enable the comparison of different RCHE as accurately as possible. This is accomplished by using indicators that are normalized, like EUI. The EUI is the average annual energy consumption normalized by net area of the building, and it is typically expressed in kWh/m^2/year.

This methodology of simple floor area normalized EUI was then developed using a multivariate linear-regression model approach to correlate EUI with factors that influence the energy consumption of the RCHE, namely HDD, number of residents, number of employees and year of construction. If the data is nonlinear, this approach may not fit very well the data and other more complex ways of data fitting might be necessary for a credible energy-consumption performance rating.

After the data collection, there is a need to treat and process this data in order to establish the energy consumption benchmarks in terms of the EUI.

The benchmarking model makes use of the “best-fitted” regression model to calculate the predicted EUI. The EUI can then be expressed based on a set of explanatory variables: X1…Xn. The linear multivariate regression is performed in Excel.

Performance Indicators

The performance indicators calculated for the benchmark are used as an energy performance rating system to compare different buildings with the same functional use.

Table 1 shows the Key Performance Indicators (KPIs) selected to be used to compare the performance of the RCHE. The following Energy Use Intensity performance indicators were considered: kWh/m2/yr, kWh/res/yr, $kWh_{heating}$/m2/yr and $kWh_{heating}$/res/yr.

Table 1 - Key Performance Indicators (KPIs)

Key Performance Indicator	Source of Energy	Units	Data Required	Comments
Energy Use Intensity (EUI1)	All sources (electricity, gas, oil, biomass, district heating, etc.).	kWh/m^2/yr	Annual energy consumption; Net area of the building	Provides information about the total energy consumption of the building per its net area.
EUI2	All sources (electricity, gas, oil, biomass, district	kWh/ residents/yr	Annual energy consumption; Number of	Provides information about the total energy consumption per

[7] Base temperatures assumption: 15ºC was established as the base temperature for degree-day-based calculations relating to the energy consumption of the heating system and 20ºC as the base temperature for degree-day based calculation related to the energy consumption of the cooling system [http://www.energylens.com].

	heating, etc.).		residents	resident.
EUI3	All sources of energy used for heating	kWh heating/m2/ yr	Heating energy consumption; net area of the building	Provides information about the heating consumption per square meters.
EUI4	All sources of energy used for heating	kWh heating/ residents/yr	Heating energy consumption; Number of residents	Provides information about the heating consumption per resident.

Selection of EUI and explanatory variables

The EUI (kWh/m^2/year and kWh/residents/year) are chosen as the dependent variables in the multiple regression models. Some factors that may affect the EUI, which were considered, are climate (degree days), number of residents, number of employees, age of the building and year of any retrofits. But there are other more qualitative factors which may also affect the EUI such as occupant's behavior, level of environmental awareness of user's, maintenance practices, etc. but these factors were not modeled since they are difficult to quantify or evaluate.

In the SAVE AGE study six explanatory variables, presented in Table 2, were considered in the multiple regression models.

Table 2: Explanatory variables considered in the model

Explanatory variable	Variable name
X1	HDD
X2	Net area (m2)
X3	Year of construction
X4	Number of residents
X5	Number of employees
X6	Year of retrofit

A random selected sample of 10 RCHE in each country was surveyed to develop a data-base for energy-efficiency benchmarking. In principle, a sample size of 100 is sufficient to provide a statistically significant model. However, due to the lack of important data for some countries and in some RCHE, there was the elimination of 8 samples, and the final number of houses considered in the analysis is 92 samples.

The multiple regression model

If we assume that the typical distribution of energy consumption is affected by the selected explanatory variables, including HDD, net area, year of construction, number of residents, number of employees and year of retrofit, (X1…X6), the multiple regression model for the EUI(kWh/m^2/yr) is given by:

$$EUI = \beta_0 + (\beta_1 * x_1) + ... + (\beta_8 * x_8) + u = \beta_0 + \sum_{i=1}^{8} \beta_i \left(\frac{x_i - \bar{x}_i}{S_i} \right) + u$$

Where x_i are the Xi explanatory variable average, Si is its variance, and β_i the regression coefficients that best fit a linear model to the available data and u represents the random error [6, 12]. The data analysis to obtain the above regression values has been carried out using Microsoft Excel. After modeling the data, an analysis of the influence of the explanatory variables in the indicators showed that the explanatory variable Year of retrofit does not have influence on the benchmark, and therefore was neglected. Therefore only the explanatory variables X1…X5 were considered in the final modeling of the data.

EUI1 (kWh/m^2/yr)

As an example, Table 3 summarizes the statistics of the survey results for EUI1. A similar procedure has been carried out for the other performance indicators EUI2, EUI3 and EUI4.[8]

Due to the presence of some outliers, the total number of houses considered in this case was 86. The Table presents the minimum and maximum values, the average and the standard deviation of EUI1 and the explanatory variables under evaluation. The linear coefficient generated by the model and the sensitivity of the model to a given variable (the product of the standard deviation of that variable by the linear coefficient generated by the model) is also presented in the Table 3.

Table 3: Summary of statistics of survey results of EUI1

	N	**Min**	**Max**	**Mean**	**SD**	**βi**	**Sensitivity to the model**
EUI1(kWh/m2/yr)	86	46	551	252	106		
X1 (HDD)	86	432	2775	1975	740	0,0329	24,35
X2 (Net area, m2)	86	220	18270	4278	2994	-0,0386	-115,84
X3 (Year of Construction)	86	1400	2010	1957	102	-0,0721	-7,32
X4 (Number of residents)	86	11	273	91	61	0,88732	54,43
X5 (Number of employees)	86	3	340	62	54	1,23484	66,12

As it can be seen the standard deviation is significant for all the explanatory variables. This is an indicator of large variability in the data sample.

R^2 is the coefficient of determination. It gives a normalized indication, ranging from 0 until 1, of the error from the model to the sampled data. If it is 1, there is a perfect correlation to the sample. Anyway, it is worth noting that with the heterogeneous data of the current sample, no model would provide a perfect fit. For the case of EUI1, R^2 is 0,4.

Figure 2 shows a frequency chart to depict the distribution of the RCHE according to their net area. This histogram is biased with most RCHE below 5,000 m^2, but the sample contains five outliers with areas above 15,000 m^2. The frequency of RCHE with more than 3,000 m^2 decrease as area increases. Houses with areas above 10,000 m^2 and with a relatively small number of residents were not properly modelled by the benchmark for the EUI1 (kWh/m^2/yr) indicator. This happened because the study includes only five houses above that area and the regression coefficient reduces too much the magnitude of the performance indicator that might result in unreasonable expected values, as happened with some cases in Germany, The Netherlands and Spain being treated as outliers.

[8] More information is available at www.saveage.eu.

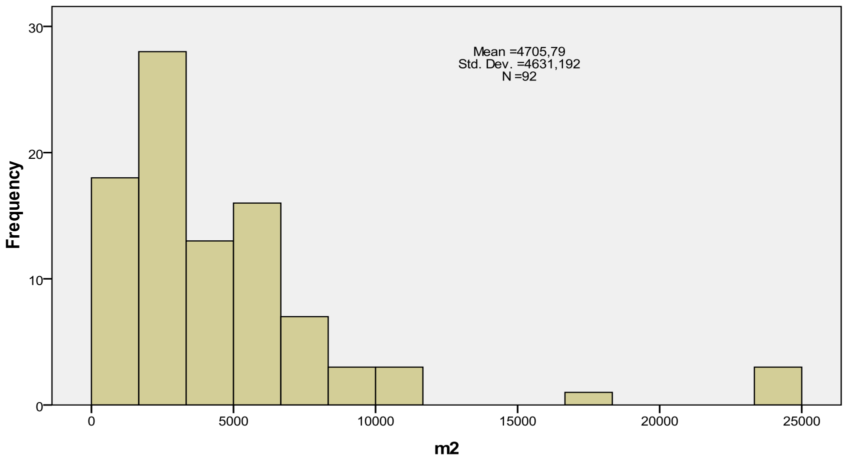

Figure 2: RCHE distribution according to the net area of the buildings

Major Findings

The multivariate linear-regression model originated, for each performance indicator, the following equations that correlate each variable with the benchmark value:

- EUI1 = 335,81 + 0,033.X1 - 0,039.X2 - 0,072.X3 + 0,887.X4 + 1,235.X5
- EUI2 = 5812,9 + 3,099.X1 + 1,107.X2 + 0,102.X3 - 76,222.X4 + 29,052.X5
- EUI3 = 224,31 + 0,025.X1 - 0,018.X2 - 0,068.X3 + 0,419.X4 + 0,429.X5
- EUI4 = 5531,2 + 1,818.X1 + 0,549.X2 - 1,285.X3 - 34,800.X4 + 5,327.X5

In Figures 3, 4, 5 and 6, the indicator EUI1 is plotted against net area, number of residents, number of employees and HDD, respectively. Real values are presented in different colours for each country. Benchmark trend lines are also plotted.

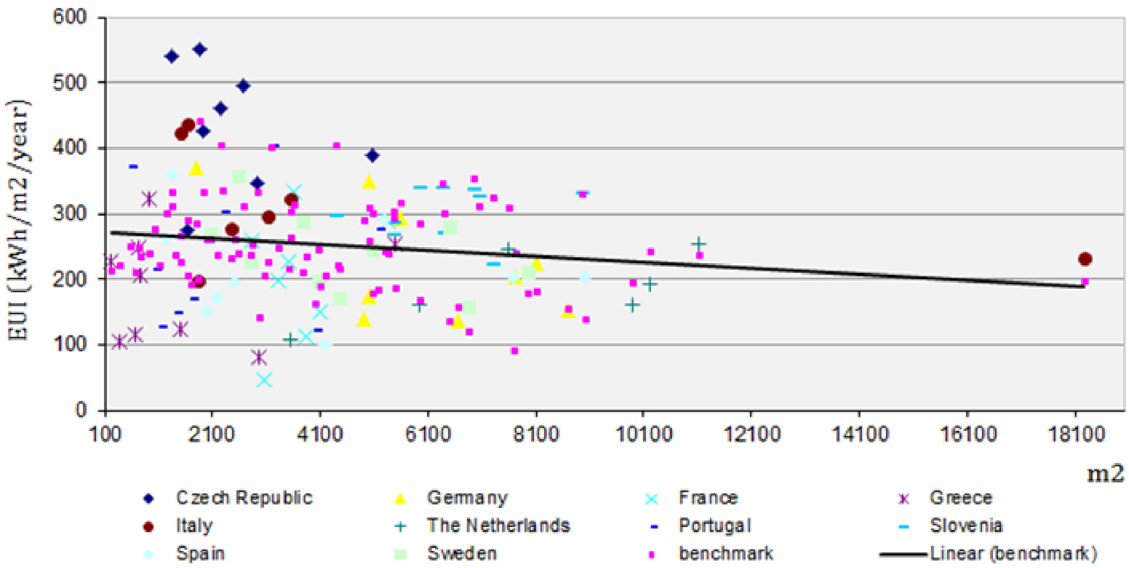

Figure 3. EUI1 (kWh/m^2/yr) versus net area (m^2)

As expected, the energy consumption per square meter decreases as the net area of the building increases. This does not mean that larger buildings perform better; it just means that a building consumption increases less per square meter as the net area increases.

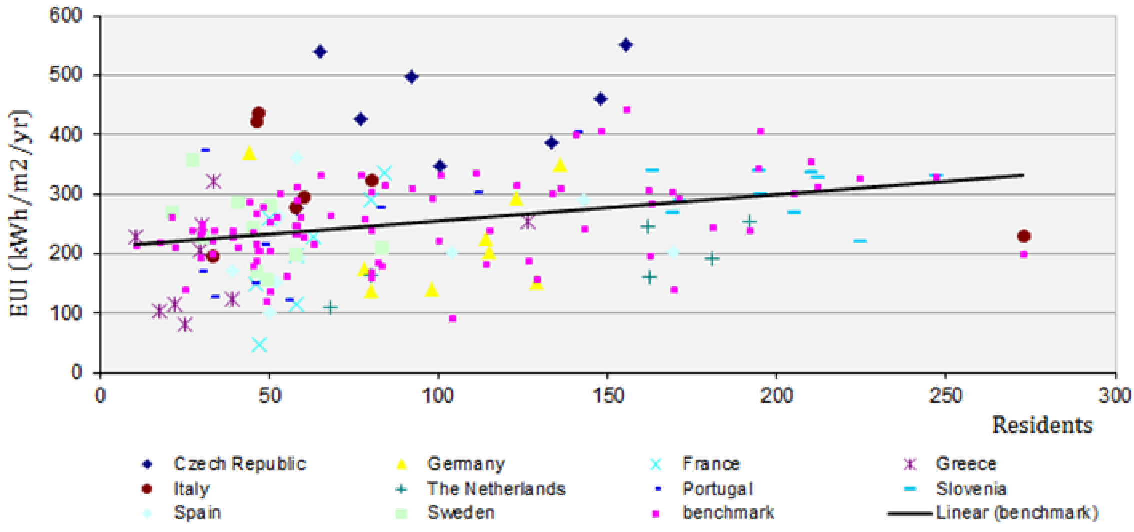

Figure 4. EUI1 (kWh/m^2/yr) versus number of residents

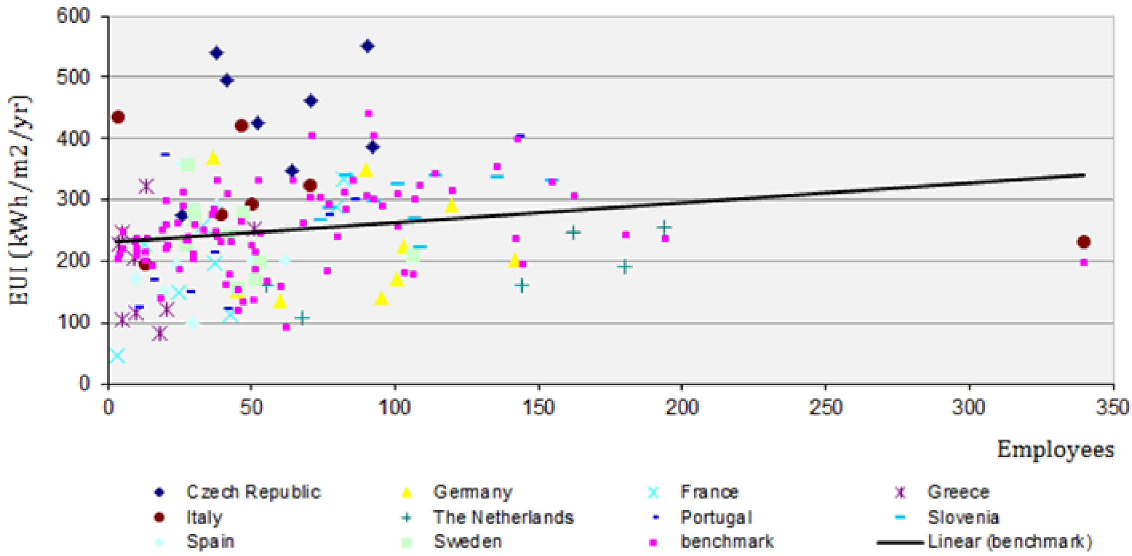

Figure 5. EUI1 (kWh/m^2/yr) versus number of employees

As it can be seen in Figures 4 and 5, there is a positive correlation between the energy consumption per square meter and both the number of residents and the number of employees. However, this relation is not very strong as the slope of the trend line is low in both cases.

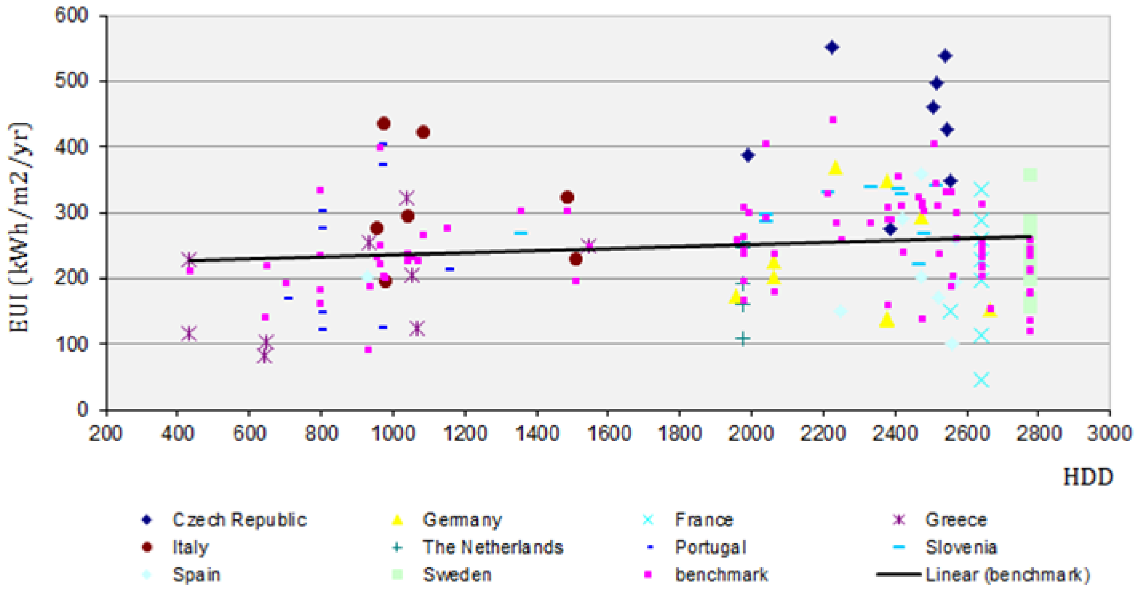

Figure 6. EUI1 (kWh/m²/yr) versus HDD

There is a very small positive correlation between HDD and energy consumption per square meter. There are two main range levels of HDD: small number of HDD: [500; 1500], and large number of HDD [2000; 3000]. It is also possible to conclude that some RCHE are performing better than others for the same order of magnitude of HDD, both within the same country and across different countries.

Figures 7 and 8 plot the EUI2, energy consumption per resident per year and the EUI4, energy consumption used for heating purposes per resident per year, respectively, against the HDD. Both indicators have a positive correlation with HDD. Due to space limitation, this paper does not present all the graphs for the four Indicators, which can be found at the project web-site. The decision was to include here the indicators presenting stronger correlation with the explanatory variables.

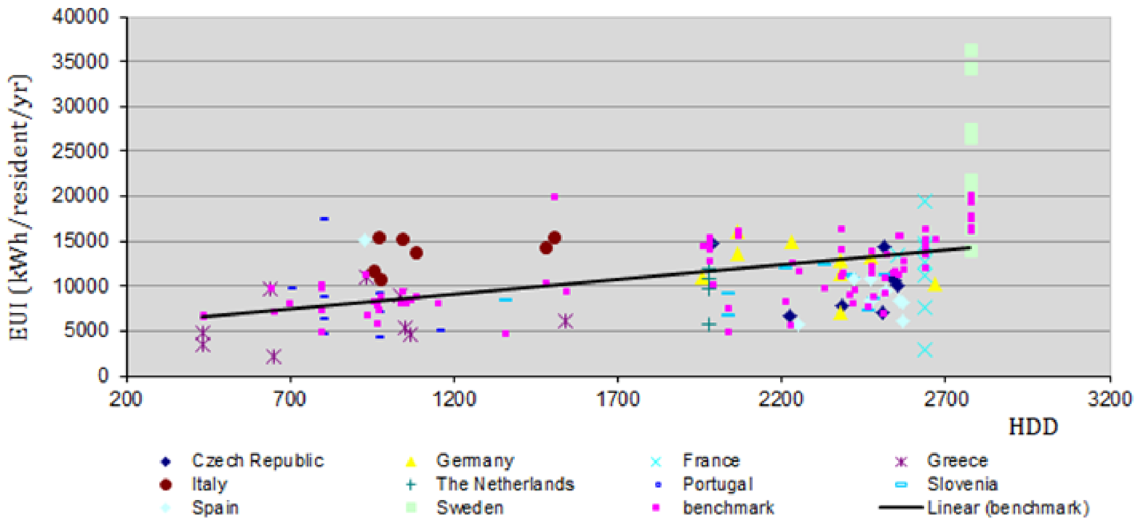

Figure 7. EUI2 (kWh/resident/yr) versus HDD

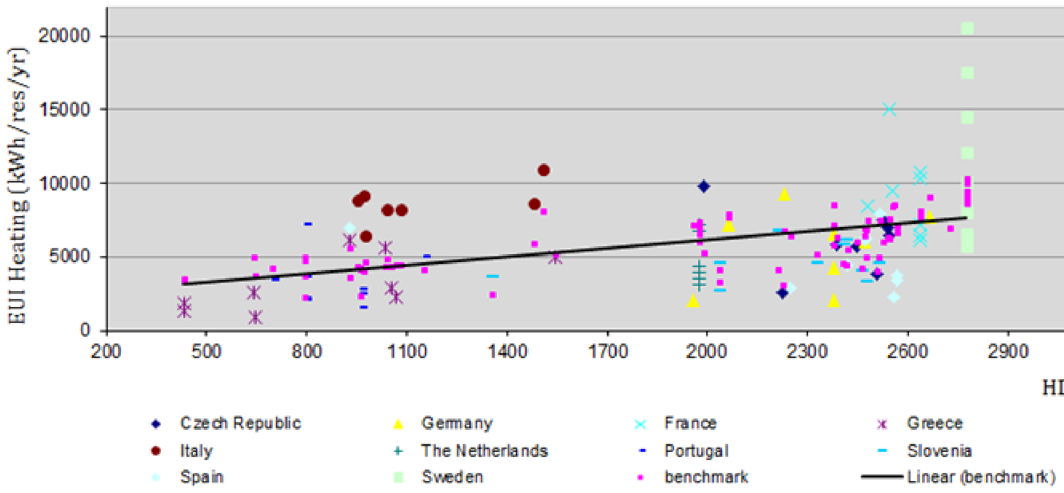

Figure 8. EUI4 (kWh/resident/yr) versus HDD

In the same country, with the same HDD, it is possible to find RCHE with very different heating consumptions per resident per year. This is particularly significant for Sweden and France but is also true in other countries like Italy, Greece and Germany.

Conclusions

If we look at the differences between the benchmark value for the different performance indicators and the real consumption value, as can be seen in Table 4, the following conclusions can be drawn:

Table 4: Real and estimated average values for indicators EUI1-4

	EUI1		EUI2		EUI3		EUI4	
	kWh/m^2/yr		kWh/residents/yr		kWhheating/m^2/yr		kWhheating/residents/yr

EUI1: The average value for EUI1 is 252 kWh/m^2/yr. Within the sample, it varies from 46 kWh/m^2/yr in one RCHE in France to 551 kWh/m2/yr in one house in Czech Republic. Czech Republic, Italy and Sweden are the countries where RCHE are using more energy than the model estimated.

EUI2 ranges from 2215 kWh per resident per year in one house in Greece to the huge amount of 36349 kWh/residents/yr in one house in Sweden. Within a given country, the energy consumption per resident per year can vary significantly. According to the model, the maximum value should be 20156 kWh/residents/yr. Czech Republic, Italy, Portugal, Slovenia and Sweden are the worst countries in terms of total energy consumption per resident.

EUI3, which represents the heating consumption per square meter per year, is estimated to be 129 kWh/m2/yr, however the maximum reaches 333 kWh/m2/yr in one RCHE in Czech Republic, while the model predicts 216 kWh/m2/yr. Czech Republic and Italy are the worst positioned countries in terms of this heating indicator.

EUI4: The heating consumption per resident per year, as with EUI2, reached a maximum value for one particular house in Sweden, with 20556 kWh/residents/yr, while the model expected value for that situation is 10351 kWh/residents/yr. The average heating consumption value per resident per year is 6109 kWh. The countries with the highest heating consumption per resident are Czech Republic, France, Italy, Slovenia and Sweden.

Lessons learned

There is a large heterogeneity in the collected data, reflected by the sparse point clouds in the figures 3-8. Additionally, no non-linear tendency can be observed. Therefore, in an attempt to establish benchmarks in the 10 countries, multivariate linear regressions were fitted to the collected data, in order to model the energy consumption. Considering such sparse data, large global deviations between the models and the data were obtained, reflected by relatively small values of R^2.

Considering the sensitivity of the model to a given variable as the product of the standard deviation of that variable with the linear coefficient obtained by multi-linear regression, we can conclude that the most relevant variable for EUI1 and EUI3 is the net area and for EUI2 and EUI4 is the number of residents.

Since some outliers were found, it is advisable to double-check the information relative to those houses and eventually to carry out complementary data able to fill in the gap in-between the normal data and the outliers. As it is the basic idea of descriptive statistics, when encountering an outlier, we have to go further on the analysis and find out its cause. Insignificant explanatory variables should also be eliminated.

Whole Home Energy Use Study with Comprehensive Metering Package

Robert Davis, Ben Larson, Michael Logsdon

Ecotope, Inc.

Abstract:

The Pacific Northwest of the United States relies on a regional energy plan which is updated every 5 years. The first plan was published in 1981 and each plan prioritizes acquisition of conservation and renewable energy sources. The next plan will be published in 2014, and a comprehensive Residential Building Stock Assessment (RBSA), began in 2011 to provide a statistically representative summary of residential building characteristics throughout the Pacific Northwest. This study involved a half-day field audit of approximately 1400 site-built and manufactured homes. A subset of these homes received more detailed audits that focused on heating/cooling distribution efficiency and house air-tightness.

The Whole Home Energy Use Study (WHEUS) is part of the RBSA and directly measures most energy uses (natural gas/electric heating, cooling, hot water, 240 volt AC (VAC) appliances), plug loads, major 120 VAC appliances, and lighting in a sample of 100 homes which are statistically linked to the RBSA sample of 1400 homes. Data are collected as 5 minute summaries and include both energy and power (and duty cycle for lighting) plus additional measurements.

This paper will focus on two elements of the WHEUS. First, it will describe the design of the metering plan, focusing on how three different data logging platforms were designed and then melded to provide nearly real-time usage data. The semi-automated error-checking that is key to ensuring data quality will be described. Second, the paper will present some of the preliminary results, including whole-house and appliance-specific usage and time of use profiles.

1. Background

Recent history of the Pacific Northwest, especially that involving electricity production and distribution, has centered on the network of federally-financed dams that are operated on the Columbia River and its tributaries by the Bonneville Power Administration. Hydroelectric power has provided almost all of the electricity for the region until very recently and regional planning has therefore largely been the province of BPA (with a limited number of natural gas and coal-fired plants, plus some nuclear energy making up the difference). Wind power generating capacity has increased rapidly in the last decade and now represents a potential resource equal to about half of the average regional demand of about 9000 MW.

In the late 1970s, projected rapid growth of electricity demand led BPA to underwrite construction of a five facility nuclear power network. Demand did not materialize as expected, the bonds that had been sold to finance the project went into default, and BPA was compelled by federal legislation to agree to a broader regional planning process overseen by a new agency, the Northwest Power Planning Council (now called the Northwest Power and Conservation Council). The Council would prepare a regional plan every five years (prioritizing conservation and renewable resources) that

BPA and its customer utilities (over 150 in all throughout the region) would use as a blueprint to acquire conservation resources. These resources would come from a combination of utility programs and changing energy codes (which are administered by the four states in the region: Idaho, Montana, Oregon, and Washington). Periodic evaluations by the Council and others have concluded that conservation programs have succeeded in delivering an accumulated 500 MWa[1] over the past thirty years [1]. This is an impressive accomplishment, especially in a region where electricity's average cost is typically under $0.10 USD/kWh. Note this graphic shows conservation gleaned from all sectors (residential, commercial, and industrial), with residential conservation estimated to have saved about 50% of the total over the past 10 years [2].

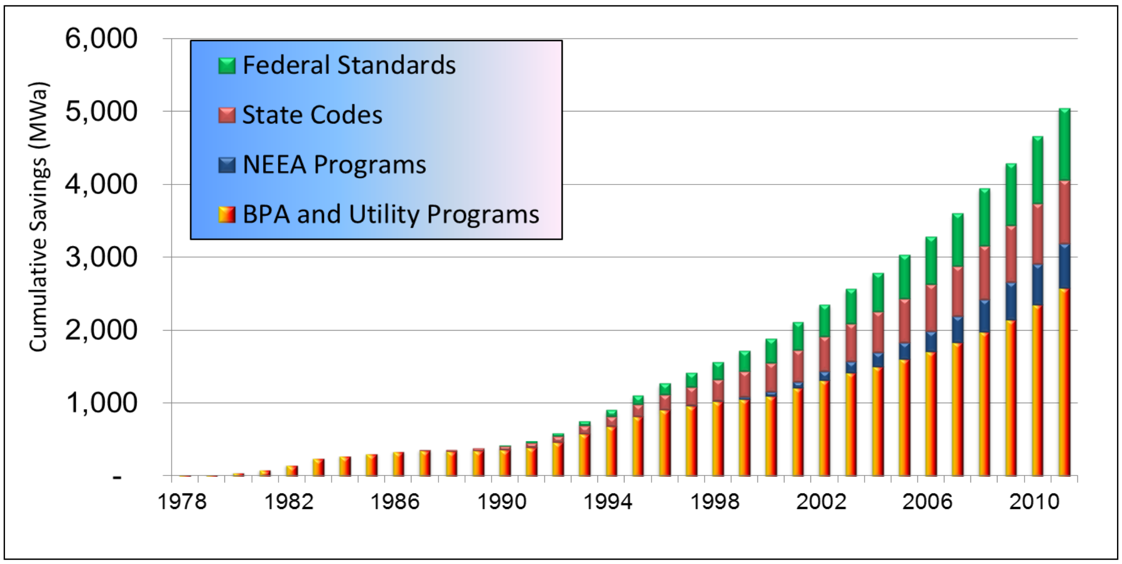

Figure 1. Historic Conservation Acquisition in United States' Pacific Northwest

The region's last major regional end use study, the End Use and Consumer Assessment Program (ELCAP) was begun in the mid-1980s, with most analysis complete by the early 1990s [3]. This was a $60 million study (1988 USD), with the bulk of its effort concentrated on commercial/industrial end uses. Still, about 400 homes were instrumented in some form (but no plug load or lighting data were collected due to limitations in metering technology). The energy use and load shape data from that study has been used by the Council and others in several regional Plans. A few additional, smaller-scale end use studies have been conducted since ELCAP but the region has badly needed an update.

The seventh regional Plan is now in preparation. A key element of the Plan is analysis of data that is now being provided by the Residential Building Stock Assessment (RBSA). This study, funded by the Northwest Energy Efficiency Alliance (NEEA) is a general survey-based study that provides a statistically representative summary of residential energy use characteristics throughout the region [4]. A subset of about 10% of the 1100 single-family homes in this study are the subject of intensive end-use metering (the Whole Home Energy Use Study (WHEUS)) and that is the subject

[1] An average megawatt is the amount of electricity produced by the continuous production of one megawatt over a period of one year.

of this paper. Results from both studies support the Council in preparation of the 7th Plan, support the region's utility conservation programs, and also may provide a test bed for new technologies of interest to the region.

There are 101 single-family sites in the study, drawn from five regions across the Northwest. The distribution is approximately population-weighted. The sample was designed to focus the sampling resources on areas with large populations (that is, clustered around the major population centers, which are typically less than 100 miles from the Pacific Ocean and therefore in a relatively mild, maritime climate) as well as areas with diverse climates. The two most populous areas (Puget Sound and western Oregon) were sampled separately; about one-third of the sample was drawn from three eastern regions, including eastern Washington, Idaho, and western Montana.

Whereas there are adequate west-side sites to ensure statistical robustness, various recruiting challenges on the east side prevented drawing of a statistically significant sample by sub-region. The minimum statistical criteria were set at 80/20. These criteria allow substantial variation while still allowing some variables to be reported that will have a wide confidence interval. Setting these criteria as a minimum ensures that most data points could be useful in establishing a generalized picture of the region's residential customer energy use. For the individual sampling areas, the coefficient of variation (CV) was set at 0.85, which means that the ratio between the mean and the standard deviation of any one metered result could be as high as 85% and still meet the minimum statistical criteria. Nevertheless, results from the east side can be viewed as broadly representative of the energy usage of the region's more continental climate (which has from 30-80% more heating degree days than the west and which also typically has more demand for mechanical cooling (even though cooling represents on average less than 20% of the house's HVAC usage).

2. Metering Plan Elements

In concert with the regions' keen interest in careful energy planning, this project had to construct a durable metering plan which would be adaptable to a range of housing sizes and energy use loads. The plan would have to be able to measure as many individual loads in the house as possible (both at the electrical panel and elsewhere), be secure, and allow for remote monitoring and retrieval of data. Sites would be spread out over several thousand square miles over a period of at least 2 years, so there would have to also be careful consideration of cellular communication service.

The final metering plan included 3 parallel platforms. The first was centered at the house electrical panel and includes direct measurement of the whole house service drop plus major 240 VAC appliances such as heating systems, water heaters, and laundry equipment. The second platform is based on a network of branch circuit measurement nodes to pick up items such as consumer electronics; this platform included both wired and wireless elements. Finally, lighting fixture on-time is measured with stand-alone data loggers. This platform is the only one that requires on-site visits to gather data.

The metering platform in this study is not limited to measurement of electrical loads but also tracks consumption of gas-fired appliances (with a focus on gas furnaces and water heaters). Very little detailed information has been available in the region on residential natural gas load shapes, especially in relation to a physical survey of the home and related usage influences, and therefore this work will improve understanding of the major end uses in natural gas homes. Measuring gas usage can be challenging [5] but the approaches used in this study (current-sensing relays and thermocouples) have allowed a reasonable, safe estimation of time of use and accumulated consumption.

The combined platforms collect nearly 600,000 data points per day across the three platforms. Most of these data can be checked nightly using automated routines (described in following sections) but the lighting data is picked up manually (since those data loggers do not permit remote access).

2.1. End Use Measurement Architecture

Data from most end uses are uploaded to Ecotope's servers once per day. These data include the heating, hot water, appliances, and plug loads. The exception is lighting loggers, which are not networked and are periodically downloaded manually.

There are multiple layers of security at every level of the system so that data and participant privacy are protected. Within the home, the dataloggers, networking equipment, and wireless networks are all locked down to prevent access. The network between the homes and Ecotope is a private network, so unauthorized access is not available from the public Internet. In addition, there are firewalls both at the entrance to the home and at the gateway to Ecotope's servers. The network runs over a virtual private network (VPN) to enhance security further.

Site, datalogger, and sensor status is monitored continuously, primarily for network latency and uptime. Data streams are automatically checked for a variety of issues including unusual gaps and out-of-range values. Problem reports are generated automatically and reviewed by program staff. This monitoring system enables Ecotope to quickly address issues with equipment that may have broken or been moved by participants.

Many network issues can be handled remotely. The custom datalogger also acts as a management platform with tools that allow other networking equipment to be updated and fixed remotely. The ability to perform these tasks remotely delivers better overall uptime and reduces the number of site visits.

Redundancy is built into the system in a number of ways. The dataloggers store log files locally in addition to transmitting them to Ecotope's servers. If an issue arises with a file on the server end, the original can be manually retrieved. The two VPN servers that run the network both have the capacity to support the entire network on their own, so if one fails the network will not go down. The 3G router within the home can perform as a backup wireless router if the primary router fails.

The entry to the home is a 3G cellular router. The 3G router is connected to two dataloggers and a wireless router. One datalogger is an off-the-shelf product that manages the heating, domestic hot water (when heated with electricity), and any appliance that has a dedicated circuit at the electrical panel. Ecotope developed a parallel datalogger platform to support the plug load meters and provide a network management platform in the home. The wireless router runs the plug load network, directing traffic to the custom datalogger. Plug load meters communicate with the router via small wireless nodes. Figure 2 shows this network.

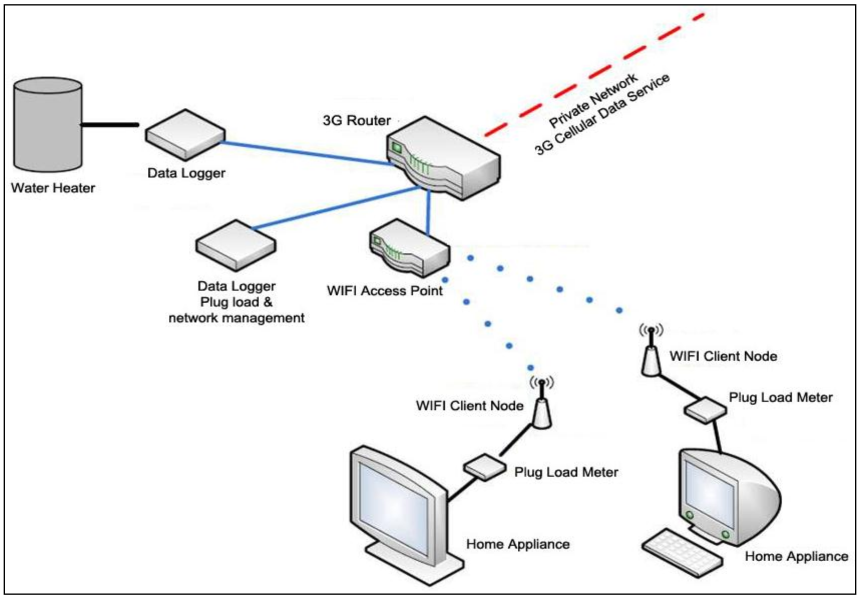

Figure 2. WHEUS Data Collection/Transfer

The 3G routers connect via a private cellular data network to redundant VPN routers at Ecotope. Traffic is routed through a firewall before reaching Ecotope's servers. Because the network is a cellular data network and not a phone network, connections are always live; this factor allows active monitoring of equipment, which helps ensure data quality. Finally, as mentioned above, the network is private, with no access to the public Internet.

2.2. Data Warehousing and Quality Control

The flowchart in Figure 3 depicts how data flow from raw sensor data and site visit forms to deliverable analysis materials. The process starts with physical sensors in the field, which send raw data in comma-separated value (CSV) log files to Ecotope's servers. From there the data are vetted, accumulated, rearranged, and eventually collapsed into high-level summaries and charts. Exploratory data analysis software and custom scripting routines are essential to this work. Very little data storage, cleaning, or analysis are done outside of these platforms.

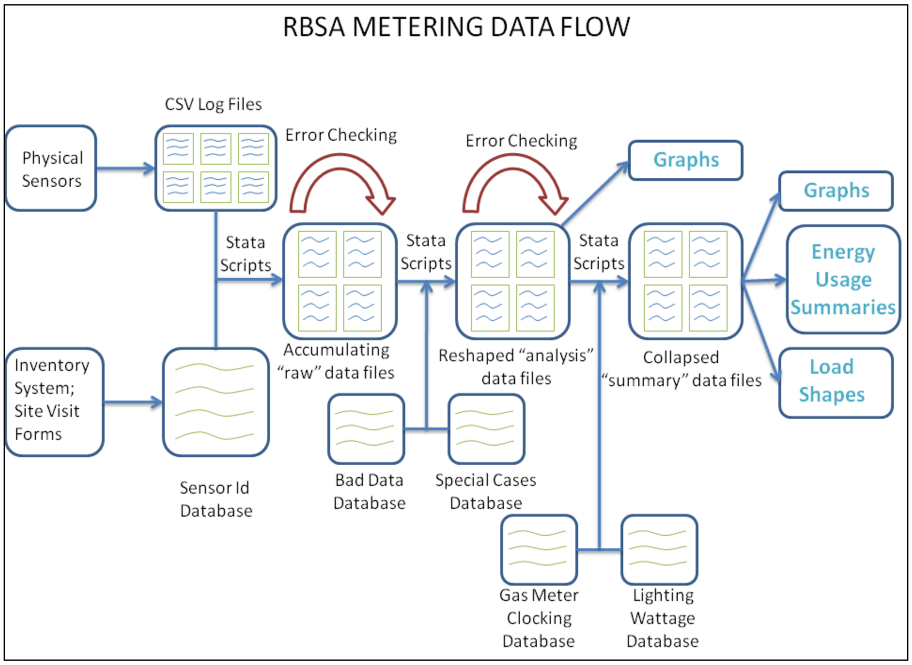

Figure 3. WHEUS Data Flow & Processing

New data are uploaded to Ecotope's servers, and aggregation code runs once daily to incorporate the most recent data. The nightly processing code performs aggregation and error checking according to two general steps.

In the first step, new log files are opened, examined, and parceled accordingly into accumulating datasets, grouped by site ID and sensor type. Stray files and files lacking usable records are discarded. Data gaps, readings in violation of preset, credible bounds, and missing or stale sensors are recorded in a nightly error report.

In the second step, accumulating files for each site are merged together into a single analysis file of five-minute raw data, with known bad data removed and special cases computed. These files are referred to as the reshaped analysis files. Residual errors (i.e., instances where the sum of metered end uses exceeds the measured service load) are tabulated and recorded in the nightly error report, along with a summary of the data fraction acquired and service fraction metered. The reshaped analysis files store the data in physically meaningful categories such as temperature, power, and time. Graphing routines referencing these files help analysts visualize the incoming data. These graphing routines prove valuable in investigating problems flagged by the error reports.

Examining each piece of raw five-minute data, even visually, quickly becomes overwhelming. Broader trends are investigated with a third analysis step, which involves collapsing the reshaped files into hourly, daily, weekly, monthly, and yearly summaries. In addition to aggregating by a coarser unit of time, all measurements of ontime from the reshaped files are converted into energy, which includes lighting and gas devices. Lighting wattages and gas appliance energy input rates are merged with the reshaped files before time aggregation. The broader time scales of the collapsed summary files assist in summarizing energy use patterns and creating end-use load shapes.

An exception to the automated file uploads and near real-time data collection are the lighting loggers, which do not upload data automatically. Each lighting logger data download includes time synchronization, to ensure that the loggers are correctly recording time, which is the basis of alignment with other data. After each download, aggregation code accumulates, reshapes, and collapses the most recent lighting data in a manner virtually identical to the continuously updating data.

The specific errors encountered are summarized and then sent to project staff in nightly reports (spreadsheet format). Gaps in the data and non-responsive sensors may indicate hardware failure, a weak wireless signal, or the fact that a participant moved or unplugged a sensor. Range checks, in which recorded values are examined against credible bounds, often indicate a malfunctioning sensor or a post-processing multiplier that must be applied or adjusted. For instance, we never expect outside air temperature to be colder than -50°F or warmer than 120°F. Power measurements should never drop below zero. Likewise, extreme energy usage data (for example, a gaming system recorded as drawing 4 kilowatts (kW) of electricity) also indicates a measurement error. Errors of this sort are bundled into the nightly report. These range checks are performed with a power "snapshot," rather than average power over the five-minute logging interval, and sometimes deliver false positives in the case of devices with motors, capturing inrush current at startup. Range violation requirements have been relaxed accordingly for devices such as gas furnace air handlers, in which we expect periodically high inrush currents. Residual violations, where the metered end-use power draws add up to a value greater than the whole-house service power draw, also indicate malfunctioning sensors or incorrect post-processing multipliers.

In addition to the automated error checking, Ecotope also performs quality control spot checks. This step involves analysts examining selected sites and sensors at random intervals. Typically, the analyst visualizes the data through various graphing routines to see if the data spin a believable narrative. For example, television usage that peaks at 1:00 p.m. and is virtually zero at 9:00 p.m. would bear further investigation. It might be an accurate pattern if the house is occupied during the day, but it does not fit with "prime-time" viewing habits. Therefore, it might indicate a time synchronization error. This approach is very time intensive so is only used sparingly, but it can sometimes find issues missed by the automated error routines or lead to the development of additional automated routines. Next, analysts also visually inspect site data after the automated error checks alert them to potential problems. Data plots allow the analyst to home in on the error and direct field staff to the specific problem, which can then be targeted in a site repair visit.

The cost of this extensive data checking totals to about 25% of the total 2 year budget of about $2.9 million. Ecotope's current estimate of believable data harvested is very high, though- about 87% of all possible data. This rate of successful capture is key to the success of the regional energy planning process.

3. Site Case Studies

The first case study is for a house (Site 22938) in East Wenatchee, Washington, with all electric loads including a tank water heater, forced-air furnace, and central air conditioner.

Figure 4 displays the most basic monitoring data output – the five-minute average power consumption by major end use. All of the loads plotted stack together to produce the total metered load. The whole-house service load drawn in black is metered separately. Whenever there is white space between the top of the colored plot and the black line, there is some load in the house that is not being separately metered (in this example, lighting is not plotted, which likely accounts for most of the white space).

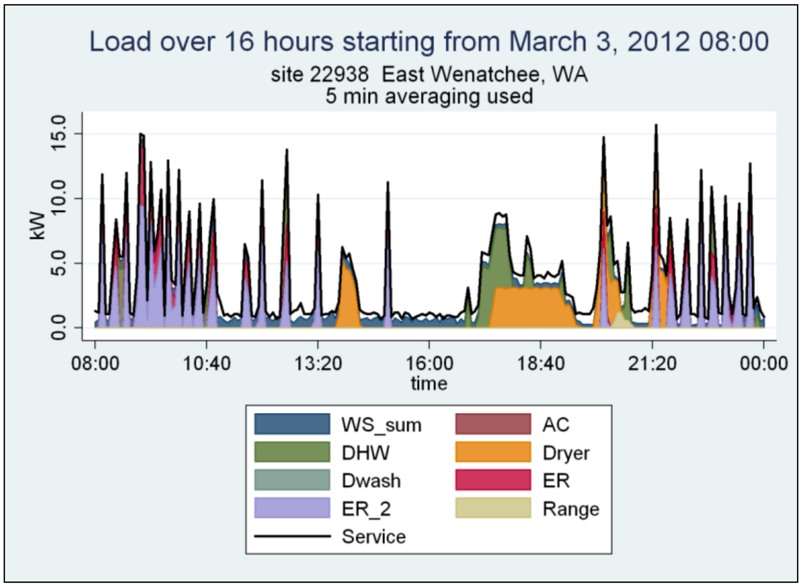

Figure 4. Five-Minute Summary Loads at Site 22938

The furnace has two stages of electric resistance (ER and ER_2). The heating elements engage simultaneously upon a call for heat and account for the largest loads during the day. Note that furnace runtime is greater in the morning than in the afternoon. The next two large loads are the water heater (DHW) and clothes dryer (Dryer). The electric tank water heater shows typical standby recoveries throughout the day and then a major water heating event starting at about 5:00 p.m. On this Saturday, the occupants used the electric dryer four times. At around 8:00 p.m., the kitchen range (Range) was used. The sum of all monitored plug loads is plotted in dark blue (WS_sum).

Using the same time period as Figure 4, Figure 5 plots many plug-in devices that are connected to standard 120-volt branch circuits. On this graph, the plots do not stack but rather show the power consumed by each device.

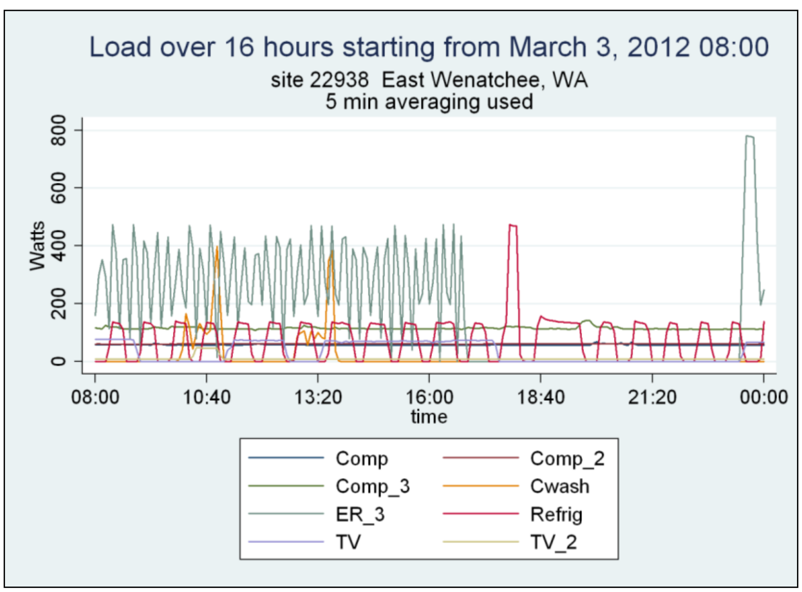

Figure 5. Monitored 120V Plug Loads at Site 22938

During installation of the metering equipment, the occupants indicated that they used a plug-in electric space heater to augment the central furnace heat output. That space heater (ER_3) shows regular use in Figure 5. The figure also shows a typical refrigerator (Refrig) usage pattern. The refrigerator compressor cycles on and off with roughly a 45-minute period to maintain the main box setpoint. Near 6:00 p.m., there is a spike in refrigerator usage, suggesting an automatic defrost event. Two clothes washing cycles (Cwash) occurred between 10:00 a.m. and 2:00 p.m., which correspond with the four dryer cycles noted in Figure 4.

The computers and televisions show more constant loads. The five electronic plug loads plotted in Figure 6 represent three computers (Comp, Comp_2, and Comp_3) and two televisions (TV and TV_2). The plots show that the computers are constantly left on throughout the day. Comp and Comp_2 draw a constant 60 watts (W), and Comp_3 uses about 120 W. One of the televisions (TV) is used for much of the day and draws 80 W when on and nearly 0 W when off. The other television (TV_2) is used for about 30 minutes from 10:30 to 11:00 a.m. TV_2 draws less power than TV when on, but has a standby consumption of nearly 10 W.

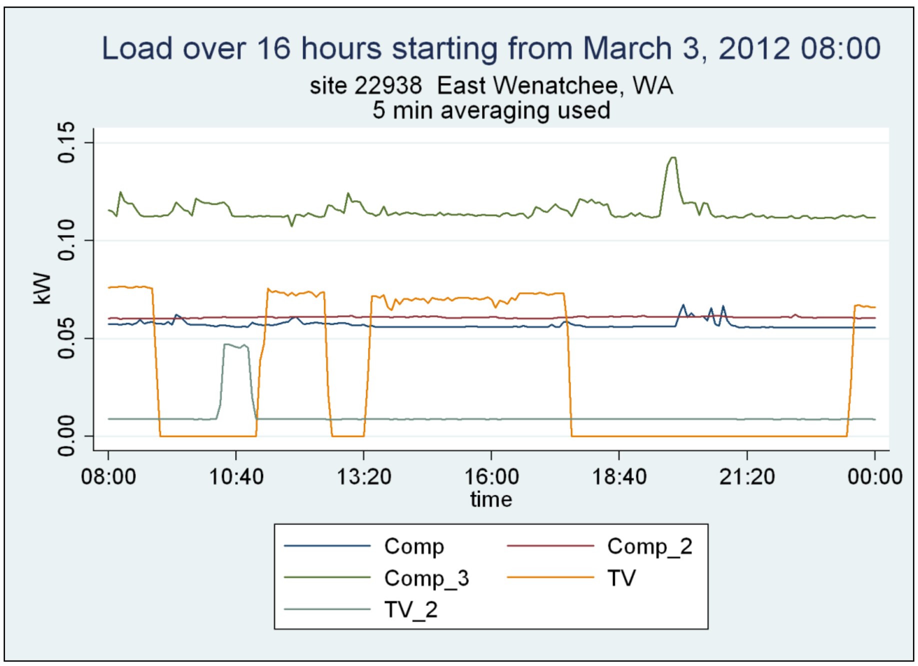

Figure 6. Televisions and Computers at Site 22938

3.1. Consolidated Data

The high-resolution plots of energy use over hours and days facilitate specific and immediate investigations into individual channels and house behavior. Looking at many of these plots at a time, however, quickly becomes overwhelming. Broader patterns are visualized with a set of tools that accompany the collapsed, summary datasets, in which usage can be investigated at hourly, daily, monthly, or yearly intervals.

For example, Figure 7 shows data collapsed by day into end use category. The figure gives an overall picture of energy use for a house (Site 11418) in Carlton, Oregon. The house employs an air source heat pump for space conditioning and an electric resistance tank for water heating. It shows relatively constant DHW and appliance usage. The HVAC usage responds as expected to decreasing outdoor temperatures (ODT). The blue area at the top of the bars shows the remaining house service load not captured by the meters.

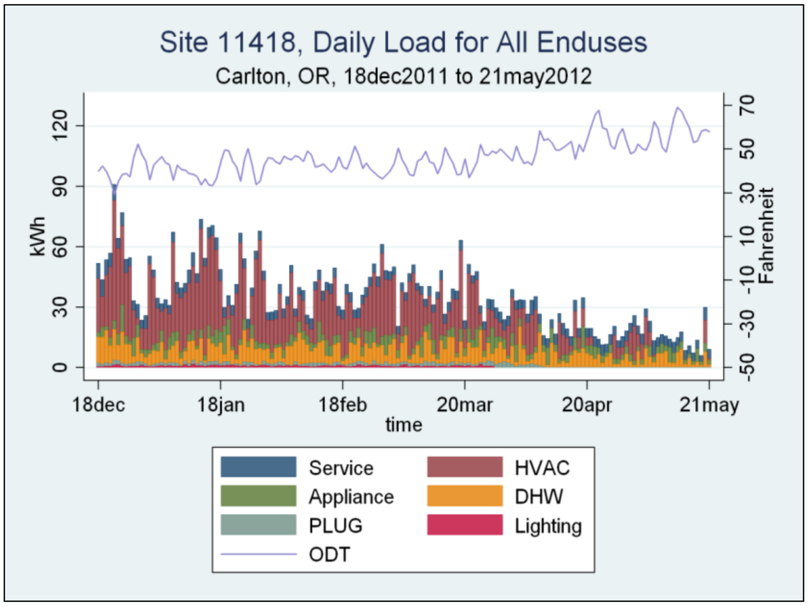

Figure 7. Daily Load by End Use at Site 11418 **(ODT = outdoor temperature, DHW = domestic hot water)**

Table 1 presents the same type of data that are used to produce graphs like Figure xx and consolidates the daily energy use for each major load category. For example, some of the data from the first winter's monitoring at Site 22938 include the coldest times of the year; the electricity usage in the house is dominated by the electric resistance heating. Note the lower number of days for lighting data; the most recent visit to retrieve lighting data was in early March, providing 122 days of data. Table 2hows that approximately 90% of the whole house service load was metered. Some of the "missing" 10% of the total service entry consumption can be attributed to lighting data yet to be collected, and the rest can be attributed to the occupants using devices not metered by our system.

Table 1. Consolidated End Use Data for Electric Resistance Heat Site 22938

Site 22938	# of days	kWh/day				% of Service Load
End Use		Mean	SD	Min	Max	
HVAC	216	56.7	38.6	0.0	145.0	69%
DHW	216	8.2	3.6	0.0	18.2	10%
Appliances (non-DHW)	216	3.4	3.4	0.0	16.2	4%
Plugs	216	5.1	1.3	0.0	6.8	6%
Lights[2]	122	0.7	0.7	0.0	3.0	1%
Total Submetered	216	74.1	40.6	0.0	161.9	90%
Whole House Service	216	82.6	41.3	0.6	173.2	100%

[2] Lighting data only for 122 days due to manual downloading. This biases the lighting fraction low in the table.

Another set of summarized end uses is presented in Table 2 for site 11418 in Carlton, Oregon. The data in the table cover 173 days from January to June 2012. Like the data from the Wenatchee site, this time period covers the cold heating season. Unlike the Wenatchee site, the HVAC energy use is a smaller fraction of the total load. One factor is that the climate is warmer in Carlton. More importantly, however, the air source heat pump is more efficient than an electric resistance furnace.

Table 2. Consolidated End Use Data for Heat Pump Conditioned Site 11418

Site 11418	**# of days**	**kWh/day**				**% of Service Load**
End Use		**Mean**	**SD**	**Min**	**Max**	
HVAC	173	15.5	13.8	0.0	59.8	47%
DHW	173	6.9	4.0	0.9	19.0	21%
Appliances (non-DHW)	173	4.4	2.4	1.7	14.2	13%
Plugs	173	1.0	0.8	0.0	2.9	3%
Lights[3]	102	0.5	0.5	0.0	1.8	1%
Total Submetered	173	28.3	16.3	2.9	83.1	85%
Whole House Service	173	33.2	16.5	6.1	90.9	100%

In addition to summary statistics, it is also possible to conduct analytical exercises with the data. Figure 8 plots HVAC energy use versus outdoor temperature. The electric resistance furnace has two stages (ER and ER_2), which nearly always operate simultaneously. The clean behavior on the graph indicates that the load is well regulated by the thermostat. The graph also shows the plug-in heater (ER_3) energy use, which appears relatively flat versus outside temperature. This sort of pattern implies that plug-in heaters may be more appropriately classified as a plug load responding strongly to occupant whim, rather than a load that responds only to outside temperature. Most notable is an encouraging, orderly relationship between outside temperature and HVAC energy usage. A linear regression of total heating energy against daily outdoor temperature results in 3.6 kWh/day-°F, or a heat loss rate of 511 Btu/hr-°F. For a home with 1,875 square feet of conditioned floor area, this heat loss rate is well within expected bounds. Last, the graph in Figure 9 shows some cooling energy use, corresponding to the end of May and beginning of June when average daily outdoor temperatures are near 70°F and the daily maximum temperature was much warmer (almost 90°F on some days according to the five-minute data).

[3] Lighting data only for 102 days due to manual downloading. This biases the lighting fraction low in the table.

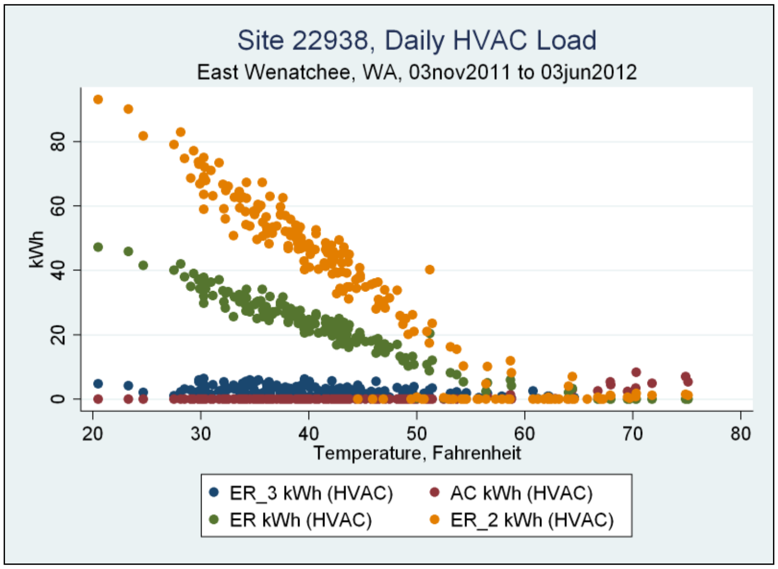

Figure 8. Daily HVAC Energy Usage Versus Outdoor Temperature

3.2. Lighting Data

The region has never conducted a thorough lighting time-of-use study. Time of use logging is challenging since it requires deployment of about 20 lighting loggers in each home and manual retrieval of data. These data can be combined with lamp/fixture information to calculate lighting usage. The first look at the data shows very promising results. (At press time, visits to pick up the remainder of the first year of time of use lighting data are being scheduled.)

Figure 10 depicts hourly lighting load shapes at one house, which has occupants who work outside of the house during the day. The occupants get up in the morning, use the bedroom and bathroom lights between 6:00 a.m. and 7:00 a.m., and then presumably leave the house. Lighting usage picks up again around 4:00 p.m. and 5:00 p.m. with the living room lights. Note that the y-axis shows average kilowatt hours per hour (kWh/hr) for each named lighting group.

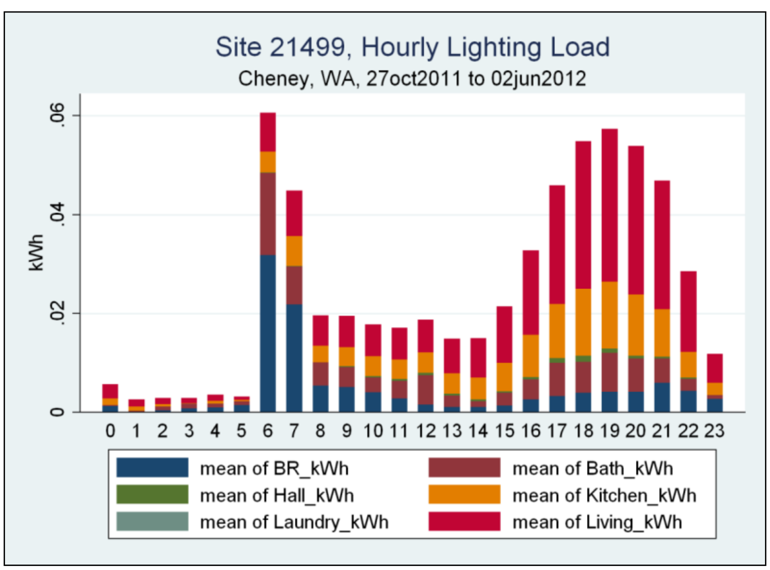

Figure 11. Hourly Lighting Load Shape – Site 21499

The daily load shape in Figure 14 also shows an expected pattern for a site where the occupants work outside of the home during the week. The Monday to Friday usage is about half of the Saturday and Sunday usage. In contrast, other sites (where homeowners are either retired or work from home) exhibits a mostly flat lighting load every day of the week.

4. Conclusion

Results from the 100 site Residential Building Stock Assessment Whole House Energy Use Study are key inputs to the 7th Northwest Power and Conservation Plan. The data collection system for this study was designed to achieve high rates of useful data recovery. A full report on the project will be available in early 2014. Because of this work, the Pacific Northwest region will have a better chance of identifying future energy conservation opportunities.

ATLETE II - Appliance Testing for Energy Label & Evaluation – Washing Machines

Co-funded by the Intelligent Energy Europe programme

Table of contents

Abstract

The ATLETE II project is developed between May 2012 and October 2014, with 11 consortium partners from across the EU. The main project goals are to assess the pan-EU compliance of washing machines with energy labelling and eco-design requirements, to identify the potential problems in the use of the testing conditions of the new standard, to improve the capacity of testing laboratories, to stimulate co-operation among national Authorities for effective market surveillance, and to support the dialogue among main stakeholders: suppliers and Market Surveillance Authorities. ATLETE II objectives are:

- Carrying out a pan-European assessment of the compliance of 50 washing machines, semi-randomly selected on the European market on the basis of agreed criteria, to the new energy labelling and ecodesign regulations through the verification of the:
  - ✓ formal compliance; check the availability of the label, product fiche and booklet of instructions provided with each appliance to the relevant requirements
  - ✓ compliance of the declared values through laboratory measurements
- Improving the know-how and testing capability of a group of laboratories having to face the more complex test conditions of the new standard: EN 60456:2011
- Verify through the field work the applicability of the new standard for the measurement of the washing machine energy and functional performance
- Support actions undertaken by the market surveillance authorities (MSA) upon the notification of the testing results highlighting products non-compliance.

The ATLETE II achievements will also include a detailed analysis of the test reports, assessing:

- the non-compliance cases: discussion of the reasons for non-compliance, in view of the revision of the washing machine labelling/ecodesign regulations
- the applicability of EN 60456:2011: in depth analysis with all the laboratories involved to evaluate the limits/problems of the new test method, if any, with a view to its improvement.

Background: history of the project – testing refrigerators

The first ATLETE project ("Appliance Testing for Energy Label Evaluation")[1] was run between 2009 and 2011, with ISIS (Research and consultancy firm, Italy), CECED (European Committee of Domestic Equipment Manufacturers), ENEA (National Agency for New Technologies, Energy and Sustainable Economic Development, Italy), ADEME (French Environment and Energy Management Agency) and SEVEn (The Energy Efficiency Center, Czech Republic) as the project partners.

That project focused on testing refrigerating appliances for their compliance with the energy label declarations and it was the first European wide testing activity focusing on market surveillance of an EU policy measure, encompassing the laboratory testing of 80 semi-randomly selected (randomly selected by a notary from certain pre-defined market segments) refrigerating appliances. The project described in detail the results of product tests and confirmed the feasibility and affordability of market surveillance.

One of the main project conclusions was that by using an agreed methodology, defined taking into consideration the international experience, market surveillance activities for household appliance energy labelling are, technically feasible, and cost effective, and an essential element in meeting energy efficiency targets.

The final test results show that 80% of appliances subjected to testing and for which testing has been concluded complied with the energy efficiency class declaration and the two related key parameters: energy consumption and storage volume. But when all five parameters (see graph below) are taken into consideration, 57% of them do not comply with at least one of the test parameters.

In 25 cases, the manufacturers accepted the results of Step I (a single unit of the model under evaluation tested) and agreed to make specific remedy actions, such as the correction of the label declarations and/or of the product fiche, the improvement of the product's documentation and user's manual, as well as the printed and web catalogues. In some other cases the production of the model was discontinued. In a specific case, due to the ATLETE test result findings, a manufacturer has discovered - and then solved - a problem having occurred in the production of batch of products. Another example of improvement also includes product updates for the succeeding model range, if the original model was no longer distributed after the publication of the test results.

Test results and test reports for each individual model are publicly available on the project website and have been shared with the EU Member State Market Surveillance Authorities, media, experts and stakeholders.

ATLETE II – a new exercise on washing machines

The ATLETE II[2] (Appliance Testing for Washing Machines Energy Label & Ecodesign Evaluation) project evaluates energy labelling and ecodesign compliance for the second most important appliance in terms of energy use in European households: the washing machine. The project lasts between May 2012 and October 2014, is supported by the European Commission's Intelligent Energy Europe (IEE) programme[3] and is conducted by eleven partners from seven different countries.

By assessing the compliance of washing machines to labelling and ecodesign ATLETE II aims to help Member States to improve the market surveillance of the EU legislation.

Energy labels and ecodesign requirements are crucial drivers for market transformation towards more efficient appliances and phasing-out of the least efficient models. In addition, consumers should be sure that the products found on the EU market comply with the legislative requirements. The goals of the ATLETE II project are to check the pan-EU compliance of washing machines with energy labelling and eco-design requirements using the new measurement method, to improve the capacity of testing laboratories and at the same time support co-operation among national Authorities for effective market surveillance.

ATLETE II encompasses:

- Detailed evaluation of the current level of market surveillance activities related to labelling and ecodesign compliance around the EU
- Semi-random selection (methodology explained on page 6) of 50 models of washing machines from the EU markets for assessing the compliance with the energy label and ecodesign requirements (except noise and standby)
- First large-scale laboratory testing of a washing machine under the new Energy labelling legislation, also applying a new measurement method: EN 60456:2011
- Organisation of mini-ring tests among some EU laboratories, ensuring improved quality and consistence in testing washing machines
- The publication of all project results, from the list of models selected for testing, through all methodologies applied, to test reports, and overall evaluation of results
- Inviting manufacturers, whose models will be tested, for undertaking voluntary remedy action in case of suspected non-compliance of their products
- Informing EU Member State Market Surveillance Authorities about all individual test results relevant to models sold on their own markets
- The organisation of EU-wide and national dissemination activities informing the stakeholders about the project's testing procedures and the consumers on the label requirements
- Concrete support to the EU and national authorities for an effective energy labelling and ecodesign implementation and verification

Through ATLETE II the project team seeks to confirm that compliance verification testing for market surveillance can be done in a systematic, effective and cost-efficient way, thus setting a major cornerstone in supporting market transformation and ensuring the highest benefit for consumers, manufacturers and the environment. Key stakeholders in the project include Market Surveillance Authorities, laboratories, suppliers, energy efficiency experts, and consumer and environmental protection organisations.

Excerpts from the project actions and results achieved[4]

Overview of market surveillance activities

One of the introductory steps of the ATLETE II project was the organisation of a survey, collecting and evaluating detailed information about the level of market surveillance activities undertaken by individual EU member states. This survey evaluated the organisation and level of activities of national Authorities related to the new commitments envisaged by the new legislation on ecodesign (Directive 2009/125/EC) and labelling (Directive 2010/30/EU) including the obligation for member states to report to the Commission and then to the Parliament on the achieved market compliance (see Art 3.3 and whereas 10 of directive 2010/30/EU).

The following aspects of the Energy label and ecodesign verification, with a specific focus on washing machines, have been researched:

- Budget available for surveillance activities
- Number of staff and inspectors available
- Number of shop inspections undertaken, including the results on compliance, types of shops visited, online shopping, etc,
- Number of product tests performed, including available information on test results and their analysis
- Complaints received from physical or legal persons
- Number of non-compliant products found on the market
- Nature of the corrective action taken and the products withdrawn from the market
- Sanctions applied and / or voluntary measures taken by companies

The survey on market surveillance activities in all member states was conducted in early 2013[5] and summarises the level of Market Surveillance activities in individual EU countries, related to product labelling and ecodesign, with a specific focus on washing machines.
The survey provides an overview on the quantity and quality of activities, e.g. the number of product testing), review of shop visits undertaken to verify the presence of energy labels, and the opinion of the market surveillance authority representatives on the possible future enlargement of the label surveillance activities:

- Majority of MSA (6 MS out of the 7 MS who provided feedback on product compliance level) estimate that the current compliance rates for energy labelling and ecodesign requirements of washing machines are approximately similar as other products.
- There is a lack of financial resources allocated to market surveillance activities from national governments as reported by six of the eight MS who do not conduct testing of products.
- Testing facilities/laboratories are insufficient at MS level and EU-wide. Majority of MSA consider the current testing costs to be expensive (6 out of 8 MS who do not perform tests reported costs as a barrier), and may be time intensive (5 out of 6 MS who provided feedback on testing period commented that it can last up to few months).

[4] Status of the project as of March 2013, submission of EEDAL 2013 paper
[5] http://www.atlete.eu/2/market-surveillance-authorities

- With the transposition of the new Directives, some (8 MS) market surveillance authorities faced human resources constraints. These constraints are primarily associated to the new work associated with these legislations. This is because although 11 MS accepted impact on their activities however only 3 of them had a corresponding change in their staff.
- Around half (6 MS out of 13 MS) of the MS that test products held detailed records of the compliance level of washing machines.
- Almost half (11 MS out of 23 MS who responded) of the MS currently control the compliance of catalogues. Control of catalogues is planned to increase regardless of the fact that their use is not widely spread among consumers in some MS.
- More than half (13 MS out of 21 MS who responded) of the MS currently control the compliance of internet sales. Control of internet offers will further increase in coming years as 5 out of the 8 MS who do not perform a control on internet offers at present, intend to do it in future.

Definition of the compliance verification approach

The main methodological approach for cost effective product compliance verification prepared within the previous ATLETE project has been re-assessed and tuned-up to adapt it to the washing machine verification. This update intends to eliminate the inconsistencies of some actions and elements that have been identified during the field work on refrigerating appliances, and the draft: *Guidelines for WM verification: models and laboratories selection, new standards and measurement methods* was prepared and published in the project website[6]. The aim of the Guidelines, which will be finalised at the end of the project, is to describe in detail a globally applicable procedure for the verification of the compliance of this product group to the implementing measures under the eco-design framework Directive 2009/125/EC and the energy labelling framework Directive 2010/30/EU. It is worth noting that within the ATLETE II project testing activities, the conformity verification of the washing machines will follow the essential requirements included in the EU legislation: a two Step verification procedure will be developed, testing first one single unit of the model under investigation.

Since one of the aims of this project is to contribute to increasing the quality of information and test reports received from individual laboratories a Test Report Template was prepared[7]. The template is aimed at improving the comparability of the test results and as a supporting tool for MSA when deciding about the compliance of a tested product. Laboratories participating in ATLETE II testing were asked to deliver their own test reports and to fill in the Test Report Template at least for the reporting of the test results of the first batch of washing machines. This will allow the template to be checked to confirm whether it is sufficiently developed to be used as the only test reporting system for the project, or if it requires further improvement. A decision will be taken by the project partners also on the basis of the comments received by the test laboratories.

Selection of washing machine models for testing

ATLETE II foresees the testing of 50 models of washing machines, covering suppliers with both a large and small market share. Based on the previous successful experience with the refrigerating appliances, the selection of the washing machines is done among the best seller models for each supplier. In particular it was decided to select:

- the bestseller products for each manufacturer/producer that has a market share above 0.1% on the EU 27 market,
- and national champions in following countries AT, BE, CZ, DK, FR, DE, IT, NL, PL, ES, SE, UK with market share above 1%,

[6] http://www.atlete.eu/2/doc/DraftGuidelinesforWMverification_September2012.pdf
[7] http://www.atlete.eu/2/test-procedures

- 5 washing machine models for each of the expected 4 manufacturers with a Market Share (MS) ≥ 10% (for a total of 20 models);
- 3 models for each of the expected 4 manufacturers with 5%≤MS<10% (for a total of 12 models);
- 2 models for each of the expected 4 manufacturers with 1%≤MS<5% (for a total of 8 modes)
- 1 model for each of the expected 4 manufacturers with 0,5%≤MS<1% (for a total of 4 modes)
- and 6 models randomly selected for the remaining 252 manufacturers with a market share < 0,5%.

The model selection process is organised following a 'semi-random' approach:

- the market is divided into market segments (based on the selling levels) - from the segment of best sellers to the segment of least sellers
- an independent company was tendered to deliver the overview of the market, including the individual models sold and their market shares and country availability, based on which the individual models have been selected
- in each of these segments, some washing machine models were randomly selected by an external notary
- models are purchased by an independent partner of the project (ICRT) and delivered to the laboratories.

The overall total is thus 50 washing machines models. Models will be selected in three batches, in order to decrease as much as possible the time to testing, i.e. the time from the selection of the model to be tested and the actual testing. This approach is expected to reduce at least partially the possibility that a selected model disappears from the market before the two step verification procedure is completed.

As of February 2013, 13 models have been selected[8] and laboratories started to perform product testing. When the full testing of all (50) models will be completed (spring 2014), the project will publish not only the list of models tested, but also the results of tests and the test reports from individual laboratories.

Voluntary protocol for manufacturers proactive participation

Manufacturers have access to the testing facilities to assist the procedure of testing their own products under a supervision of the laboratory and project representatives. All known manufacturers have been also invited to sign a voluntary protocol[9], by which, should their products be suspected of being non-compliant after the development of Step 1 of the verification procedure, they will have the possibility to stop the testing and, to take remedy actions to reflect the test results.

Within the ATLETE II project the protocol has been circulated to all known manufacturers of washing machines. By signing the protocol, the individual manufacturers confirm that they will:

- take, within 30 (calendar) days after being informed of the testing all the remedy actions necessary to correct the energy labelling declarations of the appliance model/s concerned in accordance with the results of the testing procedure, alternatively modify the product to make it comply with its energy label declaration; and
- take, within 30 (calendar) days after being informed of the results of the testing all the remedy actions necessary to fulfil the eco-design requirements for the appliance model/s concerned; and

[8] http://www.atlete.eu/2/doc/ListOfTheSelectedModels
[9] http://www.atlete.eu/2/doc/ManufacturersParticipationProtocol.pdf

- inform, within the same timeframe the ATLETE II Project Leader of the remedy actions taken to correct the energy labelling/eco-design declarations or parameters, and provide the ATLETE II Project Leader with the appropriate evidence of conformity and remedy actions taken, such as a copy of a letter sent to the trade, with a proof of the sending thereof, and a copy of brochures or leaflets marketing or advertising the concerned appliance model/s with the correct energy labelling/eco-design declarations, without disclosing any information which would be confidential.

The voluntary protocol has been circulated to the individual manufacturers before the selection of models for testing had been undertaken in February 2013. Out of 128 brands contacted, 27 manufacturers, covering approximately 90 % of the EU market share and minimum 41 out of 50 models to be tested have signed the protocol. The list of the manufacturers signing the protocol is available on the project website[10].

Selection of the test laboratories

One of the key project activities, ensuring that the project would deliver high quality results, was to select laboratories that would ensure a high capability of testing washing machines. The project has therefore organised a thorough selection procedure including[11]:

- Call for interest: independent laboratories in the EU known for being able to test washing machines have been invited to express their interest to participate to the call for tender, which took place by July 2012. The Call for tender was published also on the project website to allow all laboratories to participate
- Laboratory recognition Questionnaire: a detailed questionnaire[12] was circulated to the laboratories expressing their interest to participate to the project, asking for a confirmation of their intention to participate to the project, and collecting a large set of technical information about testing capability, instrumentation, calibration as well as laboratory experience, certification and personnel qualification and training. 9 laboratories, out of the 20 invited laboratories, have submitted the full information requested. The requirements to participate included for example:
  - Independent laboratory status
  - Ability to test automatic horizontal axis washing machines according to EN 60456:2011 and related standard(s)
  - Capability to fully follow the given test method (EN 60456:2011) without in-house interpretation of test conditions
  - Readiness to accept a visit of an expert from the project partners and of the representative of the manufacturer(s) of the tested unit(s)
  - experience in previous Round Robin Tests/Performing tests for washing machines and relevant models tested over the past years
  - periodic training of technicians who will perform the tests
  - confirmation on accuracy of equipment, including meters and calibration frequency
  - Regular supply of the consumables (i.e. standard detergent, load, etc.) needed to test washing machines from a well-known source
  - Capability to test all testing requirements for energy labelling and ecodesign.

[10] http://www.atlete.eu/2/manufacturers
[11] http://www.atlete.eu/2/laboratories
[12] http://www.atlete.eu/2/doc/LaboratoryrecognitionQuestionnaire.pdf

- Visit of external expert – before confirming the final selection, the laboratories have been personally visited by two experts appointed by the project to check the responses given in the questionnaire.
- Finally, an economic offer was asked to the laboratories, through a Call for Tender. The score achieved with the offer has been then combined with the score achieved in the Questionnaire and the overall result lead to the selection of six laboratories:

1. CTTN (France),
2. IMQ (Italy),
3. INTERTEK (UK),
4. LCOE (Spain),
5. SLG (Germany),
6. VDE (Germany).

It is expected that on average 8 to 10 models will be tested by each laboratory.

A coordination meeting with the selected laboratories took place in February 2013, and three more meetings will take place within the project, to share the experience, discuss individual testing procedures and ensure the same level of reporting to be delivered.

International Advisory Committee to the project

An International Advisory Committee (IAC) is also organised within the ATLETE II project. The IAC consists of national experts, stakeholders, MSA, representatives of the civil society, etc. IAC participants contribute to the formulation of the overall procedure, project activities and to the discussion of the specific outcomes.

The advisory committee has been established[13] at the start of the project and first two of the three foreseen meetings were held in November 2012 in Brussels and in May 2013 in Stockholm.

Other next steps

Development of mini-Round Robin Tests

Parallel to the compliance verification of the selected washing machines ATLETE II foresees that a mini-Round Robin Test exercise is developed to improve the experience of the existing testing laboratories around Europe. The aim is to support the creation of a sufficient testing capacity for an effective market surveillance action by the national Market Surveillance Authorities.

The exercise is open to laboratories able to test washing machines and not already contracted by the project. Laboratories participation is on voluntary basis, for free, and subject to some conditions. ATLETE II project will be responsible for the logistic and the purchase of some of the consumables (test loads, standard detergent, standard test strips) and for the calibration of the reference washing machine. Washing machines having passed the compliance verification tests will be circulated for the mini-Round Robin Test exercise.

The number of laboratories to be involved in the mini-Round Robin Test (at least 3 labs for each mini-ring test are needed for a meaningful statistical analysis of the tests results) and the overall number of mini-Round Robin Test will be decided considering the positive answers received to an invitation sent to a list of laboratories in February 2013

[13] http://www.atlete.eu/2/project-resources/category/5-meetings-with-target-groups

Harmonised application of the new standard for washing machines

The aim of this action is to analyse, with the contribution of all partners and involved laboratories the content of the new standard EN 60456:2011, to evaluate possible areas of uncertainty of its application in order to create – if needed - a common understanding and application of the test conditions. In this respect, if necessary, a set of recommendations to the EU Commission/DG ENER, the standardization bodies, the laboratories and the other involved stakeholders will be prepared at the end of the project

A Proposed Framework for Moving Towards International Comparability of Appliance Energy Efficiency Policies

Debbie Karpay, Collaborative Labeling and Appliance Standards Program (CLASP)

Stephen Pantano, Collaborative Labeling and Appliance Standards Program (CLASP)

Paul Waide, Waide Strategic Efficiency

Abstract

Alignment of appliance energy efficiency policy components enables consistent policy comparison around the world. Numerous policies exist, put in place product-by-product by individual economies; increased alignment can conserve national resources while accelerating policy impacts. Harmonization entails the convergence of critical elements of an appliance efficiency policy, including: test methods; product definitions/categorization; energy efficiency/performance metrics; and performance threshold tiers.

This paper proposes a framework for how to direct appliance standards and labeling analysis resources to promote greater international policy alignment. The approach includes four interrelated elements:

1. Analyzing gaps in existing policies ("gap analysis")
2. Evaluating test methods and policy stringency across economies ("benchmarking")
3. Developing suitable international standards to serve as the foundation for aligned efficiency policies
4. Tailoring information to inform economy-specific policy developments

First, policy gap analyses reveal "low-hanging fruit" on the international and national level. Second, a product benchmarking study can identify the source and magnitude of differences in existing test methods which inhibit international comparison, and provide the basis for conversion functions among energy efficiency metrics and test methods from various economies.

Third, international standards bodies such as IEC and ISO can improve the quality and comprehensiveness of international standards, encoding aligned policy elements to facilitate greater policy convergence. Finally, tailored analysis of the aforementioned information can identify the most important policy matters for consideration in a particular economy.

This technical and analytical framework for greater international harmonization of appliance efficiency policy should lead to more successful alignment of appliance energy efficiency policies around the world.

Introduction

Harmonization – the alignment or convergence of critical elements of one or more appliance efficiency policies – facilitates the comparison of policies around the world, which has the potential to promote faster and greater improvements to the stringency of energy efficiency standards and labeling (S&L) policies. Since policies are put in place product-by-product by individual countries, the quantity of policies in place is huge; increased alignment can save countries time and money while accelerating policy impacts. The elements of appliance efficiency policies that might be harmonized, or aligned, include test methods, product definitions and categorization, metrics for energy efficiency or energy performance, and performance thresholds.

It is important to note that the goal of harmonization is not to have *identical* global energy efficiency policies for all types of products; rather, it is to encourage incremental and responsible progress towards convergence. For example, it is likely that policy elements for globally-traded products such as televisions and computers can be made more consistent across economies than can policy elements for products such as air conditioners that are designed to serve climate conditions in specific markets. Harmonization objectives for air conditioners may therefore entail development of a menu of regional policy options to accommodate the range of expected climate conditions.

The benefits of convergent international energy efficiency standards are well characterized, as outlined below. [3]

- *Enhanced transparency and clarity across economies*. Aligned policy elements permit direct comparison (and benchmarking) of product efficiency and policy stringency across peer economies, and can inform prioritization and S&L policy decisions.
- *Lower cost, higher quality, more rapid, and more ambitious domestic regulations*. Harmonized policy elements facilitate the use of analyses from peer economies to determine techno-economic potentials from higher energy efficiency levels and justify the adoption of regulations set at specific energy efficiency levels.
- *Lower costs and higher quality of tests.* The cost and expertise needed to develop and maintain test procedures is shared.
- *Reduced manufacturer costs for testing and production.* Globally-traded products that attain a harmonized energy efficiency rating will be accepted for sale in any economy that adopts the policy elements concerned.
- *Accelerated market and manufacturer learning, lower consumer costs, and stimulation of innovation.* A common set of energy efficiency thresholds supports the market for high efficiency products, since manufacturers know that products that meet a given performance threshold can be sold on a larger market. This drives up the volume of higher efficiency products, lowers the production costs through economies of scale, and thereby accelerates market transformation.
- *Facilitated technology transfer*. Given the certainty that efficiency thresholds are globally linked, manufacturers have greater long-term incentives to pioneer even more energy-efficient products to meet aspirational thresholds, thus facilitating technology transfer.

Presently, a greater degree of harmonization is taking place at the regional level than at the global level [1]. Some of these regional harmonization efforts aim to establish identical policies and policy elements even for appliances with large usage variations based on climate or behavior. The EU, for example, has regional S&L policies for many of these appliances. S&L policies are often harmonized within North America, especially between the US and Canada. Additionally, the 15 economies that form the Economic Community of West African States (ECOWAS) are developing a regional policy on energy efficiency that involves "a harmonized policy, legal and regulatory framework in energy efficiency for the ECOWAS region, including energy efficiency labels and standards." [2]

This paper proposes a comprehensive framework for how to direct and apply appliance S&L research and analysis resources to promote greater international policy alignment. The approach includes four interrelated elements:

1. Analyzing gaps in existing policies ("gap analysis")

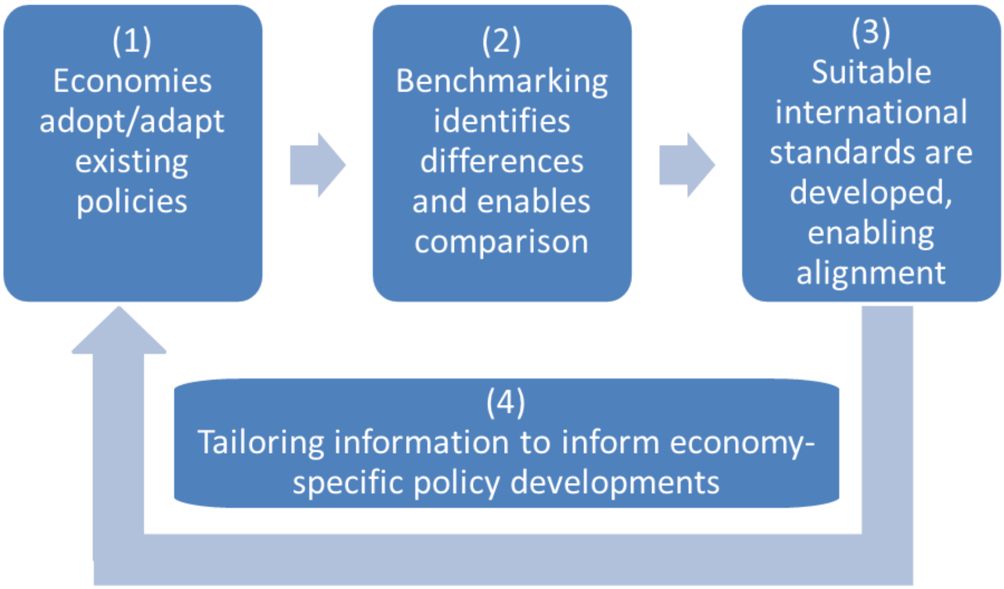
2. Evaluating test methods and energy efficiency policy stringency across economies ("benchmarking")

3. Developing suitable international standards to serve as the foundation for aligned efficiency policies

4. Tailoring information to inform policy developments in individual economies

By establishing a technical and analytical foundation for greater international harmonization of appliance efficiency policy, this framework should lead to more compelling and successful efforts to develop appliance energy efficiency policies that may be readily adopted by economies around the world.

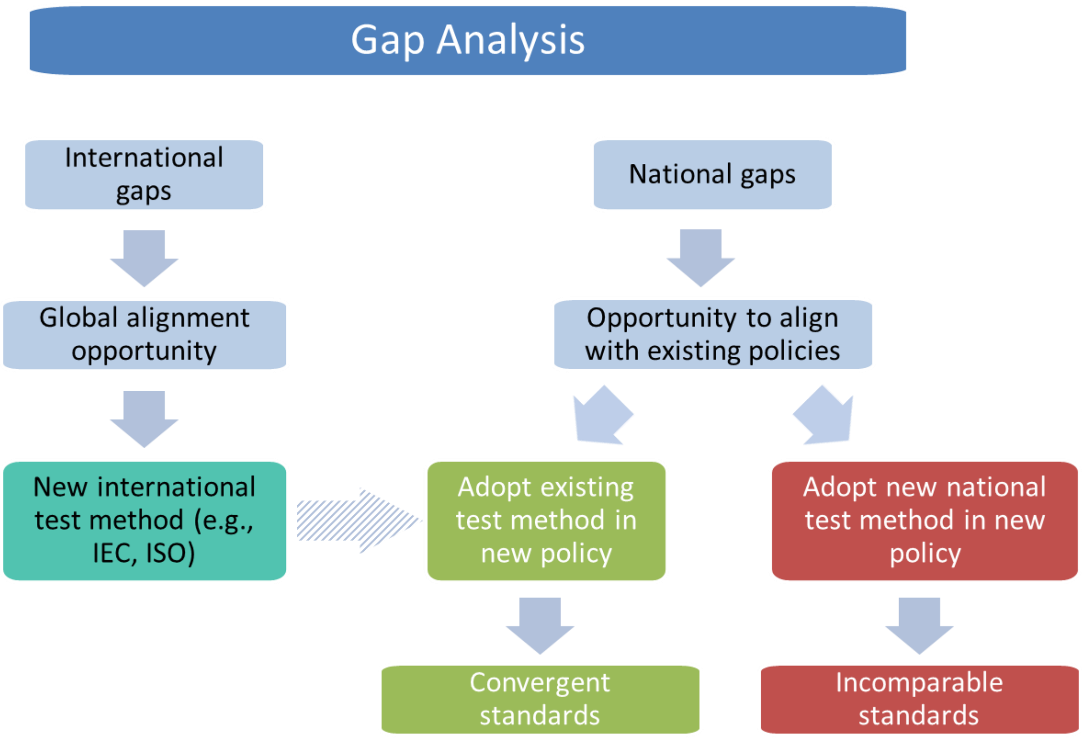
Figure 1: A proposed methodological framework for promoting greater international convergence of S&L policies and policy elements



Gap analysis of existing policies

As a first step, S&L practitioners can assess the energy-saving potentials available for different products through convergent S&L policies, and use that information to define policy priorities. A policy gap analysis reveals "low-hanging fruit" on the international and national level. Product categories that lack international energy efficiency test methods present opportunities for international standards bodies, such as IEC and ISO. Similarly, product categories for which there are few national energy efficiency policies present opportunities for decision makers to adapt policies from other countries, thereby filling policy gaps and increasing international comparability.

Figure 2: Gap analysis reveals "low-hanging fruit" for S&L policies, and can lead to aligned standards

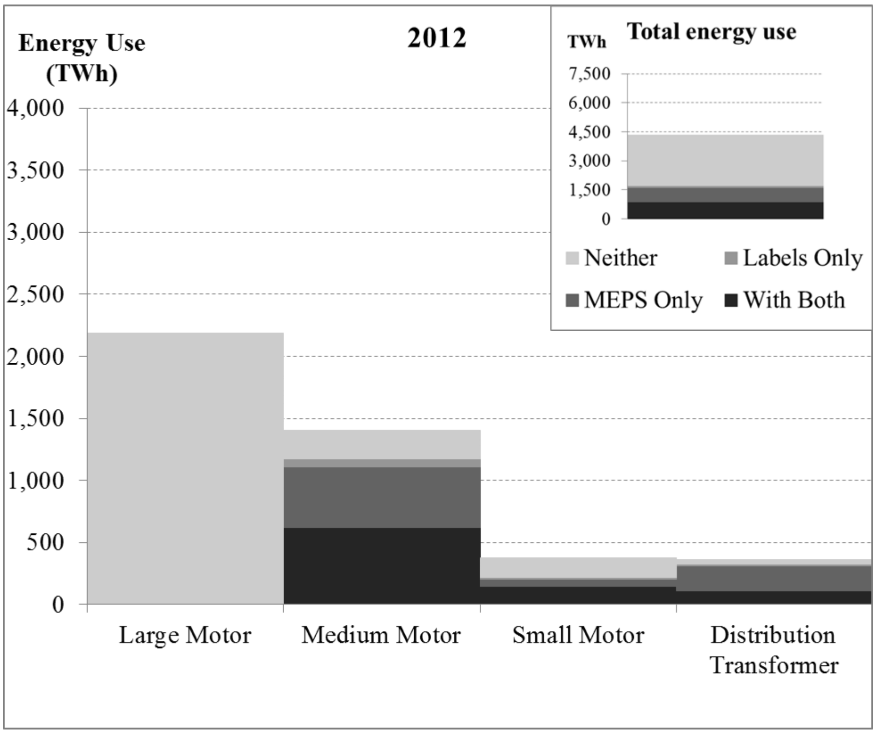


Sparsely regulated product categories: immediate global harmonization opportunities

One barrier to harmonization is a resistance to change in countries with long-standing S&L policies in place. Once domestic manufacturers, standardization bodies, and regulators have invested in the development and maintenance of a particular policy infrastructure, products may be designed to reflect the nuances of domestic test procedures, product classifications, and efficiency metrics [3].

Therefore, it is likely easier to establish convergent S&L policies for products or product categories that are sparsely regulated around the world. Gap analyses will reveal products that have less international S&L coverage and therefore would face fewer engrained structures within existing S&L programs. Figure 3 shows a gap analysis for several major energy-using products in the industrial sector, and illustrates that large motors use a large amount of energy but are not covered by S&L policies anywhere in the world. Medium-sized motors, however, are well-covered by S&L policies; furthermore, those policies are largely harmonized around the world, as will be discussed below in the section, "Facilitation of convergent international efficiency policies".

Figure 3: Energy use of industrial electric motors and distribution transformers in 2012: an example of a product-focused gap analysis [4]



Commercial refrigeration equipment, for example, has relatively few S&L policies in place around the world (i.e., mandatory or voluntary minimum energy performance requirement, comparative label, or endorsement label). Based on the CLASP S&L Database [5], only 8 economies currently have any S&L policies in place for commercial refrigeration equipment: Australia, Canada, China, Japan, Korea, Mexico, New Zealand, and the US.[1] For comparison, residential refrigerators have S&L policies in place in 35 economies. From this simple gap analysis, it is apparent that internationally-convergent S&L policies and policy components for commercial refrigeration equipment will face fewer barriers from existing S&L programs.

For these sparsely regulated products, establishing effective international menus of policy settings can also ease the path for national regulators to broaden S&L policy coverage; if an international standard is suitable to be adopted for use in an economy, it lowers the cost and time required by that economy to cover that product.

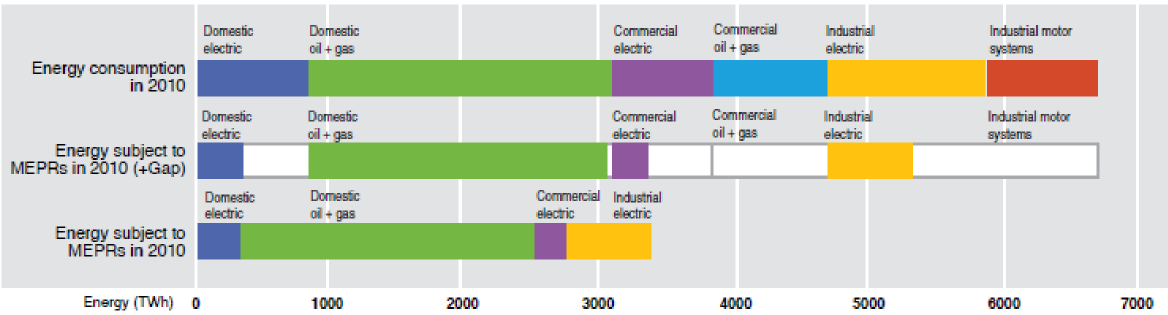
---

[1] As of 20 March 2013, the EU has policies under development for commercial refrigeration equipment.

Gaps within individual economies: opportunities to adapt existing policies

Performing a gap analysis for a specific economy shows what products or product groups are not covered. In many cases, these products are covered in other economies, providing policymakers with a starting point from which they can adapt their own S&L policies. Figure 4 shows a gap analysis for the EU based on regulations and energy use in 2010, and illustrates that the commercial and industrial sectors in the EU have far more room to increase policy coverage than the residential sector.

Figure 4: EU energy consumption and energy subject to MEPS in 2010: an example of a high-level economy-specific gap analysis [3]

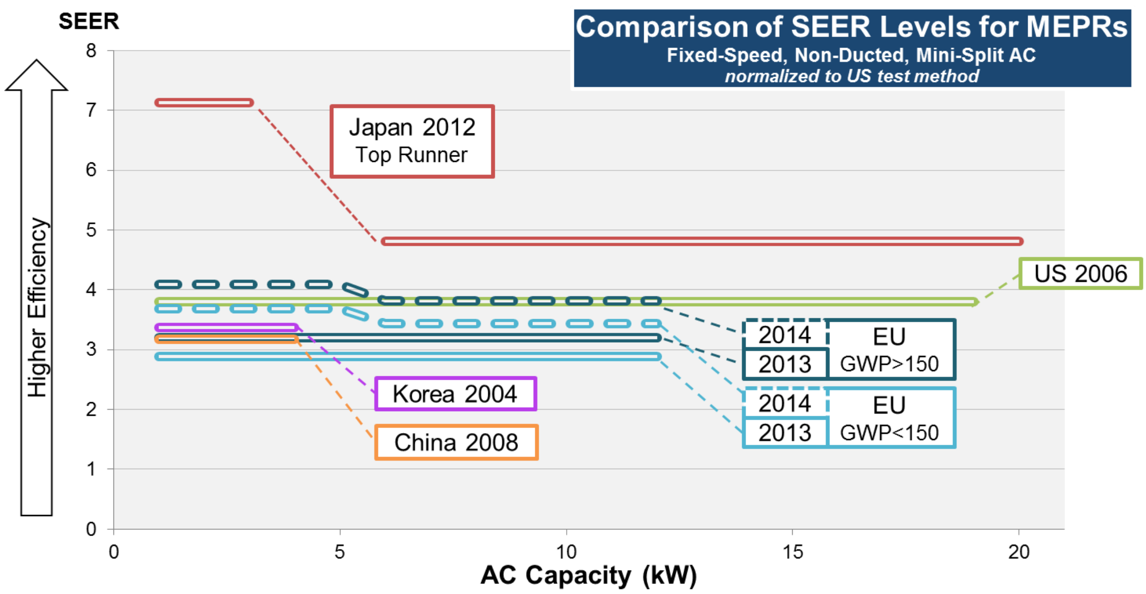


Adaptation of existing S&L policies sometimes results in divergent policy components; the causes for this divergence can be identified through a benchmarking analysis, as described below. The analysis can be used to highlight important technical issues to consider when developing future policy components to maximize future convergence, as described below in the section "Facilitation of convergent international efficiency policies".

Product benchmarking analysis

After assessing potentials and setting priorities, the second step is for S&L stakeholders to analyze existing policies and markets, and in doing so to document current best practices. A benchmarking analysis focuses on a particular product in a group of selected economies to examine existing S&L policies, identify best practices, and characterize the most efficient models on the market. By doing so, benchmarking analyses lay the foundation for strong and comparable energy performance requirements around the world.

Figure 5: Benchmarking efficiency of room air conditioners: an example of a benchmarking analysis [6]



Benchmarking analyses address another major barrier to global harmonization of appliance efficiency policy: a lack of national resources to put towards a comprehensive review of global policies, and thus understand how national policies compare to those in peer economies [3]. Figure 5 shows the results of a benchmarking study for room air conditioners that compares the minimum energy performance standards of several economies despite variations in test procedures and efficiency metric formulas. Figure 5 shows that Japan had the most stringent energy requirements for split room air conditioner units.

In order to compare policy stringency, benchmarking analyses must convert among divergent energy efficiency metrics and test methods from the selected economies. Because of this, benchmarking studies can generate conversion functions that define how to translate product S&L policy among these economies. In the absence of fully harmonized test methods, these conversion functions allow regulators some means of evaluating the stringency of a proposed policy against policies in peer economies, thereby enabling them to identify opportunities for policy improvement.

Going one step further, the generation of those conversion functions often requires a deep understanding of the source and magnitude of variations in existing test methods that otherwise inhibit international comparison. Identifying these differences can provide a path towards convergence of the policy components – once S&L stakeholders have an understanding of the variations, there is a clear direction towards addressing those differences.

Facilitation of convergent international S&L policies

Once S&L policymakers understand the variations in existing S&L policies and policy components, the third step is for international standardization processes to facilitate greater policy convergence. This can be achieved through the development of technical solutions in response to the pathways outlined through the expanded benchmarking analysis.

International standards bodies such as IEC and ISO can encode and disseminate best practice policy components in their standards. These informative classifications may include all of the key policy elements: test methods, product definitions and categorization, metrics for energy efficiency or energy performance, and suggested efficiency thresholds. For example, an air conditioner test method may include a series of test conditions that represent the various global climate zones plus conversion factors with which to compare test results depending on which test conditions are used. Policymakers could then choose to reference the test conditions most appropriate for their climate, and the results would still be comparable with other global policies based on the same test method.

An example of this type of approach exists today in the IEC standard for mid-size industrial electric motors [7].[2] The IEC developed a test method suitable for international use along with a series of recommended efficiency thresholds. The test method was subsequently adopted by many economies around the world, each of which then selected the efficiency threshold most suitable to their particular policy and local market needs. For stakeholders with diverse market transformation interests, this approach provides a single menu of thresholds from which to select efficiency levels for MEPS, labeling thresholds, and financial incentives.

The process of developing suitable international energy efficiency standards involves close coordination between policymakers and technical committees of international standards bodies. A comprehensive benchmarking analysis can provide a framework for a constructive dialogue, enabling stakeholders to focus on the specific factors within dissimilar test methods that create divergence.

---

[2] These motors are single-speed, three-phase cage induction motors with a rated output between 0.75 kW and 375 kW, and run on 50 or 60 Hz.

Table 1: Relationships between international and domestic efficiency thresholds for motors [3]

Motor efficiency	**Inter-national (new/old)**	**US**	**EU**	**China**	**India**
Aspirational	**IE4**			**2010: Grade 1 label**	
Premium	**IE3**	**2010: MEPS level** (a) 2001: Voluntary label (b)	*2015: MEPS for most motors*	**2010: Grade 2 label** (d) 2006: Grade 1 label	*2014: Recommended MEPS* **2011: Top label class**
High	**IE2** Eff1	1997: MEPS level (c)	*2015: MEPS for motors with VSDs* **2011: MEPS level**	**2010: Grade 3 label** **2006: MEPS level**	**2011: Medium label class; Recommended MEPS** (e) 2004: Top label class
Standard	**IE1** Eff2				**2011: Lowest label class** 2004: Lowest label class
Below standard	Eff3				

Current regulations are in **bold**; past regulations are in standard font; future regulations are in *italics*.
Notes:
(a) Based on Energy Independence and Security Act of 2007 (EISA); effective in 2010
(b) Voluntary label was called NEMA Premium and was based on industry consensus
(c) Based on Energy Policy Act of 1992 (EPAct); effective in 1997
(d) In China, the highest efficiency motors are represented by Grade 1 labels; efficiency decreases as Grades increase.
(e) The recommended MEPS in India are voluntary.

International efforts such as the Super-efficient Equipment and Appliance Deployment (SEAD) Initiative and the IEA-4E Implementing Agreement are among the organizations exploring ways to improve coordination between governments and standards organizations in pursuit of this goal.[3]

Tailoring policies for a specific economy

Once suitable policy foundations are in place, the fourth and final step is for economies to adopt the choices from the policy menu that are best suited to their climate, behavior, and economic conditions. This step is critical to achieving the maximum benefits of harmonization, since it translates international analysis and best practice into actual national policy. Tailored analysis for an individual economy can highlight the most appropriate policy options for consideration, and can also make policymakers aware of best practice examples they may not have otherwise considered.

In addition, a cost-benefit analysis of the selected policy options for a product can demonstrate to policymakers the potential benefits of such policies to domestic regulators, manufacturers, and consumers. Outlining the benefits in this way can create the political will needed to move from analysis to action, encouraging policymakers to undertake new policy development or policy revision to align with international standards. This assessment also contributes to policymakers' decisions regarding which efficiency threshold makes sense for adoption within their economy.

[3] More information about ongoing coordination efforts by the SEAD initiative and IEA-4E can be found online here.

Conclusions and recommendations

It is useful to begin with a global perspective to achieve the goal of local adoption of convergent appliance efficiency policies. Through gap analyses, the global view can point policymakers and technical experts to the least-regulated products globally, which should offer near-term opportunities for harmonization – resulting accelerated, cost-effective policy implementation – with few barriers from existing policies. This big-picture view can also direct national policymakers to low-hanging fruit – existing policies in other economies that can be adapted to meet national conditions.

For products that are subject to S&L policies around the world, benchmarking analyses can be used to determine which economies have the most stringent policies, and can provide conversion factors by which to translate among different economies' policies. Close examination of test methods in these analyses can result in a pathway for international standardization bodies to develop policy options suitable for different climate, behavioral, and economic conditions that exist in economies around the world.

Finally, if international standards bodies craft technical standards that work for the full range of global economies, then a cost-benefit analysis can take into account local conditions to determine the best specific policy set for an economy. This analysis can also generate political will for increasing the scope or stringency of S&L policies by illustrating to policymakers the potential benefits of adopting these internationally harmonized policies.

Are Test Procedures Passing the Test? Ensuring That Measured Results Are Representative of Energy Use in the Field

Chris Calwell

Ecova[1]

Abstract

In every test method designed to measure the performance and energy consumption of a product, there is a natural tension between emphasizing precision and repeatability on the one hand, and representativeness and relevance on the other hand. It is very difficult to optimize both simultaneously. The way consumers use products in the real world can be complex and unpredictable. In response, lab technicians often specify a simplified duty cycle and set of operating conditions for each type of product in order to measure its performance and energy use in a precise, repeatable way.

However, as residential energy-using products have evolved and their capabilities have broadened, energy efficiency test procedures have often not kept pace. Instead, to minimize manufacturers' test burden, policymakers have become increasingly content measuring aspects of a product's behavior and energy consumption that diverge significantly from the way those products are actually operated in homes. They then often apply rough mathematical correction factors to "true up" the results to real-world conditions. This causes problems when different technologies behave in the real world in fundamentally different ways that cannot be corrected uniformly, especially when policymakers employ the resulting data sets to establish voluntary and mandatory efficiency specifications.

They can develop *precise*, but often *inaccurate* estimates of the real-world energy and carbon savings that will result from the adoption of their policies. In effect, as the old adage goes, we cannot manage what we do not measure. Our laboratory test methods should capture, to the maximum extent possible, the actual energy use that occurs when products are operated in the real world by their purchasers. Likewise, we should reward manufacturers for design changes that yield meaningful savings *under those conditions*. Theoretical or potential energy savings are far less useful, both to governments seeking to reduce greenhouse gas emissions, and to product purchasers, seeking to reduce energy bills.

This paper will examine three cases in particular where this problem has arisen (automobiles, refrigerators, and clothes dryers). It will summarize early efforts by governments and researchers to modify those test procedures to more realistically reflect their products' actual operating characteristics. The paper will also lay out a set of guiding principles that can be followed in future test procedure development and revision processes to minimize these problems, and to correct for observed differences between test procedure energy use and field energy use, both when products are new and when they have been operating for a significant period of time.

Introduction

> *It is the mark of an educated man to look for precision in each class of things just so far as the nature of the subject admits. --Aristotle*

Global efforts to improve the energy efficiency of consumer products have made impressive headway in recent years, after repeated iterations of mandatory energy performance standards, voluntary and mandatory energy labeling programs, and financial incentives to encourage the sale of the best products. Indeed, we might assume from all of the efficiency gains that have been achieved in various consumer products that absolute energy consumption is dropping in a sustained way. But there is much left to do.

Refrigerators are perhaps the most commonly cited example of that success story. The average new US model has about 15% more adjusted interior volume than it did in 1972, yet consumes about 75% less electricity on the federal test procedure and costs 55% less to purchase in constant dollars (Figure 1).

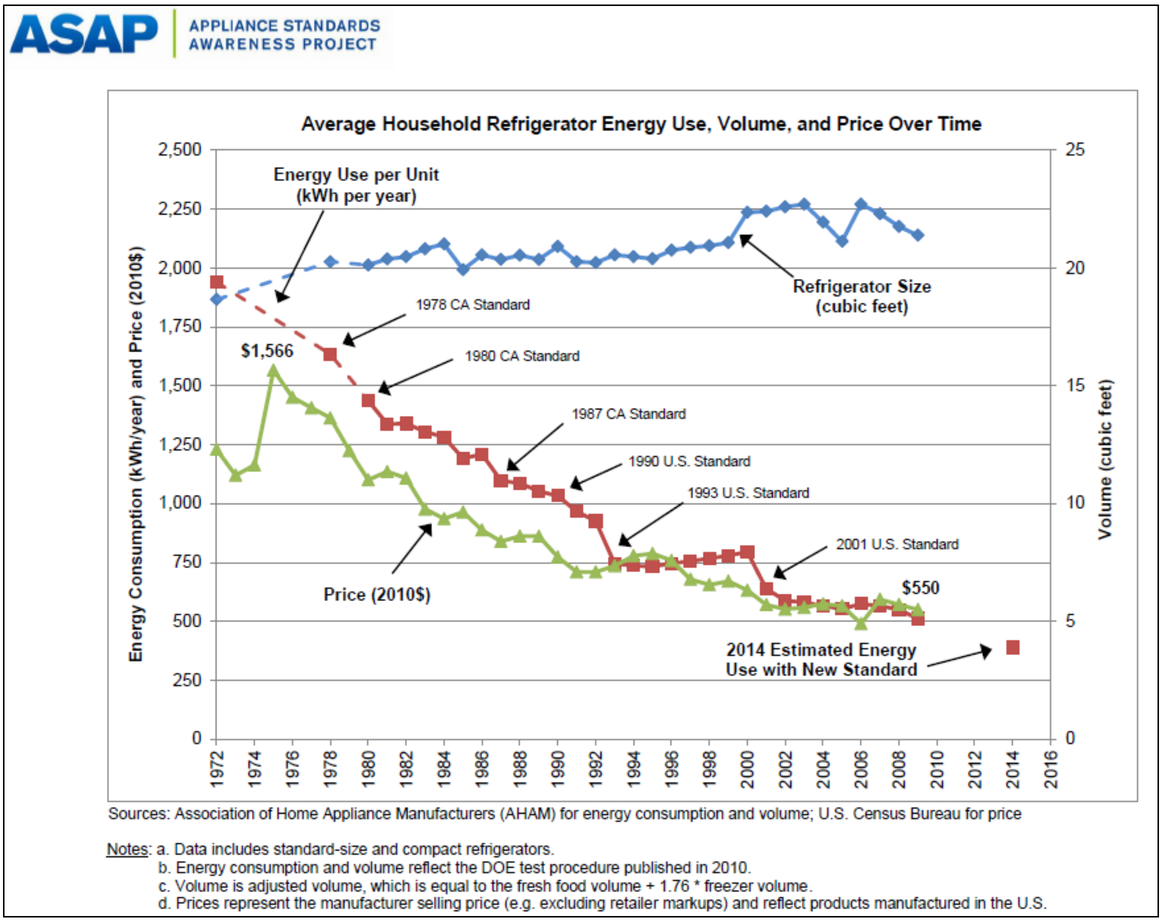

Figure 1. Average household refrigerator energy use, volume and price over time (Source: Appliance Standards Awareness Project)

European and Asian markets have also managed impressive improvements in refrigerator efficiency, yet the total energy consumed worldwide for residential refrigeration continues to rise. Why?

As noted in my earlier research for eceee and ENERGY STAR, a multitude of other factors influence total energy use beyond their energy efficiency, including steady growth in the global population, the number of refrigerators per person, and the average size and feature content of each refrigerator.[2] To the extent people upgrade and replace them more often, the efficiency of the average unit in use more closely approaches that of the newest models. However, the total amount of energy consumption associated with manufacturing, transporting, and ultimately recycling or disposing of them continues to rise as well. These factors and others are captured in a holistic equation (Figure 2) known as IPALUCEMD that attempts to address more comprehensively the overall greenhouse gas emissions impacts of a given product category:

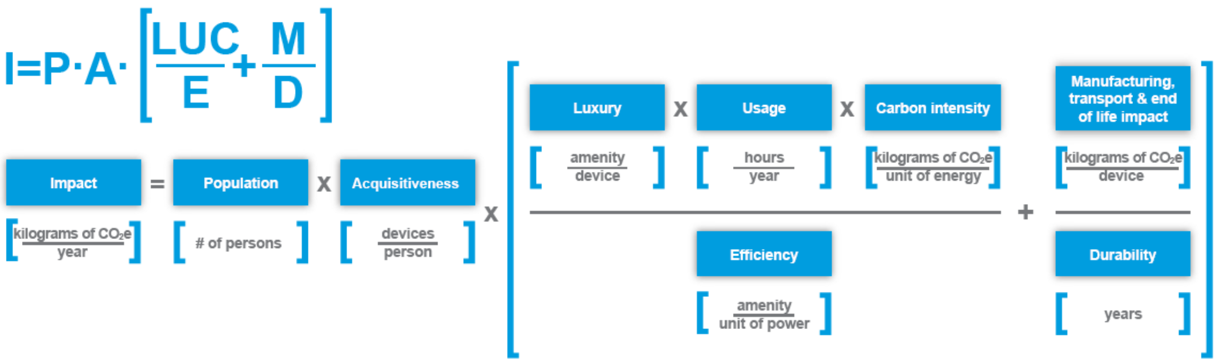

Figure 2. IPALUCEMD equation

What this formula illustrates is that a product's greenhouse gas emissions can, and routinely do, keep rising even as that product becomes more energy efficient, because so many other attributes of that product are changing in ways that increase its environmental impact.

But what if even product efficiency is also not improving as much as we think? What is missing from this formulation is any recognition that the efficiency of a new product being measured in a laboratory test procedure might differ meaningfully from its operational efficiency in a home environment, when operated by a typical user.

The Limitations of Test Procedure Results

Test procedures, methods and standards have been in widespread use for so many years that the energy efficiency community often finds itself conflating laboratory-measured energy consumption or efficiency with a product's *actual* energy performance in use. While they are indeed intended to be close or at least proportionate to each other, the degree to which that is actually achieved varies widely, both within a given end use and over time, as technologies and user behaviors change.

Paul Waide noted in a 2008 IEA presentation [3] that the ideal test procedure is:

- Reproducible
- Repeatable
- Produces measurements of an appliance's energy consumption and service provision that are representative of those in real use
- Inexpensive
- Universally recognized.

He then stated that "in reality, it is hard to find the right balance between these factors and many compromises are needed."

His list is similar to that offered by Alan Meier and James Hill in a seminal 1995 paper [4] on the question of what an ideal test procedure should do:

- Reflect actual usage conditions
- Yield repeatable, accurate results
- Accurately reflect the relative performance of different design options for a given appliance
- Cover a wide range of models within that category of appliance
- Be inexpensive to perform
- Be easy to modify to accommodate new technologies or features; and
- Produce results that can be easily compared with results from other test procedures

Meier and Hill also offered a cogent summary of the inherent tradeoffs and compromises associated with trying to optimize for so many attributes at once:

> *Clearly, an energy test procedure is a compromise: it does not fully achieve any of the criteria for an ideal test, but it satisfies enough of them to discourage excessive complaints. At a minimum, a ranking of different models by their tested energy use should correspond reasonably close to a ranking by the models' field energy use. An additional danger of compromise is that manufacturers may optimize performance for a test procedure that does not assure energy savings in the field.*

Manufacturers of the affected products and their trade associations typically have the largest financial stake in the outcome of test procedure deliberations and the greatest resources of any of the interested parties to contribute to the effort. Their engineers are also intimately familiar with the design and operation of the technologies being measured, which underscores the value of having them involved in the test procedure development process. But if they lead it or dominate it, their natural inclination will be to optimize those aspects of the test procedure that are of highest priority to them -- low cost to conduct, high repeatability and reproducibility, and universal recognition – all of which can help to minimize the engineering and legal costs associated with complying with mandatory efficiency standards and labeling programs around the world.

These are understandable, laudable goals, but the broader public interest is not being served unless test procedures also yield results that are realistic and representative of actual use. The public policies that brought these test procedures into existence or formalized their use nationally were created to help consumers understand and reduce their energy bills. Consumers can and should reasonably expect that a product labeled to use 20% less energy than another will, in fact, deliver those savings in typical use. If not, the extra money they spent purchasing the better product may have been wasted, or the money they spent on utility bills for an inefficient product not so labeled may have been equally wasted.

Meier and Hill correctly predicted, in 1995, how this mix of issues would play out over the coming decades:

> *As countries work to establish energy efficiency standards, the details of every test procedure will come under more scrutiny. Manufacturers will seek to make the testing requirements simple and inexpensive. Foreign manufacturers will regard complex or unique test procedures as a trade barrier. In addition, domestic manufacturers will want to ensure that their products appear as energy efficient as possible, while consumers will want the test procedures to reflect as realistic results as possible. Meanwhile, continuing technological innovations will undermine the ability of existing procedures to reasonably represent an appliance's energy efficiency.*

We have arrived at that juncture, and are paying the price, to varying degrees depending on the product type and the associated government agency.

The Vehicles Example

One striking example is associated with vehicles. The US Environmental Protection Agency developed two test procedures for determining vehicle fuel efficiency in 1975 – one for highway and one for city driving. [5] The maximum speed encountered under either test is 60 mph and the maximum acceleration is 3.3 mph per second, meaning that it would take 18 seconds to reach 60 mph from a standing start.

Because EPA has been carefully tracking various aspects of vehicle performance since 1975, it is possible to see how different vehicle performance has become from the test procedure conditions with each passing year. [6] Today's vehicles commonly accelerate from 0-60 mph in about 8 to 10 seconds, and the most powerful cars do so in half that time. So the majority of new cars being tested in the US can accelerate two to four times faster than these test procedures are capable of measuring. That effect of this difference, not surprisingly, is that the energy efficiency of vehicles in normal driving conditions is often not as high as the efficiency derived from the test procedure and published on the vehicle's window sticker. This gave birth to an American phrase, initially applied as a manufacturer disclaimer to EPA fuel efficiency ratings vehicles, and now used to describe any situation in which one individual's results may differ from typical ones: "your mileage may vary."

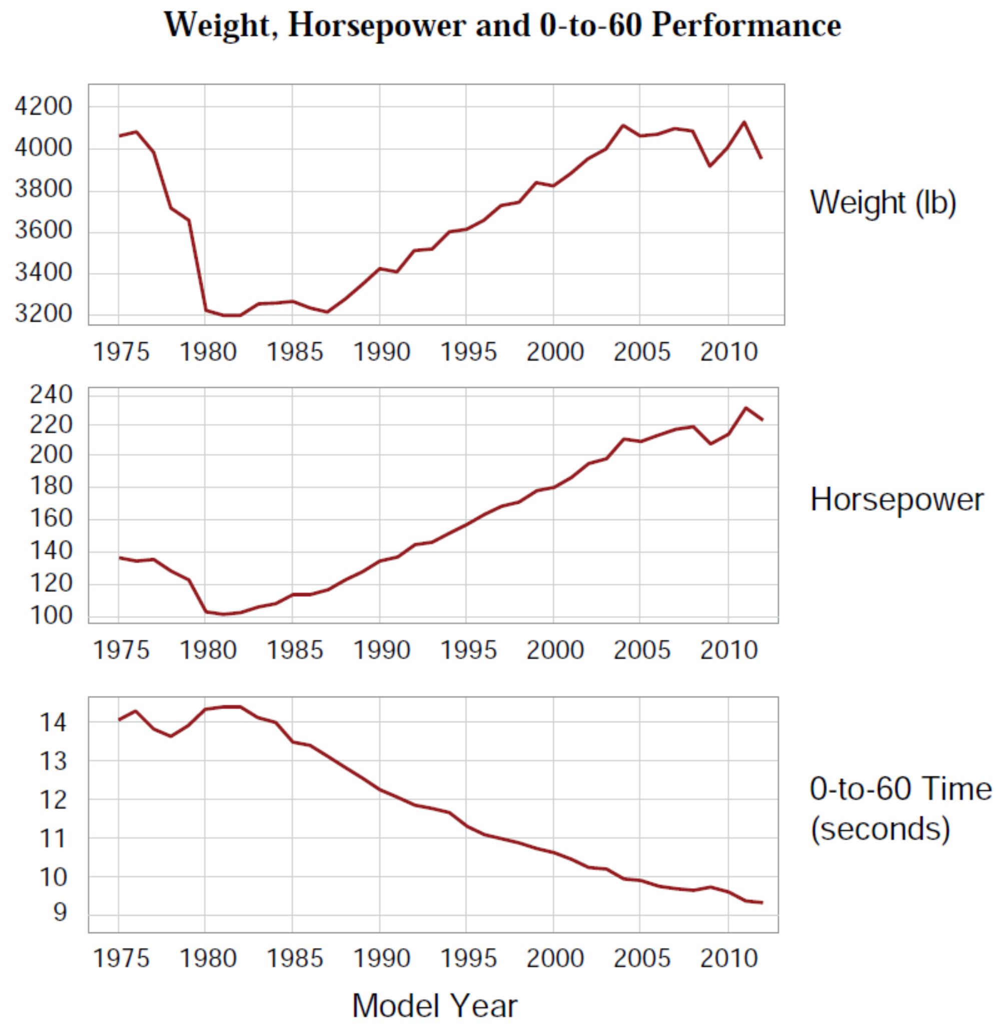

Figure 3. EPA data on US vehicles over time

Average acceleration times in US vehicles have dropped virtually every year since 1983, even while vehicle weight continues to rise, in part because of steady increases in available horsepower. Vehicle test procedures use a laboratory dynamometer to simulate a vehicle's weight, tire rolling resistance, mechanical friction, and aerodynamic drag and operate at a fixed ambient temperature of 75 degrees, so give up a considerable degree of realism and representativeness in the interest of achieving a high degree of repeatability.[7] Such vehicles experience no differences in weather, road conditions, accessory usage, weight of passengers and cargo carried, elevation, or any of the variables routinely encountered by any of us on a typical drive.

In response to criticism that its test procedures no longer represent real world driving conditions, EPA recently developed three more tests to capture the impacts of high ambient temperatures (95 degrees F) with the air conditioner running, cold start behavior at low ambient temperatures (20 degrees F), and harder accelerations and higher speeds (brief periods of operation at 70 to 80 mph). These were laudable improvements, and helped to reveal that many cars had lower "real world" efficiency than the previous tests had indicated. Typical city fuel economy values dropped by an average of 11%, and highway fuel economy values dropped slightly less. It was not uncommon for hybrid vehicles to see fuel economy drops of 12 to 20%, in part because their hybrid technology offers the most efficiency benefit at low speeds and at moderate ambient temperatures – not the conditions the new EPA tests were examining.

But rather than require the use of those new procedures to determine the fuel economy of all new vehicles, EPA allows manufacturers to apply mathematical correction factors instead to the results derived from the 38-year old test procedures. Not surprisingly, the majority of manufacturers have opted to use this correction factor approach for the majority of new models they test, obtaining optimistic numbers for expected fuel economy and lower compliance costs. Testing by consumer magazines has now shown that new Ford hybrid vehicles like the Fusion and C-Max are consistently achieving 17-21% worse fuel economy in actual driving conditions than predicted by their EPA-certified fuel economy ratings. When the vehicles are driven even more aggressively by magazine testers, their fuel economy can be as much as 32% below claimed values.[8] These kinds of discrepancies are leading to lawsuits and disgruntled purchasers, in part because the federal testing has failed to deliver the very service it was created to provide – a reasonable prediction of how many miles a particular vehicle will travel per gallon of fuel consumed.

Government agencies that manage test procedure development may update them infrequently, with or without an explicit intent to refine their approach as new field data become available. Two recent examples from the US Department of Energy (DOE) are illustrative: refrigerators and clothes dryers.

The Evolving Refrigerator Success Story

The US government has for decades been testing refrigerators at ambient temperatures of 90 degrees F, without placing food inside, opening and closing the product door during operation, or operating the refrigerator's included icemaker. The first factor tends to overestimate energy use relative to actual operating conditions, while the other mostly factors tend to underestimate it. However, we cannot intentionally err on both sides of reality in the hopes that the opposing factors will cancel out, especially when the physical mechanisms by which the energy losses occur are different.[9]

Warmer temperatures increase heat gains through the exterior of the refrigerator and cause its compressor to operate less efficiently. Putting room temperature food in the refrigerator causes it to work harder, while filling it with already-cooled food can help it maintain thermal mass when the door is opened. Opening the door causes a replacement of cooled air volume with ambient air that must be cooled again to the desired temperature. Likewise, refrigerators need a significant amount of energy per year to operate their automatic icemakers and detach the ice from cooling trays. This was a small enough share of total annual energy use to be ignored when refrigerators used more than 1,500 kWh/year, but not now, when the most efficient models can use less than 400 kWh/year. These mechanisms explain some of the observed differences in new models, but those differences can become greater over time, as discussed further below. Refrigerator compressors, insulation, gaskets, and heat exchanging coils can simply become less effective over time due to loss of lubrication, or dirt and dust build-up, or mechanical wear.

Measurements conducted in the field and in the laboratory when California utilities were collecting and recycling old refrigerators revealed the extent of these problems. [10] Of the 157 refrigerator models for which an original Energy Guide label value could be located for annual energy use, the average value found was 1,274 kWh/year. Yet measurement of those refrigerators in the homes where they were found suggested an average energy use of 1,573 kWh/year, or 23% more than the label value. Even more interestingly, when those refrigerators were taken back to the laboratory to have their original DOE energy efficiency test repeated, their average energy use was 1,809 kWh/year, or 42% more than the original label value. In both cases, the variation was quite inconsistent from model to model, with in situ (field) measurements often reflecting *lower* energy consumption than the original Energy Guide label value. Simply applying correction factors of 23 or 42% to the original Energy Guide label values would not have consistently predicted the consumption of individual models after multiple years spent in the field.

However, the results did show that utilities could save more energy, at least initially, than originally expected by replacing older refrigerators with highly efficient new models. It also meant that utilities needed to monitor degradation over time, to better understand how those savings might persist in the newest refrigerator designs.

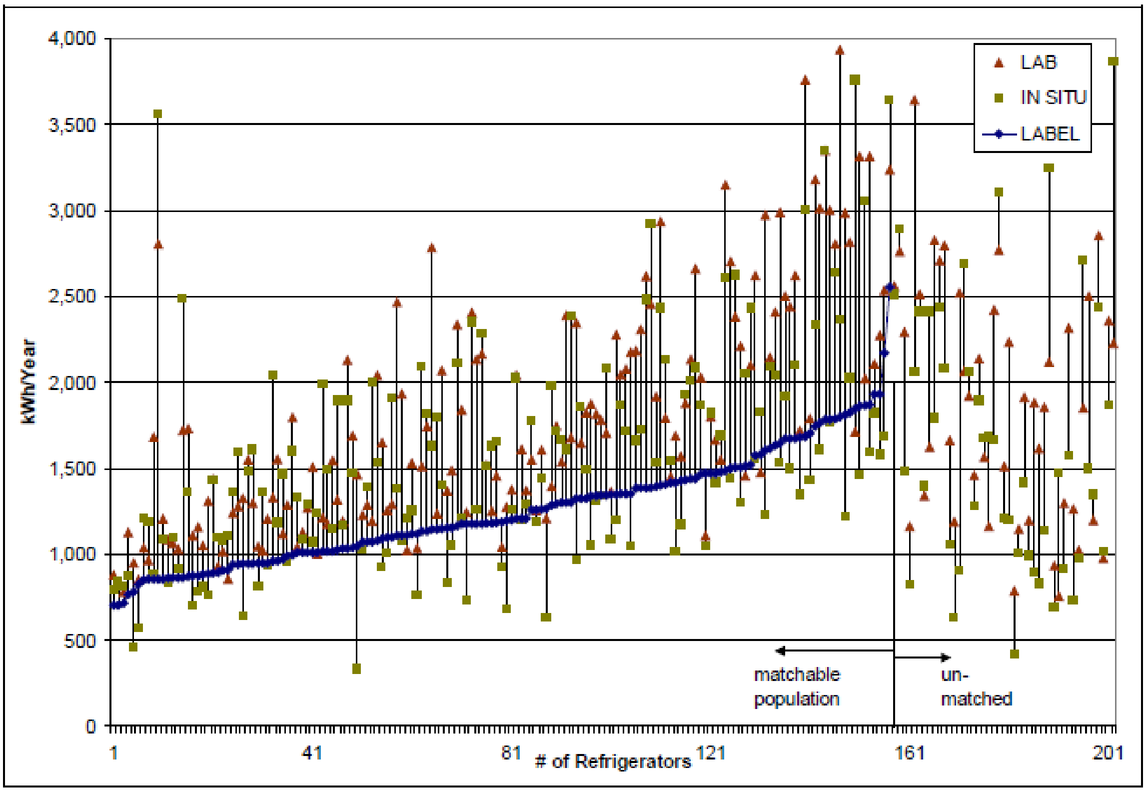

Figure 4. Measured differences in older refrigerator energy use in the field

Given the concerns expressed by multiple stakeholders to its appliance standards process, DOE recently commissioned a comprehensive and mathematically robust analysis [11] of multiple refrigerator field measurement studies conducted over more than a decade. This helped DOE understand the extent to which field energy use of refrigerators was diverging from test procedure values, and the principal causes of that divergence, providing the government with a sound technical basis for updating its test procedure over time and its near-term energy savings analysis. The result was an increase of 0.35 quads in the expected energy savings from refrigerators and freezers over a 30 year period, yielding $1.57 to $4.1 billion of additional net present value benefits to society over that timeframe.

Clothes Dryers: The Challenge of Obtaining Meaningful Energy Savings from a Constrained Test Procedure

By contrast, clothes dryers in the United States have long been considered an appliance where all of the available models have similar efficiency and few options exist to significantly improve energy efficiency. Yet they are the largest source of US residential energy consumption for which there are no ENERGY STAR or Energy Guide labels in place, and no incentives or promotions by utilities to encourage the sale of the most efficient models.[12] Yet, empirically, we know that clothes dryer energy use varies widely. When the Florida Solar Energy Center researchers placed identical clothes dryer models into identical houses in the same part of Florida, they found variation in clothes dryer energy consumption from 949 to 2,592 kWh/year, largely driven by differences in number of occupants per home and the behavior of those occupants.[13]

When different clothes dryer models of various sizes and ages are added into the mix, observed differences in annual energy use become even greater, and operational efficiency differences contribute strongly to that. Recent field measurements by the Northwest Energy Efficiency Alliance (NEEA) found that dryers in homes were drying an average of 2.4 pounds of clothing per kWh of electricity consumed, while the DOE test procedure predicted efficiencies of 3.7 to 4.2 pounds of clothing per kWh for similar dryer models. [14] While some of this can be attributed to differences in initial load size and moisture content, the degree of duct restriction observed in homes, and the variety of settings and modes selected by users, one of the largest observed causes of variation was the load composition itself. Typical laundry users place items in their dryers that are simply and obviously more difficult to dry than the thin, two-dimensional, uniformly sized, 50% synthetic test cloths utilized by DOE. These cloths are prized by DOE for the precision and repeatability they bring to the testing process, but they behave differently than clothing and only offer slight advantages in repeatability over the more realistic IEC test load. Real clothing is three-dimensional, having internal and external surfaces and pockets that experience differing amounts of contact with warm air in a dryer. Most of the dried items are thicker and have larger percentages of cotton content than the DOE test cloths as well, making them more likely to soak up and retain moisture than DOE test cloths. Historically the DOE test procedure for dryers has ascribed a fixed energy savings credits to dryers offering automatic termination capability as well, rather than measuring its effectiveness directly.

US DOE's recently completed clothes dryer test procedure final rule [15] represented an opportunity to correct these discrepancies. DOE asked for and received detailed, intensively analyzed, recent field data and comments from NEEA and the California utilities [16] regarding typical dryer load fabric types and sizes, initial moisture content, cycle selection preferences, degree of duct restriction, number of cycles occurring per year, and laboratory-normalized annual energy consumption data. DOE elected not to utilize any of that field data in its analysis, relying instead on two clothes dryer field studies conducted in the 1970s, manufacturer assertions of consumer usage patterns, and its own 2009 Residential Energy Consumption Survey (RECS) results. RECS ascribes portions of whole-house energy consumption in a national cross section of homes to particular end uses like washers and dryers from consumer self-reported answers to questions of approximately how many loads of laundry they wash per week and approximately what share of those loads they typically place in clothes dryers.

DOE also declined to entertain any changes to its test load composition, in its present or pending test procedure versions. This will continue to constrain the usefulness of DOE test data for dryer labeling or utility rebate program purposes, as the California utilities noted in their comments:

> *When the items being dried do not resemble what consumers actually place in their dryers, no amount of mathematical adjustment after the fact can compensate to reasonably predict how much energy consumers will use in the home if they purchase one dryer model instead of another. And isn't that the whole point of having a clothes dryer energy efficiency test procedure in the first place?*

In the end, DOE also decided not to require that manufacturers actually measure the effectiveness of their automatic termination controls to comply with mandatory federal standards – the key dryer test procedure change that both manufacturers and efficiency advocates had jointly petitioned DOE to make. This is remarkable because DOE's own testing showed that dryers that terminate properly and promptly can reduce per-cycle energy consumption by 4 to 38% (with an average savings of 20%), relative to dryers that do not. Instead, DOE made the use of a new and more realistic test procedure *voluntary* – able to be used by manufacturers who wish to participate voluntarily in the newly proposed ENERGY STAR labeling program for clothes dryers. The likely effect of having two fundamentally different test procedures for clothes dryers operative simultaneously in the US will be that inefficient products will continue to be measured the old way and efficient products will increasingly be measured the new way, leading to inaccurate estimates of how much energy could be saved by switching from one to the other.

DOE did, however, eliminate a proposed 0.8 "field use factor" that would have had the effect of arbitrarily reducing by 20% the measured energy use during an automatic termination cycle. This helped to ensure that the full measured differences found in the voluntary test procedure would be visible in labeling programs, which will assist ENERGY STAR in promoting the most efficient models.

By not seeking out significant differences in dryer performance and energy efficiency in their mandatory test procedure, though, DOE indeed did not find them. It reached the conclusion in its associated mandatory efficiency standards analysis [17] that only about 5% of dryer energy use could be cost-effectively saved. Meanwhile, heat pump dryer models saving 30 to 50% of baseline energy consumption continue to achieve ever-greater market share in Europe, in part because they are tested and labeled in ways that intentionally help to reveal those differences. No heat pump dryers have yet been introduced in the US market.

The difference between the approaches to refrigerators and clothes dryers taken by the same government agency is stark and reveals a missed opportunity to save substantially more energy cost-effectively in a widely used appliance.

Causes of Divergence between Laboratory and Field Measurements of Product Energy Use

The case studies referenced above provide some examples of the reasons for major differences between laboratory and field measurements, but it can be helpful to understand them more generally. Even products that are new, can, and routinely do, behave differently on efficiency test procedures conducted in a laboratory setting than they do in a typical home or office environment, for a variety of reasons:

- Test procedures are often conducted on one or a limited number of samples of a particular model, so may miss some of the sample-to-sample variation in performance that is expected when products are manufactured by workers on an assembly line.
- Ambient temperature and humidity levels can be different than those specified in the test procedure and quite variable over time, or products can be operated at a different elevation than sea level.
- Known contributors to product energy use are often intentionally ignored by test procedures, as was the case with automatic ice makers in refrigerators, air conditioning systems in vehicles, and network standby power use in many electronic products until recently.
- Workloads can vary widely and continuously, and can be much more heterogeneous than they are in test procedures. Increasingly, products have the size and capability to be used for a wide variety of tasks, so we should not be surprised if the ways they get used increasingly differ from the simplistic scenarios under which they are tested.
- Most energy-using products are capable of operating in far more modes or with a far wider variety of chosen product settings than those default or dominant conditions that efficiency procedures are intended to test. Moreover, customer preferences for particular settings can shift over time, such that defaults no longer occur the majority of the time.
- Customers can install firmware updates, external peripherals, or additional applications to electronic products that did not have them when originally tested in the laboratory, increasing power use in idle mode or decreasing the percentage of time spent in idle mode.
- Human interaction with products is unpredictable; users may start and stop a product frequently instead of allowing it to run uninterrupted, or modify its settings mid-way through, or fail to read directions about how to setup and operate a product, or simply make an intentional operational choice that goes against manufacturer recommendations.
- Manufacturers may design their products to recognize standard test conditions and behave in ways that maximize efficiency under those conditions, but not under other conditions more commonly encountered in the field.

We can characterize most of these issues as sources of *field variance*. Field variance can either be addressed in the test procedure itself, by trying to make it as realistic and representative of real world product behavior as possible, or in a mathematical term that is multiplied by the test procedure value to obtain a term more likely to resemble field performance. Addressing as much of the field variance as possible in a revised and updated test procedure is preferable, because the ways in which actual consumption can vary from measured consumption under standardized conditions are often not linear or entirely predictable from one technology to the next. A deeply flawed test procedure will not even predict the correct rank order of appliances from least to most efficient if they were measured in the field, failing one of its primary reasons to exist. It is better to ensure that the range of conditions and modes likely to be encountered in the field is fully represented in the test procedure, giving policymakers better, more meaningful data to work with in constructing duty cycles and energy efficiency metrics. Once that is done, smaller and more straightforward sources of field variance can be addressed through an adjustment factor (see below).

As CLASP researchers have recently noted [18], a second key cause of divergence is simply the fact that the majority of energy-using products in operation are no longer new, and so can experience a drop in performance and a change in energy consumption over time that together shift their efficiency. Motors and other moving parts suffer mechanical wear or fail to receive needed maintenance, lubrication or brush replacements, steadily experiencing more friction with age. Coils, fins and other heat transfer surfaces become coated with dust and dirt, losing the ability to conduct heat as readily. Insulating materials break down, phosphors degrade, dirt and dust accumulate on the surface of light-emitting and diffusing elements, and heat alters the behavior and performance of electronic components. In short, entropy is the enemy of efficiency, and time is entropy's chief ally. With each passing day, energy-using products behave less like they did when they were new, and very rarely in ways that reduce energy consumption.

We can refer to this issue as *degradation over time*. For the most part, government test procedures do not attempt to capture this effect at all; they concern themselves primarily with product performance when the product is new and operating optimally, or after, at most, a brief break-in period of operation (as with lamps). And yet, if government and utility energy planning processes assume that the savings from an efficiency measure will be steady over time, they could be counting on savings that fail to materialize in later years. Or, they could be underestimating savings if the new, efficient technologies do a better job of preventing degradation than the conventional product designs do.

Promising Solutions

Provided that the test procedure is reasonably comprehensive and realistic, what else can be done to improve efficiency estimates? Including field adjustment and degradation factors changes our equation for comprehensively addressing the greenhouse gas impacts of energy-using products as follows:

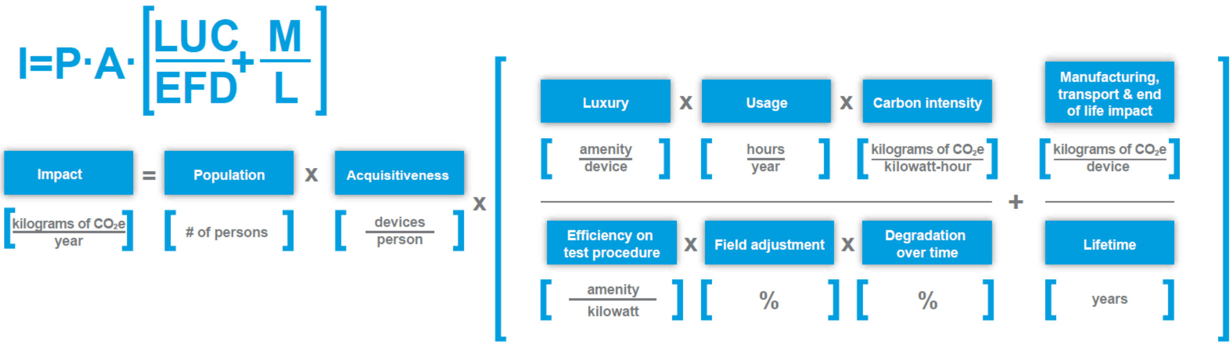

Figure 5. Proposed approach to account for energy efficiency differences in the field and over time

In this revised IPALUCEFDML equation, efficiency is now clearly labeled as "efficiency on test procedure" so as to distinguish from field or typical efficiency values in practice. Then a field adjustment percentage (upward or downward) is made to that value to better approximate real world efficiency when the product is new. Then a degradation over time adjustment percentage (upward or downward) is made to that value to better approximate the efficiency of products that might have been in use in the field for a number of years. "Durability" is also reframed as "Lifetime" in this updated equation form, in part to reduce confusion about how to measure and express that particular term. Note that many of these terms can change over time, such that the degree of luxury being delivered, or the hours of operation, or the carbon intensity of the energy source, or the degradation in efficiency performance can be different when a product is new than when it is has been in use for five years.

Beyond changes to the calculation process, however, changes to the testing *process* itself are urgently needed, and can be summarized as follows. First, measure power use in the laboratory under a precise, repeatable, and diverse set of operating conditions and modes. Put the products through their paces, so that most of the ways a consumer is likely to use them are reasonably captured and measured. Then log data in the field, in a representative sample of homes, to determine how much time products spend in each of their operating modes or performing each of their various functions. Log power consumption data in the field at the same time to confirm that a product's range of operating conditions in the field is captured by the original testing that was done in the lab. Provided that the two line up, regularly updated field data can be analyzed annually and used to update governments' annual energy usage and energy savings potential estimates for each product category. These field data can also supplement or even supplant extensive reliance on survey tools like the Residential Energy Consumption Survey (RECS) to develop baselines of residential energy consumption by device.

An analogy to cooking may be helpful in explaining the merits of a philosophical change in our approach to energy efficiency test procedures. The goal of a good test procedure should not be to correctly bake the best cake, or even to surmise the precise recipe for doing so, which will invariably change over time as consumer preferences change. Rather, the goal of a good test procedure should be to inventory as many of the ingredients as possible that might be used to bake the range of cakes people prefer, and quantify the nutritional aspects and properties of each. Armed with that information, we can help consumers understand how much fat, protein and carbohydrates they might ingest from the various types of common cakes they could choose to bake from those ingredients. The error today comes in assuming that everyone will bake the same cake – they won't. But with the answers to just a few questions about preferences for flavor, texture and portion size, the government could give many different buyers a reasonable sense of what they might expect from the resulting mix.

Similarly, there is no way to know what percentage of the time a given dryer will spend drying jeans, but if one element of the test procedure assesses how rapidly and efficiently they dry jeans, that aspect can be incorporated into the ultimate duty cycle and efficiency metric. And jeans are so widely worn, washed, and dried throughout the developed world (450 million pairs purchased annually in the US alone) [20], that it seems odd that we would decline to measure dryer performance with them at all.

The Internet makes it increasingly easy to combine those measurements of how a product performs under various specific conditions with some simple information about how a purchaser intends to use the product, to provide product comparative energy consumption and savings information for his or her particular situation. This kind of meaningful context is largely absent from the one-size-fits-all, traditional physical energy labels placed on most energy-using products today.

Conclusions

Of all the goals a good test procedure can achieve, surely we can agree that producing values reasonably representative of actual usage in the field is among the most important. If test procedure results are unrealistic, mandatory labels provide incorrect information to buyers, voluntary labels imply greater or lesser benefits to buyers of an efficient product than they will actually realize, mandatory standards make the wrong decisions about the extent to which more efficient technologies are cost effective, and utilities assume they will achieve more or less energy from rebating the resulting products than they actually will. This is particularly problematic for utilities, since they rely on their savings estimates in resource planning, and may face electricity shortages and severe financial penalties from their regulators if they do not achieve the energy savings claimed for rebated products.

One truism that emerges from the last 20 years of refinements in appliance design is this: the better the technology, the more behavior matters. In other words, as products have made steady, remarkable gains in technological efficiency, most forms of gross, obvious energy waste have been removed from the system. Likewise, the products have been optimized to perform incredibly well on standardized test procedures, after repeated iterations of laboratory testing, product redesign, and tweaks to the software that controls product operation. Not surprisingly, then, the variation in product functionality and performance introduced by customer behavior ends up being one of the largest remaining contributors to differences in product energy use. We cannot strictly control for variations in user behavior in a laboratory setting, but we can monitor products under a wider range of usage patterns and conditions to understand how they might behave.

In the past, some efficiency test procedures were found to have measured precisely the wrong thing, and those wholesale problems were typically corrected reasonably quickly. Today's test procedures can suffer from a slightly less severe problem – they measure the wrong thing, precisely. They are, with laudable precision and repeatability, measuring things that can be increasingly irrelevant about a product's performance under a narrow set of laboratory conditions rarely found in the real world. This quest for false precision leads, not to the truth, but to overconfidence in the relevance and usefulness of what is being measured.

The history of recent energy efficiency test procedures is filled with reasons for hope that greater realism and representativeness are achievable. In the past, ENERGY STAR measured only the standby power consumption of televisions in determining which models to label. US DOE only measured the power use associated with static test patterns on black and white cathode ray tube televisions, long after color, flat panel, and high definition capability came to televisions. Today, both agencies now utilize an internationally standardized high definition color video test clip and a range of ambient lighting levels interacting with televisions' automatic brightness control circuitry to more reasonably approximate actual viewing conditions, which represents remarkable progress. Likewise, the latest IEC test procedure revision for refrigerators shifts meaningfully toward the goal of testing a broad range of functions and capabilities, leaving to policymakers the option of constructing different "recipes" or duty cycles of those functions to mirror typical usage patterns in their part of the world.[19]

These types of shifts in our approach to test procedures are a healthy adaptation to changing technologies and capabilities in consumer products, and the changing ways in which all of us use those products. While this may introduce less precision and repeatability into measured values, it brings something much more valuable – an unvarnished honesty about what can and can't be known with precision.

Development of a Communicating Power Supply to Assist in Energy Monitoring and Management

Alan Meier

Steven Lanzisera

Anna Liao

Andrew Weber

Lawrence Berkeley National Laboratory

Abstract

Saving energy in buildings is often hampered by lack of detailed information about what is using energy and how much. The problem is especially acute for the large number of small, energy-using devices that are present in both residential and commercial buildings. Most of these products use a power supply to operate electronic and other internal components. We developed a "communicating power supply" to enable communication of energy information to a building management system or other central entity. A related goal was to assign to each power supply or device a unique identifier, that is, a kind of "electronic UPC" (Universal Product Code) that can be recognized by a building energy management system or other networked entity. The communicating power supply must be flexible enough to transmit data through power line carrier (PLC) or wireless networks, or piggyback on communications capabilities of downstream devices.

We worked with a large manufacturer of power supplies and a large designer of microprocessors to miniaturize these functions onto a single chip which will, ultimately, add very little extra cost or complexity to existing power supply designs. We anticipate that Energy Star and other efficiency endorsement programs will include communications capability in future technical specifications. Our longer-term goal is to add control capabilities to the communicating power supplies.

Background and Project Goals

Saving energy in buildings is often hampered by lack of adequate information about which device is using energy and how much it is using. This problem is especially acute for the large number of smaller energy-using devices that are present in both residential and commercial buildings (e.g., plug loads). A large fraction of these loads are electronics, that is, devices that process information in some manner. In especially efficient homes, plug loads often represent 30% of total electricity use [1] and a similar fraction in commercial buildings [2]. Moreover, the amount of electricity used by plug loads is growing faster than any other load category in both sectors [3]. For example, in the United States, space heating and cooling have now fallen to less than half of total site residential energy use and has been overtaken by appliances, plug loads, and electronics [4]. Most major economies have begun to regulate the efficiencies of the energy-intensive appliances, but hundreds of other products are not expected to be regulated. The growth in these end uses makes their control and management increasingly important.

Today's solutions do a poor job of economically monitoring and controlling plug loads [5]. Furthermore, the in-building consumption is often strongly affected by individual operating practices and are therefore impossible to regulate. Effective energy *management* cannot occur until more information about energy *consumption* is obtained. To date, however, there is no cheap method to know and control the energy consumption of plugged-in devices. Numerous products have recently become available that offer monitoring and control capabilities incorporated in the wall outlet or as an independent power-strip [6]. These partly address the problem but have important drawbacks. First, they must be individually installed and programmed. If the device is moved, or additional devices are plugged in, then the information and control aspects are undermined. Second, many of the products rely on proprietary communications protocols, which leads to incompatibilities and legacy networks. Finally, the products are still relatively expensive so installation of a network connected to all of the devices in a building can easily cost thousands of euros. Thus, they are adequate for short-term or limited operation but not suited for a permanent, scalable, system.

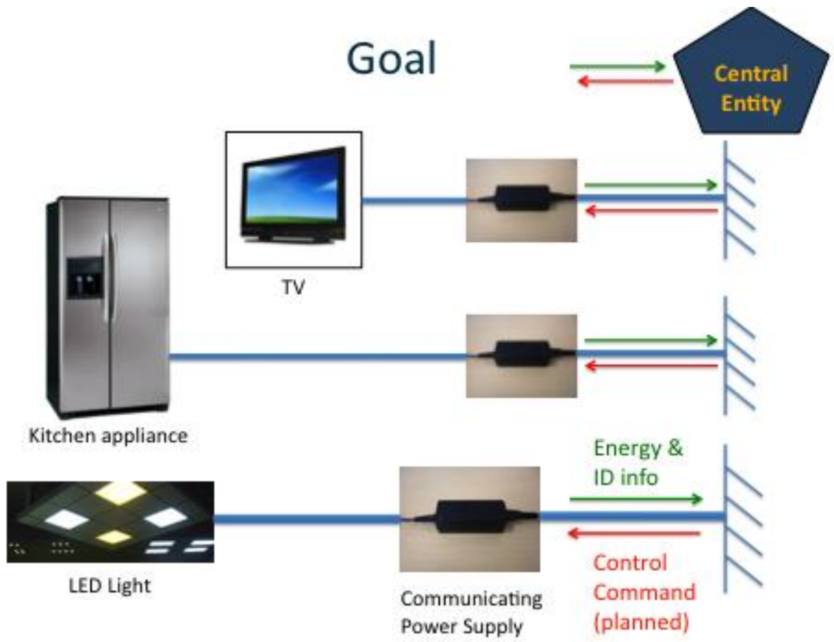

Figure 1. Relationship of the communicating power supply to appliances and the central entity

The goal of this project is to incorporate standard power measurement and reporting capability into power supplies in such a manner so that the incremental cost is very low. The power supply (typically converting AC to DC) is the first destination of electricity flowing to nearly all electronics and in a majority of the small loads. Figure 1 illustrates the general goal of the communicating power supply.

These capabilities will greatly increase the ability to understand energy use in buildings and identify opportunities for savings. These same features may also be exploited in other ways to provide new applications that we cannot predict today, such as to enhance health and safety.

The fundamental building block of this infrastructure is the conventional, switch-mode power supply. Billions of power supplies are manufactured every year for all types of IT equipment, audio and video equipment, mobile phones, and other products. These power supplies are a commodity, costing less than a few euros each for wholesale purchases. The market for these components is extremely competitive, so manufacturers of power supplies are reluctant to add capabilities unless they can be confident that the features are desired by their customers and will pay a higher price.

We collaborated with two companies to develop a technically feasible, economic solution. Power Integrations is a major supplier of high-performance electronic components used in high-voltage power-conversion systems. Its solutions enable compact, energy-efficient AC-DC power supplies for a vast range of electronic products, including TVs, PCs, appliances, smart utility meters and LED lights. We also collaborated with ARM, a supplier of microprocessors in many advanced digital products.

Technical Features of the Communicating Power Supply

The communicating power supply has three features beyond those found in a standard power supply. These are:

- A unique identity for each power supply
- A means for the power supply to measure its energy consumption
- A means for the power supply to communicate that information to the network

Ultimately, the communicating power supply will have a fourth feature: a means of controlling the power use of the device, that is, to switch off the device.

The communicating power supply must participate in a network to deliver information about its activities. This capability requires two features:

- A central entity to receive and process the data
- Standardized protocols for communicating between the communicating power supply and the central entity

A schematic of the network is shown in Figure 2. Product A represents an electronic device without networking capability such as a compact fluorescent light, battery charger, etc. The communicating power supply in this case an external unit, collects product information, controls signals, and energy consumption from Product A. The communicating power supply transmits these data, plus a unique identifier, via power line communication (PLC), and the information is collected in a central entity (that is, a database). Product B represents a networked device, such as a computer, blu-ray, etc. Product B is similar to Product A, with one important difference: the data are transmitted by the networked device via the Ethernet to the central database.

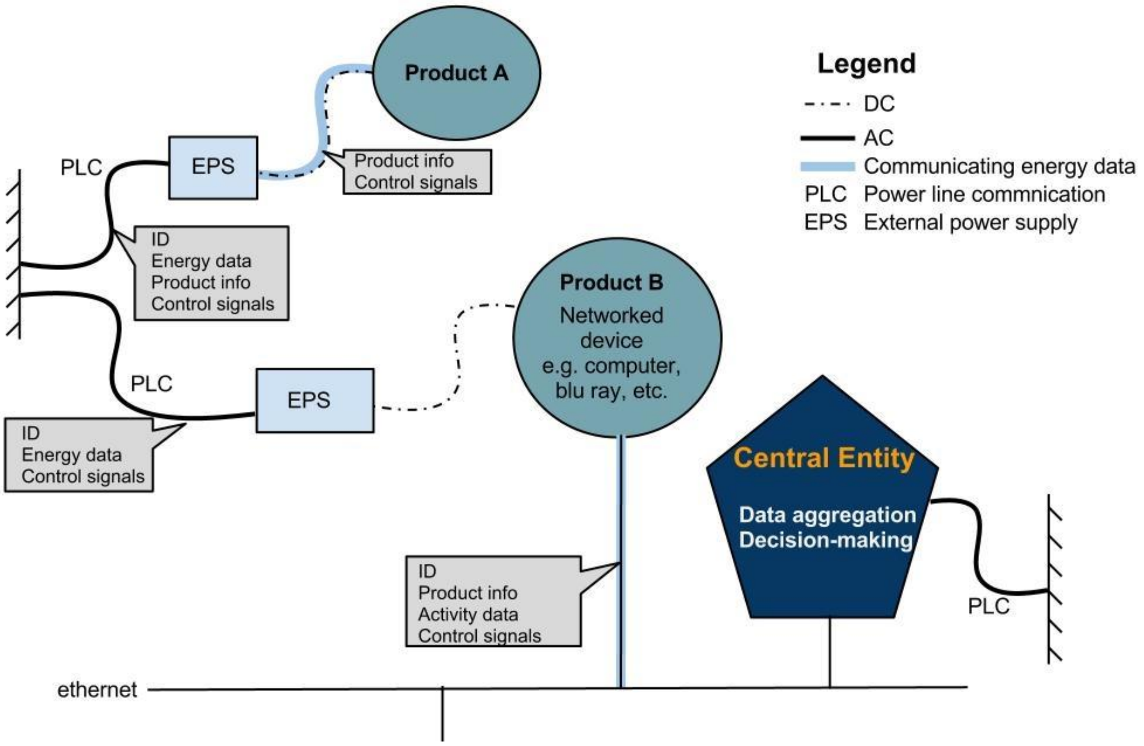

Figure 2. System overview of communicating power supplies

The key aspects of the communicating power supply are described in the following sections.

Unique Identity

Each power supply will need to have a unique identity that no other device will have. In computers today, we use MAC address, a 48 bit identifier, to uniquely identify anything with an Ethernet or Wi-Fi connection. As many more devices are network-connected, there is concern that we may one day run out of MAC addresses because they are inefficiently distributed (i.e., many addresses will never be used, but it is not possible to be sure this is true). As a result the Extended Unique Identifier is new

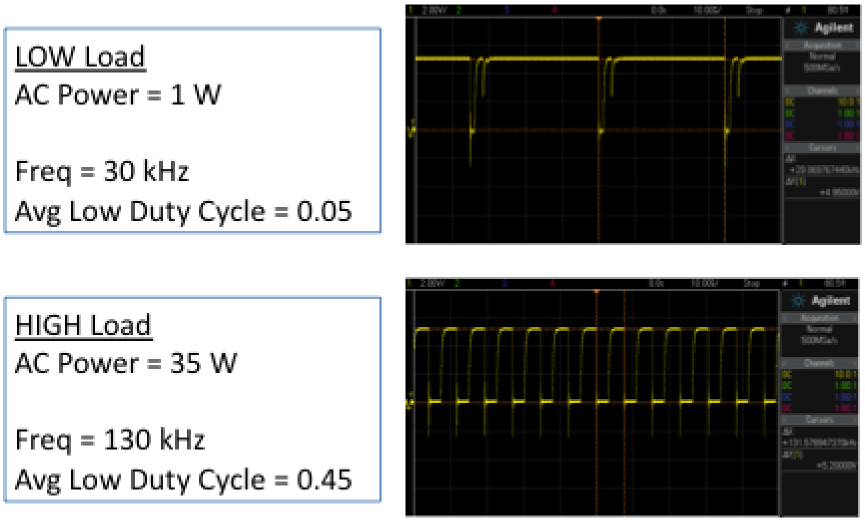
standard in place to replace the MAC address [7], and it is a 64 bit sequence with 2×10^{19} possible addresses. The EUI-64 is the standard unique identifier for the new generation of Internet Protocol networking (IPv6) and the Internet of Things. We have selected the EUI-64 as the unique identifier for this work.

In addition to unique identity, it is useful to have a means to identify the type of device and any other information about that device. The Universal Serial Bus (USB) specification includes a device classification system [8], and this system always includes the use of a few numbers to uniquely identify the vendor, the product (unique for a particular vendor), and the version of the product. It can also include long text strings or binary values to provide information to the user. In the case where only a few numbers are exchanged, the connected system must either be able to interpret these values on its own or connect to a database on the Internet to download the corresponding descriptions. A similar approach is appropriate for communicating power supplies. We propose to use a vendor ID, a vendor-specified device type, a vendor-specified product ID, and a version number. Allowing the vendor to specify these values provides flexibility and allows for innovation. However, if a vendor does not register these values with a central entity, end users and energy management systems will have no way to determine the device type. The alternative is to prescribe a taxonomy of device types rather than allowing for vendor selected values, and this improves device identification at the cost of flexibility. Because understanding the vendor stated device capabilities is critical and must be specified by the vendor, the downside to vendor specified device type seems small.

Measure and Accumulate Data

We developed a system to measure power and energy in a switching power supply using very low-cost components. The switching power supply modulates its switching properties based on the power needed by the load. Measuring these switching properties enables a microprocessor to estimate the load. Figure 3 shows two oscilloscope traces of the switching node of the power supply for low load and high load. The duty cycle (low spent time as a fraction of the total time) varies from 0.05 to 0.45 from low load to maximum load, and the waveform switches value tens or hundreds of thousands of times per second. To cheaply measure this duty cycle, we first take this high speed signal and use an analog filter to determine its average value. The average value is measured using an analog to digital converter, and the resulting digital value is turned into a power value using a look up table with interpolation. Look up tables are very efficient methods for storing non-linear functions on low-cost microprocessor systems.

Low-cost microprocessors often have analog to digital converters with sufficient accuracy to provide better than 1% accuracy over the full range of loads a power supply has to offer. The variability between different power supplies in terms of switching duty cycle versus the load is likely to be a few percent, and the overall accuracy and repeatability will be about 5%. Therefore, even very low-cost analog to digital converters will provide the accuracy needed. The sample rate of this analog signal can be quite low as well, which will further reduce costs. Our implementation has a signal bandwidth of about 1Hz; thus, a sampling rate of only a few times a second will enable the system to fully capture all of the system dynamics.



(Time scale is 10µs/div for both plots.)

Figure 3. Oscilloscope traces demonstrating that a low-cost analog-to-digital monitoring method can achieve acceptable accuracy over a wide range of loads

Communicate via a Network

The communicating power supply must have a network interface to enable communication. Initially, we identified two high-level communication strategies: network communication in the power supply or local communication to another processor in the system that already has a network connection. The second method is preferred to lower system costs if the device is already connected to the network (e.g., an Ethernet or Wi-Fi enabled television). In many cases (e.g., light bulbs), the device will not already be connected to a network, and the lowest cost network connection that provides the required performance is desired. We previously surveyed a variety of network connections possible, and low-cost wireless connections such as Zigbee, Z-wave, or 6LoWPAN are the best options. Power line carrier communication requires not only expensive chips but also expensive passive components. The chips and passives required for Zigbee of 6LoWPAN can be purchased for under one euro in moderate volumes, and it seems likely these chips will decrease in cost further as volumes increase. Z-wave chips are more expensive but have enhanced interoperability. We do not want to pick a “winner” technology in this space, but it is clear that the low-cost wireless options have a significant advantage in terms of cost and implementation complexity.

Results and Future Work

Our goal was to demonstrate a proof of concept, that is, a power supply that can measure power use, store its identity, and then communicate this information to a central entity. As indicated, this is a hardware, software, and communications problem, extending beyond the power supply itself.

We successfully created a prototype communicating power supply (see Figure 4). This has already undergone one generation of miniaturization. Ultimately, the components will need to be integrated into a single chip (or two) so that it does not enlarge the form factor of existing power supplies.

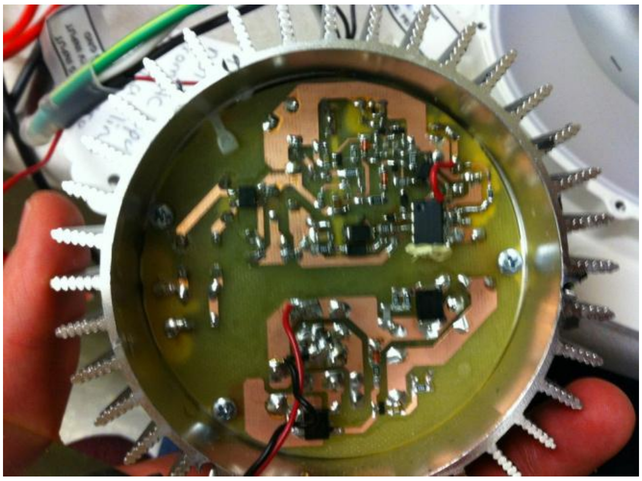


Figure 4. Second-generation prototype of communicating power supply

We also created a network consisting of three devices, each with a communicating power supply. These products report identity and energy information over a wireless network (based on IEEE 802.15.4, the same wireless standard as Zigbee [9] and 6LoWPAN [10] . Finally, we created a basic energy dashboard that can display energy information collected by the system. This dashboard offers sufficient features to demonstrate functionality of the whole system. The data will be stored to a database, and users will be able to view data at will.

The same hardware and network can, in principle, be used in reverse to send control messages from the central entity to specific equipment. This will enable the devices to be remotely switched on and off. Remote control will be the subject of future work.

A communicating power supply will cost more than conventional power supplies. Our goal is to make the incremental cost very small. The measurement feature will cost less than €0.10 when mass produced. For appliances already equipped with communications capability, the communicating power supply could piggy-back; this will lower the cost since communications is the most expensive feature. However, external incentives will still be needed to encourage manufacturers to add this feature. Voluntary programs, such as Energy Star, could easily make communications part of their specifications. These programs could assure a market and encourage economies of scale.

Communicating power supplies, and the ecosystem in which they operate, will permit much more detailed understanding of electricity consumption. This offers the potential for reducing energy consumption of products whose services are not required at that specific time without the active involvement of the occupants.

Abstract

This paper presents a survey on the most promising wireless communications candidates to be used as part of a smart grid home area network. Particular attention is devoted to the systems' physical layer due to its implications on the coverage area and on the provided service throughput and latency. Different cellular networks (GSM/GPRS and UMTS) and wireless data networks (Bluetooth, ZigBee, Wi-Fi and WIMAX) are analyzed. Moreover, two very simple smart energy applications were designed and implemented in order to validate the selected wireless communication solutions. The first aims to accomplish vehicle to grid (V2G) energy exchange, thus allowing efficient energy management on the smart grid. The communications between the electric vehicle and the infrastructure is performed via WLAN at home and using SMS messages otherwise. The second application implements a home lighting automation process using the ZigBee/IEEE 802.15.4 protocol.

INTRODUCTION

The "Smart grid" concept intends to improve the efficiency, reliability, and sustainability of electrical energy production and distribution using the energy consumption information on the consumer side and utility pricing [1]. Wireless technologies are promising candidates to perform that crucial, last mile, exchange of information because they inherently provide terminal mobility, low installation cost, rapid deployment and extended coverage. The accessibility to multiple radio access technology standards such as cellular networks (2G; 3G and 4G), IEEE 802.11 a/b/g/n wireless LAN, WiMAX and ZigBee supported on IEEE 802.15.4 provides the mentioned benefits and redundancy and therefore a clear advantage over wired technologies.

Among the loads present at home, the EV is perhaps the most promising candidate to optimize residential energy consumption due to the involved high power value, its energy storage capability and to its potential bidirectional transmission of electricity. Indeed, EV batteries can serve as an energy storage unit that can return energy back to the grid when parked, accomplishing the vehicle to grid (V2G) concept. Consequently, the accurate identification, on a given area, of the vehicle's location, parking status, and, mainly, its storage capacity and state of charge (SOC) can be used to design an energy efficiency strategy. When parked at home the EV can use available wireless networks to communicate with the smart grid. Home area network (HAN) communications typically require a relatively low data transfer rate (< 1 Mbps), high reliability, low latency, low power consumption, secure communication and a medium range coverage area [2].

Subsequent sections describe the radio interface of the most important cellular systems used nowadays, namely the GSM/GPRS, EDGE and UMTS systems. This description also includes wireless systems like ZigBee, Wi-Fi and WiMAX. Finally, an SMS-based application was developed to support the information exchange between EVs and the electric grid. The implemented communication solution used to send and receive data information is fully explained.

WIRELESS COMMUNICATION SYSTEMS

Wireless communications systems are natural candidates to be used in smart grids and particularly in a home area network. The lack of wired connections enables equipment mobility, offers low-cost solutions and provides flexibility in the communications network configuration, aspects that are of particular value. Among the multiple wireless technologies that were examined, particular attention was given to mobile cellular systems (e.g. GSM and UMTS) and to wireless networks such as WiMAX, Wi-Fi and ZigBee.

Global System for Mobile Communications (GSM) - Cellular System

Cellular systems topology consists in multiple overlapping cells that provide coverage, obtained from relatively low power transmitters located on base stations. GSM is a second generation (2G) mobile system based on digital technology, designed and optimized to support the voice service.

GSM frequency bands or frequency ranges are the cellular frequencies designated worldwide by the International Telecommunication Union (ITU) for the operation of GSM mobile phones. In Europe most used frequencies to support GSM/GPRS are the 900 and 1800 MHz bands. However, according to the Third Generation Partnership Project (3GPP), there are fourteen licensed frequency bands defined to this system [3]. The available spectrum is divided into radio carriers, each having a bandwidth of 200 kHz. One or more carrier frequencies are then assigned to each base station. Each of these carrier frequencies is then divided in time, using a time division multiple access (TDMA) scheme, into eight distinct time slots which will be used to support speech and data channels. One time slot is used for transmission by the mobile and another one for reception. They are separated in time so that the mobile unit does not receive and transmit at the same time (as represented in Fig. 1).

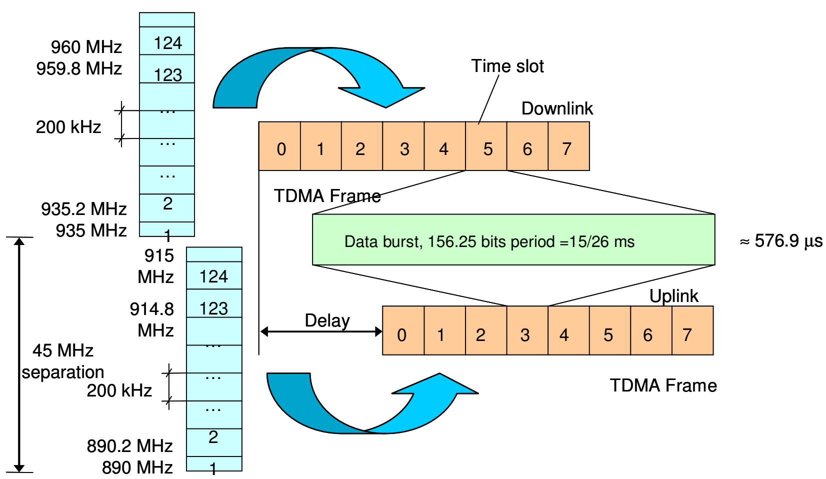

Fig. 1 - GSM 900 carriers and TDMA frame structure. (Adapted from [4])

Enhanced Data Rates for GSM Evolution (EDGE) and General Packet Radio Service (GPRS)

Enhanced Data for GSM Evolution (EDGE) is a GSM evolution that provides third generation (3G) capabilities in the existing frequency bands. EDGE enables services like web browsing, email, multimedia and video conferencing to be accessible from its mobile terminals.

The GSM standard provides data services with bit transfer rates up to 14.4 kbps for circuit-switched data and up to 22.8 kbps for packet data (per time slot). Thus higher bit rates can only be achieved with multislot operation. The General Packet Radio Service (GPRS) provides bit transfer rates up to 171.2 kbps depending on the radio link quality, the number of other users sharing the service and the user-negotiated quality of service (QoS) [4, 5].

Both GSM and GPRS systems are based on the Gaussian minimum shift keying (GMSK) modulation technique that has a spectral efficiency of 1.35 bps/Hz, which correspond to an aggregate data rate per carrier of 270.833 kbps. The core of the EDGE concept includes the introduction of a new phase shift keying modulation scheme 8-PSK, which allows data to be sent at speeds up to 384 kbps [5]. This data rate increase is obtained from the usage of 8-PSK modulation technique that has a 3 bit per symbol efficiency. Note that the symbol rate for both modulations is 270.8(3) ksymb/s, leading to gross bit rates per time slot of 22.8 kbps and 59.2 kbps for GMSK and 8-PSK respectively.

Universal Mobile Telecommunications System (UMTS)

UMTS is a third generation cellular technology designed to provide mobile personal communications (with anyone, anywhere and anytime) with transmission rates up to 2 Mbps according to the environments of use, support universal roaming and wideband multimedia services offer. The UMTS system is based on a set of basic requirements that includes: a high spectral efficiency, a large traffic capacity, the support of different services and applications, indoor and outdoor coverage, the use of small, light, low price and high autonomy terminals, high quality service, and the establishment of secure communications. The system provides a broad range of services to a large number of users. The services provided by the system include the telephony voice service, new multimedia and Internet services, which should be available from a variety of terminals and platforms.

The first 3GPP version of the UMTS, known as Release 99, is an evolution of the GSM/GPRS network architecture, the main difference for these generations is the radio access network. The original base station system (BSS) was replaced by a new entity named UMTS terrestrial radio access network (UTRAN), where the radio network controller (RNC) and node B, replace the base station controller (BSC) and the base transceiver station (BTS), respectively. Subsequently, a second version was specified for UMTS, the 3GPP release 4, that was appropriated for new cellular network operators that initiate 3G services provision without a 2G network. In this version the main change occurs in the core network where the MSC is separated into two new network elements, the Media Gateway (MGW) and MSC server. The aim of these new elements is to separate the control/signalling tasks and transmission/support in order to use a single routing and transmission technology, making possible the support of services with different QoS requirements.

High Speed Downlink Packet Access (HSDPA)

HSDPA introduces a set of new features in the UTRAN (3GPP R5) that when combined enable a significant increase in data transmission rates up to a maximum of 14.4 Mbps. HSDPA creates a high-speed DSCH (HS-DSCH) by replacing the variable spreading factor (VSF) and fast power control with adaptive modulation and coding (AMC), short packet size, multi-code operation, and fast hybrid automatic repeat request (HARQ). A higher performance is obtained from the ability to share the HS-PDSCH channel that is dynamically partitioned by the HSDPA users, up to a maximum of 15 parallel in each cell. The channelization channels can be assigned to a single user or shared by multiple users in each transmission time interval (TTI). The observed reduction on the packet duration time, as it decreases from 10 or 20 ms (UMTS R99/R4) to a fixed duration of 2 ms (HSPDA), allows faster adaptation to changes in traffic conditions. Moreover, when the radio channel conditions are quite good HSDPA promotes the 16-QAM modulation technique usage. The 16-QAM modulation technique allows faster transmission rates than traditional quaternary phase shift keying QPSK modulation technique used for UMTS R99/R4 due to its increased spectral efficiency.

High Speed Unlink Packet Access (HSUPA)

HSUPA introduces a set of new features in the UTRAN (3GPP R6) that improves uplink performance (compared to R99 UMTS) and provides a higher throughput/data rates (up to 5.8 Mbps), superior capacity and reduced latency. The enhanced features in the uplink comprise several improvements, similar to those performed by the HSDPA, including multi-code transmission, short transmission time interval (TTI = 2 ms), fast scheduling and fast HARQ.

IEEE 802.11 protocol Wi-Fi

A wireless local area network (WLAN) is a wireless communication system that allows notebooks, computers, PDAs and tablets PC to access and share data, internet access or other network resources in the same way as for wired networks. Its main advantages comprise terminal mobility, short term usage, speed of deployment and scalability. There are also some disadvantages such as power consumption, low safety levels and operating frequencies that differ from country to country.

The IEEE 802.11 protocol usually referred as wireless fidelity, or simply Wi-Fi, is a network access technology that provides connectivity between wireless stations know as access points (APs) and wired networking infrastructures. The different versions of IEEE 802.11, presented in table 1, include:

- 802.11b - is the older version, transmits in the 2.4 GHz band and supports transmission rate of 11 Mbps and uses complementary code keying (CCK) encoding;
- 802.11g - also transmits in the 2.4 GHz band, but supports maximum speeds of 54 Mbps, the usage of orthogonal frequency division multiplexing (OFDM) increases the efficiency;
- 802.11a - same as 802.11g, but it uses channels in the 5 GHz band;
- 802.11n - introduces multiple input multiple output MIMO; a wider channel bandwidth 40 MHz as an option and considers beam forming and diversity in the antennas technology.

Table 1 - Comparison of Wi-Fi variants [5]

Parameters	802.11a	802.11b	802.11g	802.11n
Approval date	July 1999	July 1999	June 2003	October 2009
Frequency band	5 GHz	2.4 GHz	5 GHz	2.4 / 5 GHz
Max data rate	up to 54 Mbps	11 Mbps	up to 54 Mbps	up to 300 Mbps
Modulation	OFDM	CCK, PBCC, DSSS	OFDM, PBCC, CCK, DSSS	OFDM, CCK or DSSS

Worldwide Interoperability for Microwave Access (WiMAX)

WiMAX is broadband wireless access (BWA) technology, based on IEEE 802.16 standard created with the aim of providing wireless access to the Internet with the following characteristics: large geographical coverage area; huge number of simultaneous users accessing the network; high transmission rate and low cost. It fits a wide range of applications and environments: data, voice and multimedia fixed and mobile, licensed and unlicensed. The WiMAX original standard specified a frequency range of 10-66 GHz with a theoretical maximum bandwidth of 120 Mbps and maximum transmission range of 50 km [6]. It was designed to bring end-user wireless Internet without the expense and inconvenience of wiring or the distance limitations of digital subscriber line (DSL).

WiMAX physical layer is based on OFDM (in 802.16d) or OFDMA (in 802.16e). This guarantees two advantages: firstly the robustness against the multipath spatial multiplexing, i.e., transmitting independent streams performed in parallel for different antennas, and secondly the flexibility to include algorithms and techniques such as adaptive modulation and coding techniques and efficient multiple access techniques.

The signal is composed by 256 carriers (fixed) or 128-2048 carriers (mobile) depending on the bandwidth (restricted to 20 MHz or less and an integer multiple of 1.25 MHz, 1.5 MHz, or 1.75 MHz). From these carriers only 3/4 are actually used for data being remainders used as guard bands and as pilots. The pilot carrier always uses binary phase shift keying (BPSK) modulation and data modulation uses BPSK, QPSK, 16-QAM or 64-QAM depending on channel conditions. At closer ranges WiMAX can use M-ary QAM and support throughputs higher than 50 Mbps. At longer ranges, lower-order modulations with lower-rate coding must be used, hence decreasing the data throughput [6]. WiMAX can use both time division duplexing (TDD) and frequency division duplexing (FDD). The main differences between WiMAX variants are presented in table 2.

WiMAX is supported by the WiMAX Forum, whose primary mission is to ensure compatibility and interoperability between devices based on the IEEE 802.16 and is mainly composed of chipsets equipment manufacturers. The WiMAX Forum is the equivalent of the Wi-Fi Alliance, responsible for the great development and success of Wi-Fi all over the world.

Table 2 - Comparison of WIMAX variants [5]

Parameters	802.16	802.16a/d	802.16e
Approval date	Dec 2001	Jan. 2003/June 2004	End of 2005
Spectrum	10 to 66 GHz	2 to 11 GHz	2 to 6 GHz
Max data rate	134 Mbps (64-QAM, 28 MHz Ch)	75 Mbps (20 MHz Ch)	15 Mbps (5 MHz Ch)
Modulation	QPSK, QAM	BPSK, QPSK, QAM, OFDM	BPSK,QPSK, QAM, OFDM
Mobility	Fixed	Fixed and portable	Mobility, roaming

Bluetooth / IEEE 802.15.1

The Bluetooth protocol includes a specification for wireless personal area networks (PAN), developed by the Bluetooth Special Interest Group with the aim of connecting devices via a radio link of small range. Although operating on the same 2.4 GHz (2.4–2.5 GHz band) as Wi-Fi systems, the industrial, scientific and medical (ISM) band uses a different multiplex scheme, allowing their coexistence. The protocol allows data transfer at a speed of 1 Mbps with distances that can range from 1 m to 100 m. The fact that it is a standard protocol designed for low power and short range has allowed its dissemination into various types of devices.

ZigBee / IEEE 802.15.4

ZigBee is a low-cost, low-power, secure and reliable wireless mesh network standard appropriate for applications such as home automation (lighting control systems, intruder alarms), energy management, automatic meter reading systems, environmental and agricultural monitoring, video audio remote controls and personal health care (e.g. heart rate monitoring). The term ZigBee refers to a set of protocols that enable wireless communications between devices and is intended to replace the proliferation of cables and individual remote controls. One of the ZigBee protocol’s major advantages is its low power consumption, allowing small batteries with a long life cycle, ideal to install and forget purposes. Another ZigBee characteristic is its potential widespread implementation on a huge number of wireless devices. ZigBee also has high throughput and extremely low latency, making it suitable for real time applications. ZigBee implements a fully reliable “hand shake” protocol and three network topologies possibilities: star, mesh and cluster-tree; allowing up to 65535 device network supported in a up to 64 bit IEEE address. ZigBee includes two layers of the OSI model, the Application Layer (APL) and the Network Layer (NWL) that operate on top of the IEEE 802.15.4 PHY and MAC layers.

There are three types of devices in a ZigBee network: a coordinator (single device on the network) that creates and configures the network, acts as an IEEE 802.15.4 PAN coordinator. However, once the network is formed it is a Full Functional Device (FFD) that implements the full protocol stack and makes the interconnection between other networks. A router that is also a FFD implementing the full protocol stack, will forward the packets on the network, relaying data. Finally, a ZigBee end node that can only transmit data packets to the network without additional functionality and does not participate in routing. ZigBee end devices are Reduced Function Device (RFD) that implements a reduced subset of the protocol stack. This equipment (typically a mobile device) is where one wishes to obtain low energy consumption, operating at a low duty cycle.

Physical Layer

The physical layer of IEEE 802.15.4 is responsible for the following tasks: activation and deactivation of the radio transceiver; energy detection; link quality indication; clear channel assessment and channel frequency selection. IEEE 802.15.4 operates in three ISM unlicensed bands: 2.4 GHz (global), 915 MHz (Americas), and 868 MHz (Europe) [8]. As Fig. 2 shows, there is a single channel between 868 and 868.6 MHz (numbered 0), 10 channels between 902 and 928 MHz (numbered 1-10), and 16 channels between 2.4 and 2.4835 GHz (numbered 11-26).

Each channel in the 2.4 GHz band provides a raw data transfer rate of 250 kbps. The channel width is 2 MHz with 5 MHz of channel spacing in a way that allows interoperability with IEEE 802.11b. Direct sequence spread spectrum (DSSS) is used in conjunction with offset quadrature phase-shift modulation (OQPSK). On the other hand, channels in the 915 MHz band use the BPSK modulation technique that results in a lower data transfer rate (40 kbps). The receiver sensitivity should be larger than -92 dBm for channels in the 915 MHz band and larger than -85 dBm for channels in the 2.4 GHz band.

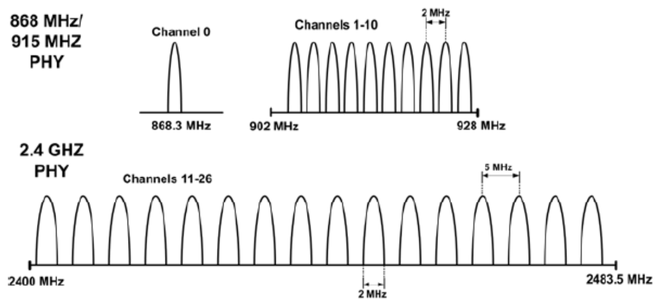

Fig. 2 – IEEE 802.15.4 operating frequencies and bands [8]

Medium Access Control (MAC) Sub-layer

The MAC data service is responsible for the transmission and reception of MAC protocol data units across the PHY data service. The features of the MAC sublayer are beacon management, channel access, GTS management, frame validation, acknowledged frame delivery, association and disassociation.

The MAC protocol supports two operational modes (as shown in Fig. 3). In the <u>non-beacon enable mode,</u> a standard ALOHA mechanism is used to rule the medium access and neither beacons nor superframes are used when the coordinator selects this mode. In the <u>beacon enable mode</u>, the coordinator periodically sends beacons to other network devices in order to synchronize nodes. The beacon defines the start of a superframe used to control channel access. The proposed frame structure assures dedicated bandwidth and low latency to 16 equal width time slots. Medium access is ruled by slotted carrier sense medium access with collision avoidance (CSMA/CA).

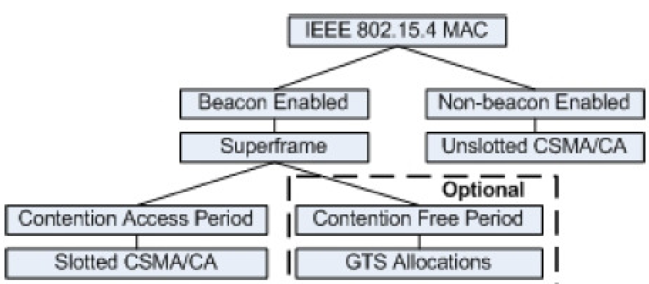

Fig. 3 – IEEE 802.15.4 operational modes [8]

V2G communications based on SMS

In the scope of this paper, efforts have been made in the V2G communications implementation [9]. The used onboard unit consists in a microprocessor, a GPS module and a GSM/GPRS module with a SIM card. The implemented test bed includes the LinkSprite GSM/GPRS module named SM5100B [10], a miniature single-side board, quad-band GSM 850/EGSM 900/DCS 1800/PCS 1900.

V2G communication required information

The considered information includes the following fields [11]:

- Vehicle/onboard unit identification; (using SIM module ID)
- Vehicle location; (using GPS and the GSM Cell ID)
- Vehicle speed; (using GPS)
- Charging station(s) location; (GPS)
- Driving destination;
- Driving cycle history; (supported on a high rate communication e.g. IEEE 802.11.b/g)
- Power demand profile;
- Power supplied or charged by the sources;
- Battery state of charge (SoC);
- Charging/discharging time and current data;
- Power electronics module parameters.

The Short Message Service (SMS)

The SMS is one of the most successful telecommunication services in terms of number of users and cost-effectiveness. SMS is supported by cellular networks such as GSM and UMTS. Initially the SMS specifications were written into the ETSI scope and included the service definition, network architecture, protocols and functionalities. Later, an innovative concept, the 3GPP, was created in order to define a radio access technology for a future generation cellular system that was intended to be global. The success of GSM system and its upgrades that include the GPRS and EDGE have led to the preservation of the GSM as a part of the future system's core.

The SMS provides short text messages transfer, in a connectionless mode, supported by the cellular networks radio resources. SMS offers a mean of sending messages, up to 160 characters (7 bit coding), to and from a mobile phone, fax machine and/or IP address [12]. SMS is a store and forward service that uses a Short Message Service Center (SMSC), to relay the messages from sender to the appropriate recipient. The cellular network, checks if the originating mobile station (MS) is allowed to use the short message service, by querying the Home Location Register (HLR) database. If the mobile is allowed to send the message, then MSC routes the short text message to the SMSC which must then direct it to the appropriate mobile device. The SMSC sends a SMS Request to the HLR in order to find the destination. The HLR responds to the query by sending the serving MSCs address of the terminating MS. The message in a Short Message Delivery Point-to-Point format is transferred from the SMSC to the serving system. Once the location of the receiver MS is found, the MSC further queries its Visitor Location Register (VLR) database, the system pages the recipient device, if it responds, the short message is delivered by the serving cell BSS. The final step in this protocol is the verification that the message was properly received [13].

The implemented data communication system

The implemented solution in this paper uses the well known AT commands in order to configure the message format, send a message and read, write and delete SMS messages. The 3GPP TS 27.005, (ETSI 07.05) specifies AT commands and interface protocols for control of SMS functions within a typical mobile cellular unit (e.g. SM5100B modem), from a remote terminal via an asynchronous interface [14].

In order to send SMS messages (V2G information), it is necessary to place a valid SIM card on the modem external socket that is directly connected with the Arduino Uno. The Arduino Uno presented in figure 4 is a microcontroller board based on the ATmega328. It has 14 digital input/output pins, 6 analog inputs, a 16 MHz crystal oscillator, and a USB connection. The serial communication between the Arduino Uno board and the SM5100B modem is established using TTL serial data.

Fig 4 - Arduino plus the GSM/GPRS shield containing the SM5100B modem

After that it is necessary to verify if the modem is waiting for a Personal Identification Number (PIN) using for example the AT command "AT+CPIN?". In order to overcome this step it is advisable to disable the PIN usage before place the SIM card on the modem. In order to operate in text mode it is necessary to set the cellular modem for that purpose using the command “AT+CMGF”. To send a SMS message, the microprocessor should write the following command: AT+CMGS= "+35196xxxxxxx" <ENTER>. If the modem responds positively the message text can be inserted reporting the available EV information following a proprietary protocol. The message is sent when the <CTRL><Z> is inserted.

In addition, it is necessary to configure the communication link in the opposite direction (grid to the vehicle). The EV receives information and/or commands also by SMSs. Thus, it is necessary to know how the newly arrived SMS messages should be handled by the modem. The command AT +CNMI is used to specify that the newly arrived SMS messages forward directly to the serial port disabling that way its storage in the SIM card. The information available in the serial port is handled by the micro processor that decodes the messages and/or commands and performs the required actions.

Basic home automation system based on IEEE 802.15.4 communication

Home lighting and air conditioning are two very important systems to our well-being. However, they must be redesigned in order to increase energy efficiency. Nowadays home lighting systems use so far non efficient incandescent and fluorescent technologies instead of light emitting diode (LED) illumination. In addition, natural sunlight is not properly used in conjunction with artificial light resulting in excessive illumination in some daylight hours. Thus, future systems should be able of dimming the artificial light smartly based on light sensor information. Moreover, often lighting systems remain turned on unintentionally, even if nobody is in a particular room or office leading to severe energy inefficiencies.

In order to cope with the mentioned problems a simple prototype was developed in order to centrally switch on/off a particular room illumination based on human presence. It also monitors room temperature. The proposed solution is based on two different models modules: the sensor and the actuator. The communication between them (sensor and actuator) is performed using low power RF modules MRF24J40MA from Microchip [15]. The MRF24J40 is a 2.4 GHz transceiver that supports ZigBee and MiWi protocols over IEEE 802.15.4. However other private protocols can be used.

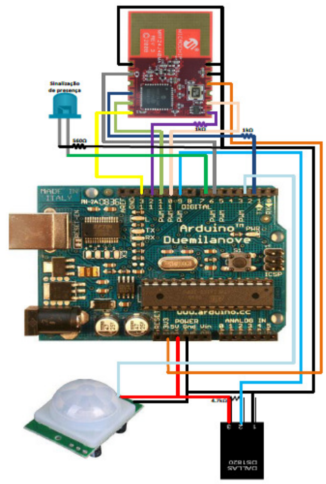

Fig 5 - Arduino plus the Microchip ZigBee MRF24J40 transceiver and sensors

The sensor module presented in Figure 5 has a motion sensor attached that must be installed on top of the room and one or more temperature sensors. The collected information (motion and temperature) is sent to the actuator module to perform both lighting system management and room temperature monitoring.

The microcontroller of sensor module was programmed as follows: every ten seconds, the room temperature is measured by each individual sensor being the obtained values transmitted to the actuator module. Thereafter, it stores the received temperature values in a database that can be accessed by Internet to monitoring purposes. The developed system does not implement any form of control over the air conditioning system, however from performed tests it is expected that future implementations integrate that functionality.

With a correct position of the motion sensor is possible to identify when people leave/came a/to a particular room. Thus, if the system identifies an empty room with the lights on it overrides manual mode and switch off the room lightning system. However, every time a movement is detected inside a likely empty room the module instantaneously switch on the lighting system. It is possible to know in real time what is happening in each module using an USB port to read the serial communications data. These readings can be accomplished using either the Arduino serial port or the Internet.

Conclusions

This paper presents a survey on wireless communication systems in order to investigate their feasibility for smart grid home area networks. Particular attention was devoted to cellular systems such as GSM/GPRS, EDGE and UMTS. Cellular systems offer ubiquitous coverage over existing network operators' infrastructure and low latency; however, the provision of data communication between smart entities and data aggregators is costly. This is because the network radio resources are shared with the mobile network users without QoS and availability guaranties. Moreover, offered QoS is directly related with the received radio signal strength and quality precluding high performance services usage in cells' boundaries.

The simple message service (SMS) common to all cellular systems is, however, very useful to support non-critical applications with low requirements such as home automation networks and alarms. Internet based services are possible using GPRS; EDGE and UMTS networks. Cellular systems coverage area extends the strictly HAN and is also available in neighborhood area network (NAN).

Wireless sensor networks are by nature skilled to interchange information between metering sensors and a data aggregator entity in a HAN scenario. Among the existent solutions ZigBee technology is probably the most suited for these application due to its inherent low power consumption, low cost of deployment, relatively large communication range (near to 100 m) and technical reliability supported on the IEEE 802.15.4 standardized protocol. Nevertheless, ZigBee operation at the 2.4 GHz frequency band is subject of interference from other radio systems and wireless networks that use the same part of the ISM band spectrum. The coordinated channels allocation on both network ZigBee and IEEE 802.11.g is complex but possible and simultaneous operation of both networks was considered in standardization.

The communication between EVs and the electrical grid, crucial to a reliable V2G implementation was analyzed in this paper. The EV location, speed, destination and parking status in conjunction with the batteries SoC is sent to a data aggregator entity using SMS supported by all the cellular networks. The retrieved data is then used to forecast the vehicle capacity to provide energy to the grid when parked. The EV might also furnish important statistics data such as the driving cycle history and the power demand profile using Wi-Fi when located on the home premises. The presented solution allows the V2G concept implementation by means of a more efficient energy management technique implementation on the smart grid.

Energy efficiency in Inovcity Évora

Paulo Líbano Monteiro

Inovgrid, Head of Solution Development, EDP Distribuição

Abstract

EDP Distribuição, the Portuguese Distribution System Operator (DSO) for electricity, has been progressively developing a solution for the implementation of a smarter grid – the Inovgrid project. The municipality of Évora, in Portugal, was chosen as the ideal place to implement, measure, evaluate and enhance the Inovgrid solution – this specific implementation of the project is called the Inovcity.

The main objectives of Inovcity were (i) to validate the technical solution and its associated installation and operation processes, (ii) to validate the business case of the solution, evaluating its main costs and benefits and (iii) to promote energy efficiency and rational use of energy.

This paper intends to describe the energy efficiency results within the Inovcity, while giving an integrated view of the project that made possible those achievements and the importance of energy efficiency in the business case for the development of smart grids. Thus, the paper addresses the strategy of EDP for the smart grids, describes the main characteristics of the solution implemented in the Inovcity, highlights the most relevant benefits supporting the business case of such a solution, details the energy efficiency results obtained, presents the international cooperation context of the project and draws some conclusions focused on the results achieved and the next steps of the work.

EDP's smart grids strategy

Inovgrid is EDP's umbrella project for smart grids. With this project, EDP Distribuição seeks to transform its distribution grid and position it as a robust answer to the main challenges ahead: the need for increased energy efficiency; the pressure to reduce costs and to increase operational efficiency; the commitment to keep and improve quality of service; the integration of a large share of dispersed renewables generation; the management of electric vehicles charging; the need to empower customers and to promote the development of new energy services. Beyond the technological aspects, project InovGrid is providing EDP Distribuição with the know-how and experience that will enable a smooth transition of the organization to the smart grid paradigm.

Inovgrid is a distinctive project in the European landscape because it combines a reasonable size (in its most known implementation in the city and region of Évora, the Inovcity) in terms of the number of customers reached, with a strong focus on the smart grid vision (as opposed to projects purely smart meter oriented). After compiling a catalogue of all European Smart Grid projects, the Joint Research Centre (JRC) of the European Commission (EC) has recognized the unique positioning of project Inovgrid by choosing it as the single case study on which to base the development of its "Guidelines for Conducting a Cost-Benefit Analysis of Smart Grid Projects" [1].

EDP believes that smart grids have the potential to help Distribution System Operators address the technical challenges posed by new technologies, such as dispersed generation and electric vehicles, while contributing to the ever-present challenges of efficiency and quality of service. The evolution towards a smarter grid is touching a number of different areas at EDP Distribuição, supporting the various components of the solution presented in figure 1. With project Inovgrid, we seek an integrated approach to this change process.

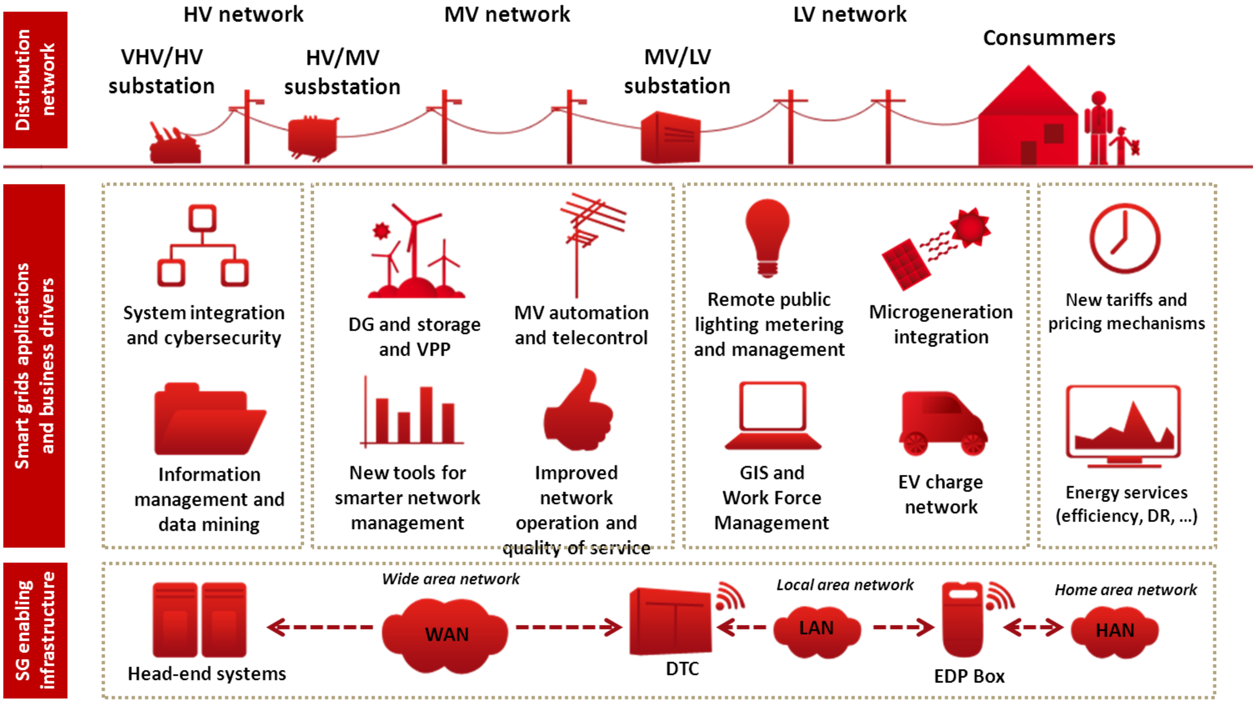

Figure 1: Smart grid components

Évora Inovcity

The main development of project Inovgrid so far has been the implementation of a Smart Grid infrastructure in the Portuguese municipality of Évora, called the Inovcity [2]. The infrastructure spans the entire municipality, around 1.300 km^2, reaching around 31.000 electricity customers with an annual consumption of approximately 270 GWh, and encompasses 340 secondary substations. Additionally, there are 140 medium voltage customers with an annual consumption of 110 GWh. In this non-residential segment, industrial activities account for 57% of electricity use, while services account for 34% and agriculture and other activities for the remaining 9%.

Évora Inovcity is a living lab for the Inovgrid project, with a set of different initiatives in several areas of the electricity grid and involving multiple players of the local community. The field implementation of the project took place during 2010 and 2011. Tuning of the solution, mainly in what concerns communications, systems and processes occurred essentially in 2011/2012.

In order to make visible and promote the Inovcity, EDP built a project showroom in one of the main squares of the city (Praça do Sertório), and ensured that several points of interest could be found in that same square, making it easier to explain and to understand, in short organized visits, the relevant characteristics of the solution. Thus, one can find, within a very short area, the following demo-sites as depicted in figure 2:

- the Inovcity showroom, presenting a demo-station with the main physical components of the implemented solution, several video presentations about smart grids and the Inovcity, a set of devices for in-home energy monitoring and control;
- the Vinyl Café, equipped with an EDP Box and energy control devices, presenting a real use case of the interaction with the costumer;
- the City Hall, where energy consumption and own production are presented, together with other information, in a totem at the entrance of the building;
- efficient public lighting system, based on LED luminaries with advanced sensing and remote control;

- electric vehicle public charging station;
- underground automated secondary substation, equipped with Distribution Transformer Controller (DTC) for monitoring and control, and EDP Boxes for metering the power transformers; this dual transformer secondary substation includes also the automation devices and a multiple sensors system for ambient and transformer oil temperature, humidity, melted fuse in feeders, door open.

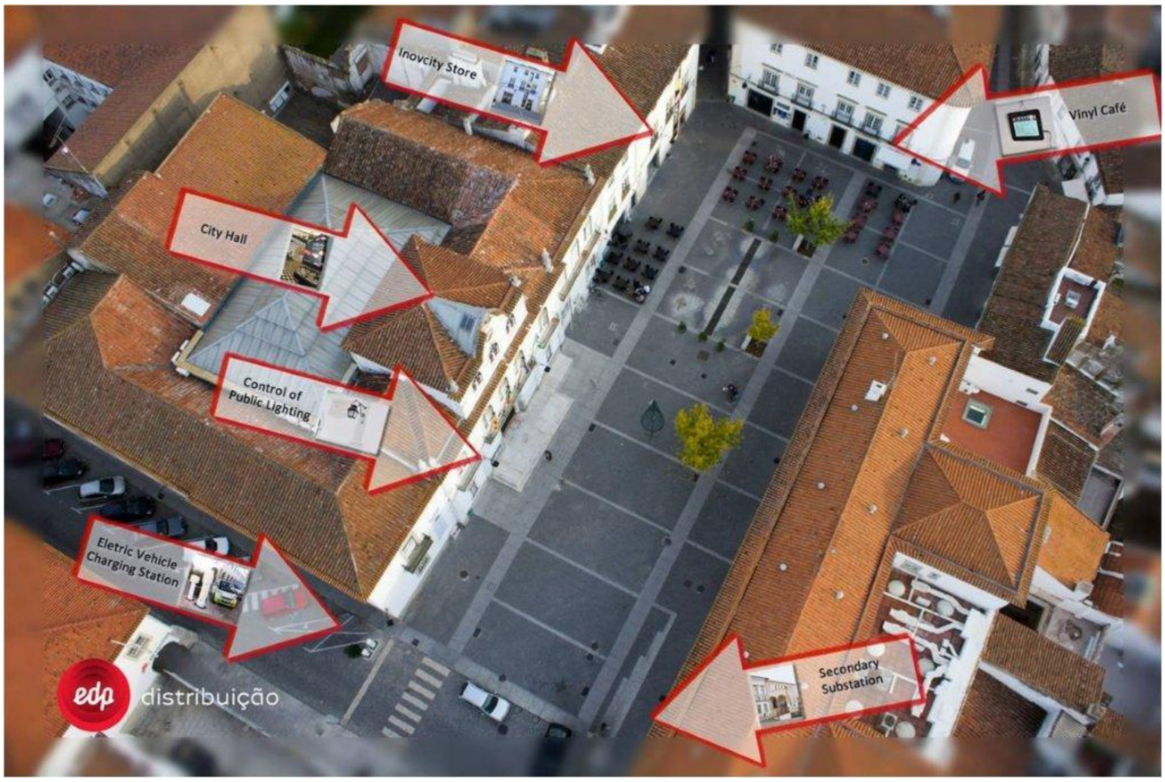

Figure 2: Demo sites in the Inovcity (Sertório square, Évora)

From a technical perspective, the architecture of the system deployed in Évora includes the following components:

- EDP Boxes (EB), installed in all low voltage customers, offering advanced smart meter functionalities, such as real time readings on demand, load diagrams, voltage monitoring and remote services (connect/disconnect, contracted power and tariff setup, tampering alarms, etc.); it also offers a local connection for establishing a Home Area Network (HAN), allowing the consumer to access the information in the EB in real time (ZigBee and WiFi technologies have been used for the HAN);
- Distribution Transformer Controllers (DTC) installed in every secondary substation, acting as data concentrators and local measuring, monitoring and automation devices (power quality monitoring, medium voltage switching, local sensors, etc.); the DTC controls every EB connected to its low voltage network, independently of the technology used for communications;
- A communications network based on Power Line Carrier (PLC) and GPRS technologies between EBs and DTC (Radio Frequency Mesh has been also tested), and based on GPRS or any other TCP/IP supporting technology for connecting DTCs to the central systems;

- Central commercial system (head end + meter data management) for metering data and low voltage SCADA-like system for grid operation data, both communicating with DTCs, but using different protocols.

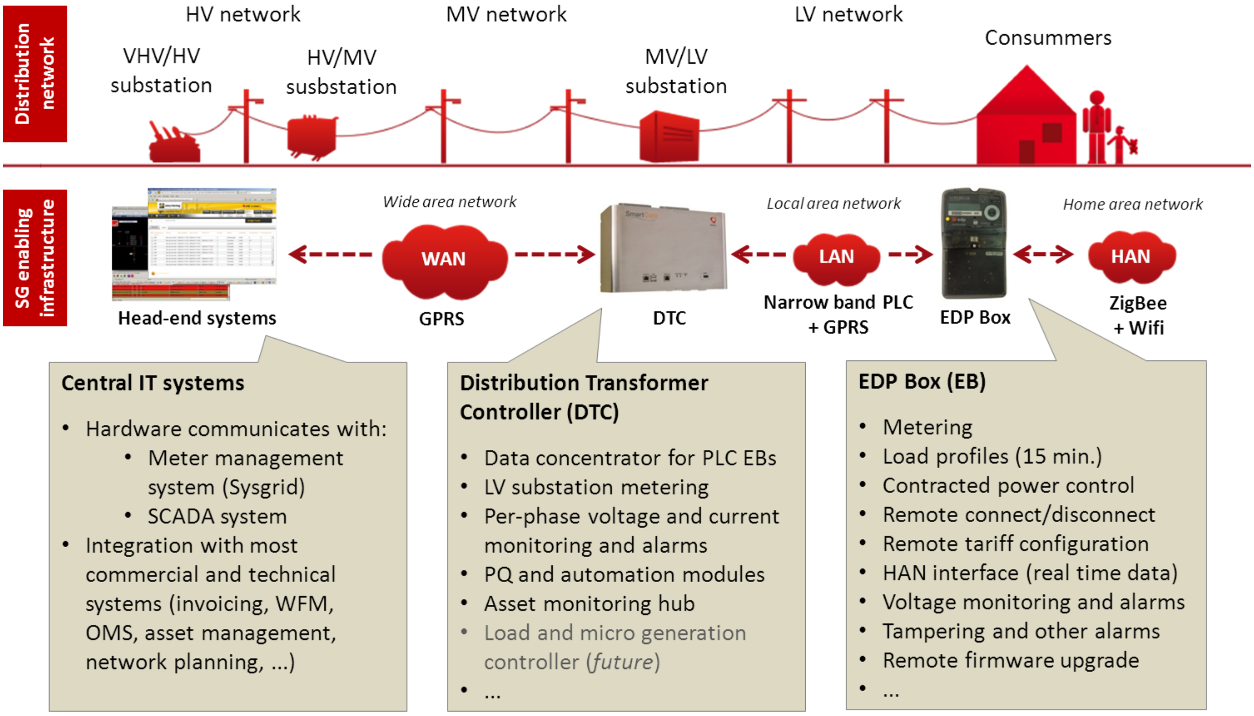

Figure 3: Inovgrid architecture

The mix of components and technical architecture used in Évora, depicted in figure 3, goes well beyond smart metering, serving other applications such as LV substation monitoring and automation.

The business case

Inovgrid embraces all the different aspects of the smart grid ecosystem, from the central information systems to the end users, from the smart meter to the electric vehicle charging infrastructure, and being an open platform by construction it fosters innovation from all the participants in the ecosystem and provides the favourable environment that allows the evolution and creation of new business models, services and products that will ultimately benefit the different stakeholders.

The business case for Inovgrid is based on a set of benefits of the project accruing to several stakeholders, including the DSO itself, electricity users, electricity retailers, producers, energy services companies, and the economic and ecological impact in society in general. The deployment in Évora provided ample evidence about many of these benefits.

The diagram in figure 4 illustrates the main estimated and/or measured benefits of the project. For each of those benefits, Inovgrid created a team responsible for analysing, promoting and measuring it, whenever possible. This effort paid well, because it allowed EDP Distribuição to reach and measure some relevant results supporting the business case, and definitely contributed to the credibility of the project.

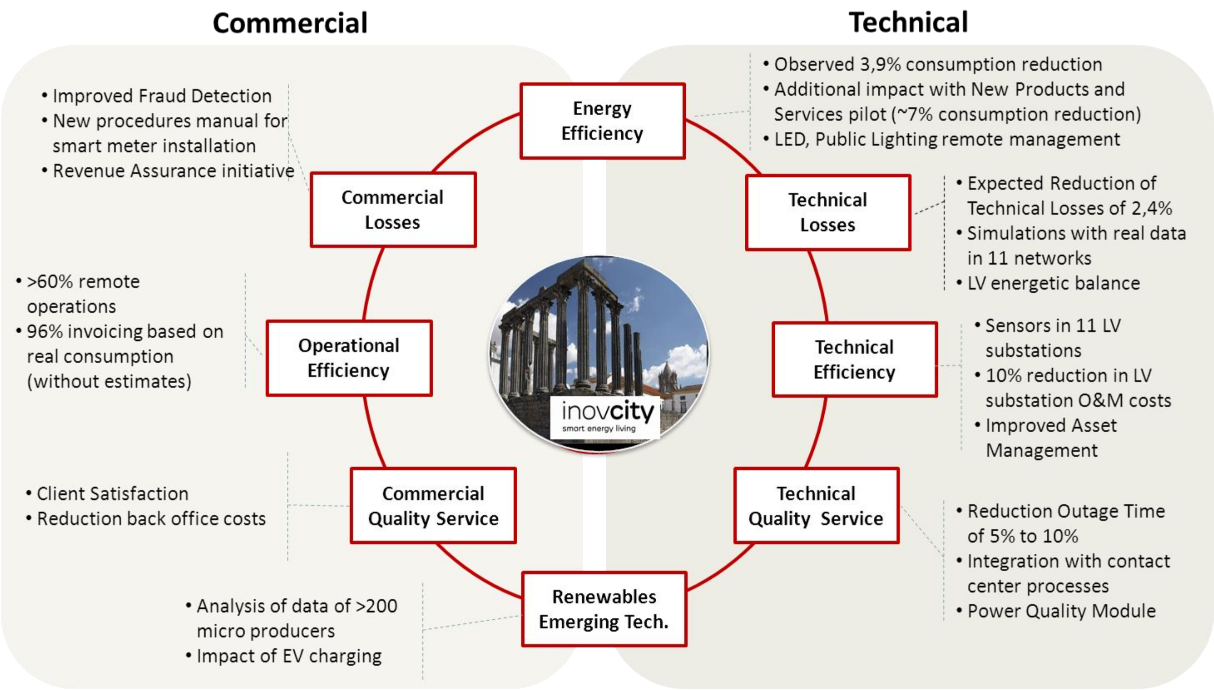

Figure 4: Areas of benefit of the project

The evidence obtained has supported EDP's assessment of the societal implications and cost-benefit analysis of a full smart grids rollout and the conclusion that smart grids have the potential to create substantial value for the society as a whole. Meanwhile, an independent study commissioned by the Portuguese regulator (ERSE) and produced by KEMA [3] reached very similar results and conclusions. The graph in figure 5 illustrates how the main benefits of a smart grid rollout are divided among different value drivers, in EDP's business case analysis.

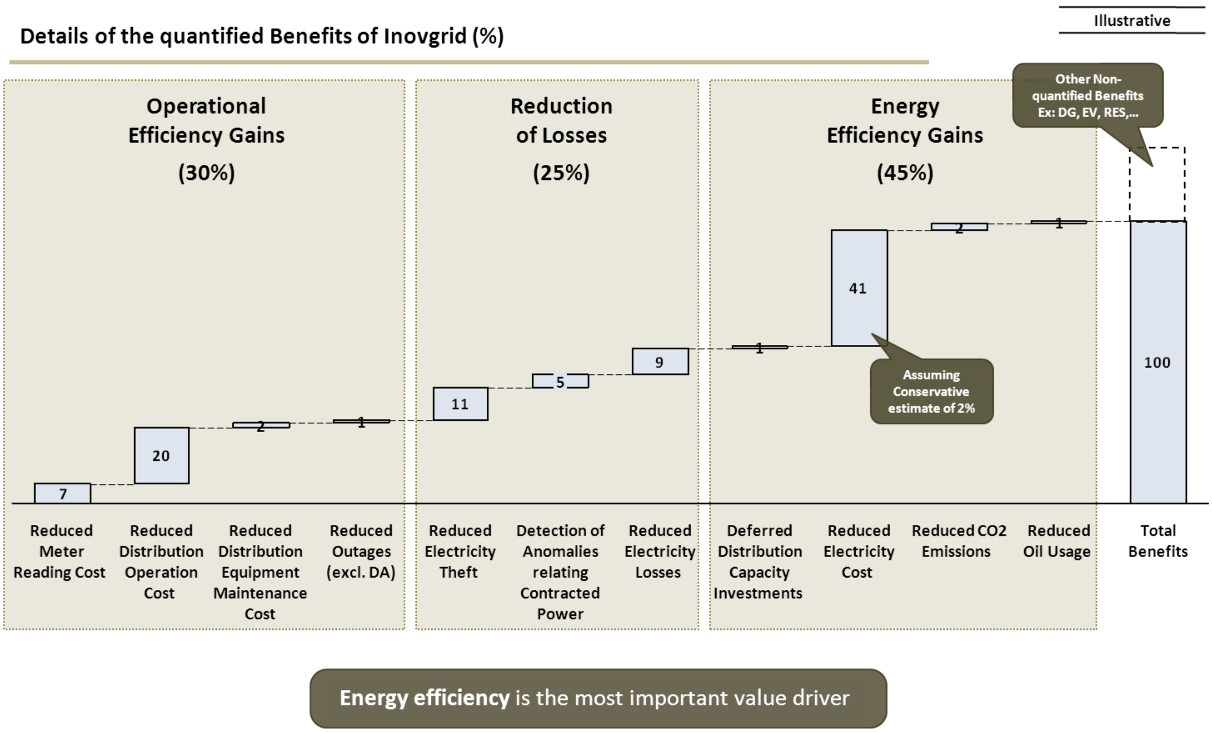

Figure 5: Main benefits

Energy efficiency results from the Inovcity

From the beginning of the pilot in Évora, EDP understood the crucial impact of energy efficiency on the value of the project. Considering the critical role that customer engagement plays as a prerequisite to change behaviours and increase energy efficiency, EDP implemented in Évora a mix of initiatives aimed at raising awareness about the project and creating a special Inovcity dynamic. Key stakeholders were identified and multiple initiatives were designed to target specific customer groups and other stakeholders, such as schools, energy professionals and local authorities. Several activities of communication and dissemination of the project were key to get the involvement of different stakeholders, as shown in figure 6: the Inovcity showroom, the Energy Bus, the information spread around the city of Évora, the organization of Conferences and events, the presence in the local press or even the public sessions held for customers' clarifications of the project. Additionally, surveys were used to continuously monitor customer behaviour and guide communication decisions.

Figure 6: Local initiatives promoted awareness about the project

Regarding residential low voltage clients, a very broad study, including data from more than 30 thousand customers was developed together with Qmetrics, an independent company specialized in market studies and integrating university Professors from Universidade Nova de Lisboa. The basis of the study consisted in monitoring the electricity consumption of customers in Évora and comparing it to a control group in a nearby municipality, with similar socioeconomic and climatic conditions. An evaluation of results was done after gathering an initial 12 month of data, and their persistence was evaluated by monitoring consumption for an additional year.

The group under evaluation had their meter replaced by an EDP Box, started receiving monthly invoices based on real consumption (instead of estimates), had the possibility to monitor their consumption online (web portal) and were exposed to the general project communication effort in Évora, which included generic energy efficiency advice.

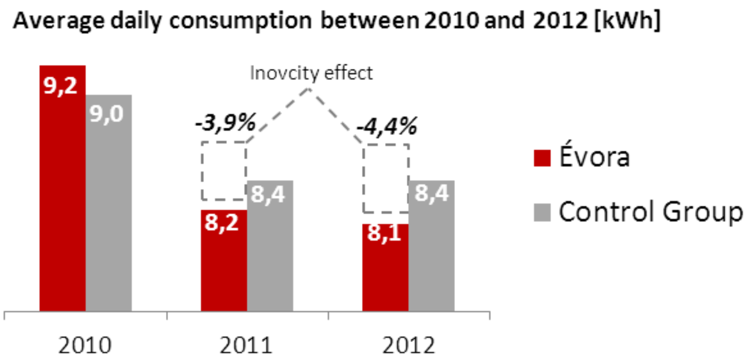

Figure 7: Average daily consumption between 2010 and 2012

The results in terms of energy efficiency, shown in figure 7, were highly encouraging: in the first year an average reduction of consumption of 3.9% vs. the control group was observed. Furthermore, this was a statistically significant result, with the result falling in the interval of 1.8% to 6% for a 95% confidence interval (2.1% error margin). This applies to the whole Inovcity, around 31.000 consumers, assuming basically indirect feedback.

The data gathered so far also shows that the effect is persistent (4.4% energy reduction in the second year), at least two years after the project was launched. This result of about 4% increase in energy efficiency provides a comfortable margin when compared with the conservative estimate of 2% used in EDP's business case. The previously mentioned study performed by KEMA [3] considered several analytical scenarios, using figures of 1% and 2% for energy efficiency using indirect feedback, and 3% for direct feedback using in-home displays.

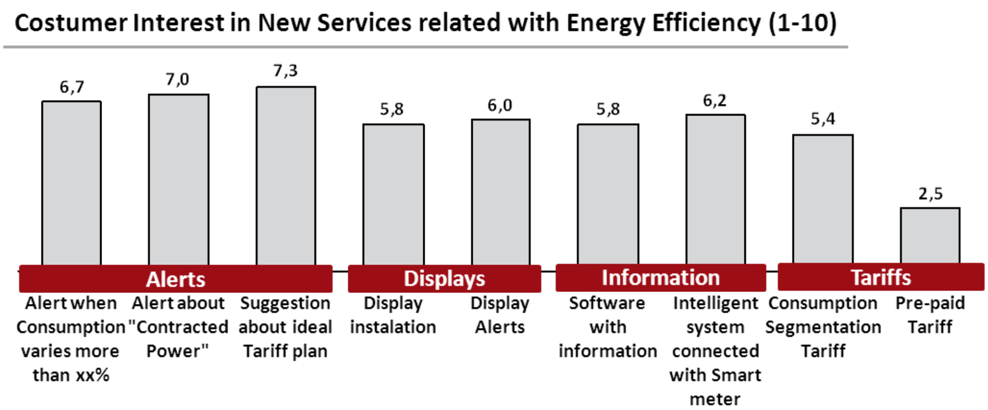

Figure 8: Costumer interest in new services for energy efficiency

Beyond the impact of the project in the general population of Évora, EDP used the pilot to test the impact of more sophisticated smart grids products and services, using smaller test groups. The first step consisted in conducting surveys and focus group sessions to understand customers' preferences, whose results are presented in figure 8. From several possible new services (such as alerts, in-home displays, applications for delivering useful information and tariffs), customers elected the alerts as the most interesting ones. Pre-payment was considered the least interesting service.

In order to touch different customer segments, several innovative services were tested in a set of customers ranging from large companies to individuals. Aspects like energy efficiency, CO^2 reduction, energy consumption reduction, smart consumption patterns were taken into account in providing these innovative services, which targeted not only economic aspects but also social and behavioural aspects.

EDP's desire to promote the active participation of customers was reflected in the technical specification of the EDP Boxes, which are prepared to accept a HAN module that allows the flow of information from the EDP Box to the customer premises, interacting in real time with devices such as in-home displays, energy controllers or the customer's WiFi router (figure 9), thus providing direct feedback.

In Évora, EDP provided in-home displays to a test group of customers and instructed them on how to use this data for their own benefit. Complementary, for another test group, simulated tariffs were introduced to allow customers to compare their real consumption pattern with what they would have achieved if they had chosen a different tariff and rewarding their energy efficiency. Frequent surveys were conducted near the target population to have a deep understanding of the evolving customers' perception, and focus groups were organized to extract additional feedback. For both, groups alerts were sent to customers based on individual consumption information (e.g. SMS, email). Results from these two groups are also encouraging, with observed increases in energy efficiency of around 7% (6.7% to 6.9%), but a higher error margin.

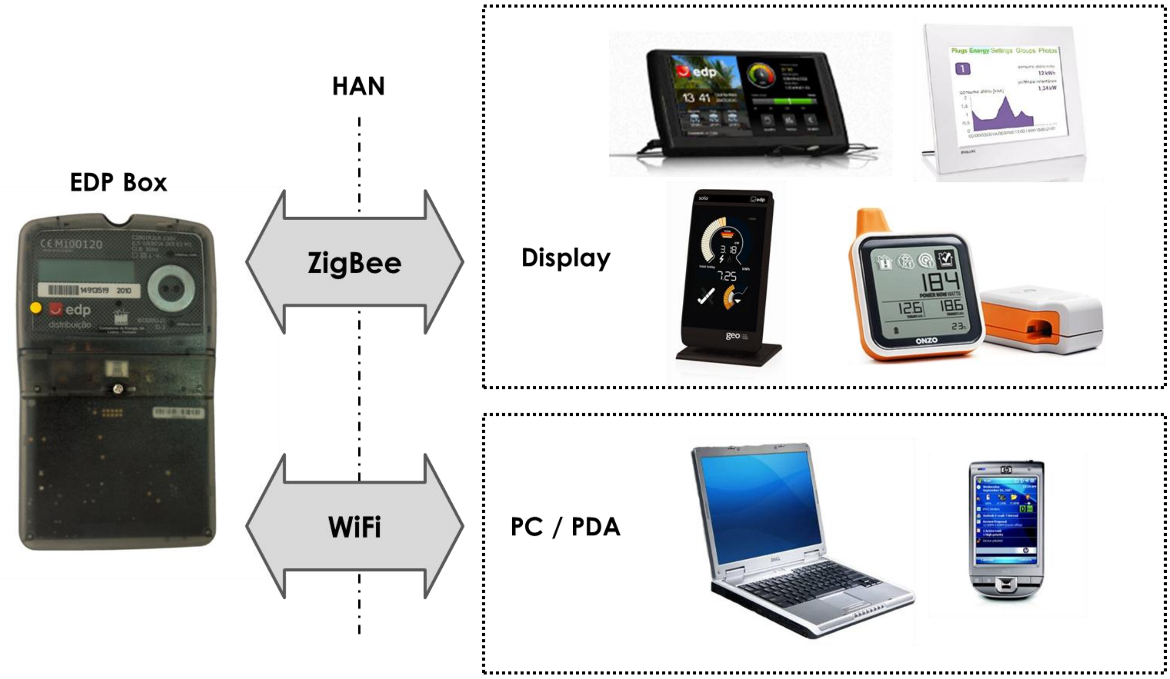

Figure 9: Home Area Network (HAN) interaction

Inovgrid technology is currently used as an open platform, based on public standards, by other independent companies developing new in-home tools and services supporting customers' involvement, which allow to deeply empowering consumers to make smart decisions about electricity consumption. Customer innovative products are under test, leveraging on Inovgrid platform but developed by independent companies.

So far results for heavy consumption customers' with sophisticated energy management systems, like Hospitals, Museums, Public Buildings and others show that significant energy savings are achievable and gains between 12% and 20% of consumption reduction were observed.

International cooperation

The Inovgrid project is being developed in close cooperation with several organizations including Research Institutes and Universities across Europe, Industrial Partners, Local and National Authorities, Energy Sector Associations and Regulators, the involved Communities and other relevant stakeholders. Delegations from more than 30 countries from all continents, ranging from Australia to China, or Brazil to Angola, have visited Inovcity Évora.

The company participates in several European projects with major R&D components included in FP7 or IEE programs which foster innovative beyond the state of the art research and validation across different European Member States. EDP Distribuição leading a consortium of 8 partners was chosen to implement a major European Research and Development project named Sustainable. Partners include several R&D Institutions like INESC Porto, Comillas University from Madrid, National Technical University of Athens, University of Manchester or the Technical University of Berlin. The focus is the shift of paradigm in the distribution network concept of operation which strongly leverages in recent smart grid projects and aims at an increasing capacity of renewable energy hosting, allowing decarbonizing the economy. Other relevant projects where EDP participates is the EcoGrid project, which is an European project whose objective is the development of a new type of market with electricity prices in near real-time information, and which was nominated in the UN Conference of Sustainable Development (Rio+20) in June 2012 as one of the 100 most sustainable projects in the world, and it was one of the 10 finalists in the category of "Best IT Solution".

From a universe of more than 200 Smart Grid projects under development in Europe, compiled in a Smart Grids Project Catalogue by the Joint Research Centre Institute for Energy and Transport (JRC) and Eurelectric in 2011, Inovgrid was selected as the single case study for testing and validation of the EPRI Business Case assessment methodology. Following this selection and building in the work done at European level, Inovgrid was assigned the "Core Project" label [4] from the European Electricity Grid Initiative (EEGI), being one of the 4 projects that achieved it so far and being the only national project of the group. This shows full commitment and alignment between the identified European project needs and Inovgrid project, not only targeting new technological developments but also a very strong focus on customer service innovation. Figure 10 illustrates this international involvement.

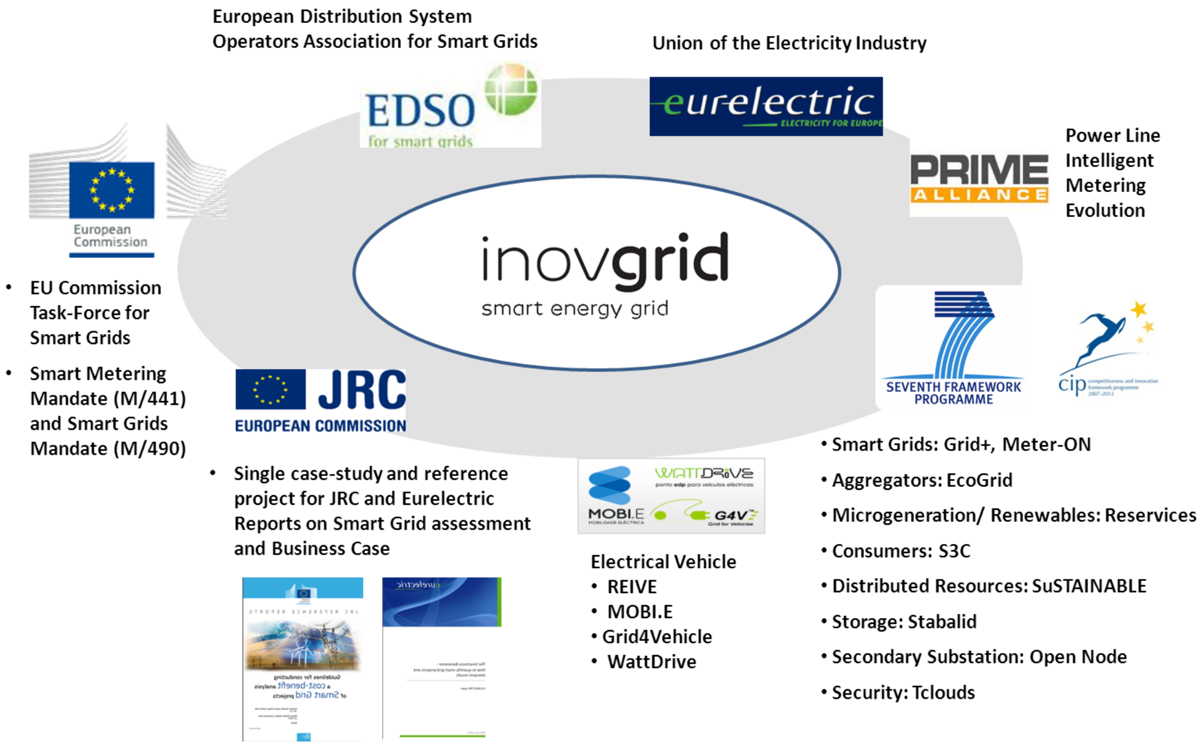

Figure 10: International cooperation in Inovgrid

Conclusions

Results from Évora provide ample support for EDP's business case for a nationwide rollout. Furthermore, EDP's results are aligned with those of the Portuguese regulator in concluding that the rollout of the Inovgrid solution would create value for society.

Consumer engagement is key to unlock the smart grid potential. Utilities face big issues today as they search to maximize consumer engagement – being able to manage the millions of data available, understanding the new and all different consumers, being able to build-in innovations in their operations and also focusing on maximizing value for all stakeholders.

Évora is a living lab for the Inovgrid project, with different valences from smart metering, public lighting, electric vehicles, energy efficiency and Client interaction, and the project has developed a strong involvement of local stakeholders and population which was key for its success

The results of the Energy Efficiency Study in Évora show that the implementation of a Smart Grids infrastructure led to an increase in energy efficiency of around 4%. Additionally, new products & services are being tested on selected segments of customers to understand the impact of different incentives in consumer behaviour.

EDP Distribuição is looking ahead in the smart grids and consumer engagement topic: first, it plans to install an additional 100k EDP Boxes in 6 locations with different network characteristics in Portugal; secondly, EDP Distribuição is aligned with the most important standardization projects in Europe and actively participates in several international forums and projects.

Abstract

Electric vehicles are seen as an option to reduce greenhouse emissions from the transportation sector and their number on the road is growing in a daily basis. However, with their widespread adoption the increase in the demand for electricity to charge these vehicles could pose significant challenges to the electrical grid in terms of additional load due to unmanaged charge strategies. In order to mitigate this problem, the charging of the electrical vehicles must be managed. This paper presents the development of a hardware and software architecture to dynamically control the charge of electric vehicles to maintain the proper operation of the local distribution grid, by reducing the possibility of power outages due to overload, in a Smart Grid context. The hardware consists in two modules, a meter and controllable plugs both with communication capabilities, while the software consists in a load forecast and scheduler module. The load forecast is calculated based on the power consumption behavior and is used to assign the best time slot to charge the vehicle. The system aims to minimize the load peaks and flatten the load profile.

Based on the user preferences, system characteristics and consumption forecast, the system will assign the most suitable time slot to charge the electric vehicle. For the case of multiple electric vehicles, the system will schedule their charge based on a calculated priority level, in order to maintain a reliable operation of the local electrical grid.

1. Introduction

Electric Vehicles (EVs) are expected to have a large share in the future of the transportation system in order to reduce the share of Greenhouse Gas (GHG) emissions associated to personal transport and also due to the increasing costs of fossil fuels [1] [2]. This electrification of the transport system will cause an additional load on the electric grid, since the EVs will require a connection to the grid to charge the batteries. Currently, due to the EVs low penetration rate the additional load imposed to the grid by the vehicles charging is not an issue, however in the future, with a higher penetration rate, this could bring serious consequences to the grid reliability due to overload [3] [4]. The main problem is not in the extra energy required to charge the batteries, since the grid has enough capacity, but the peak load of the charging [5] [6].

Since the majority of EVs will be charged at home, it is expected that the vehicle will be plugged in when their owners get home, at the end of the afternoon. This behavior will lead to a considerable additional load that can overload the grid. In order to mitigate these problems, the charging cycle of EVs must be managed in some way [7]. This concept of coordinate charging is being explored due to the wake of smart grids, where the exchange of information using several communication technologies can improve the efficiency, reliability, economics, and sustainability of the production and distribution of electricity [5] [8]. Coordinate charging can also be beneficial for grids with a large share of renewable energy sources by absorbing the excess energy produced [9].

Alternatives to uncoordinated charging are currently being investigated by using devices with bi-directional communication capabilities to perform a coordinated charging [10] [11] [12]. This type of coordination is intended to minimize the negative impacts on the grid, due to a large number of vehicles charging at the same time by distributing this charge over a large period of time, flattening the load peak. Efficient operation in a smart grid environment usually is focused in reducing energy losses and increasing efficiency [13] [14], in this paper the focus is in maintain the grid stability by avoiding the overload due to the uncoordinated introduction of additional loads.

2. Motivation and Problem Definition

Intelligent control over the introduction of new loads into the grid has the potential to provide economic benefits since peak demands affect the grid investments and operational costs [15] [16]. Minimizing demand peaks by distributing the load over a longer period of time will contribute to reducing the transmission and distribution losses, since these losses grow with the square of the current, and stress in the grid equipment [17] [25]. In order to flatten the load profile, some utilities apply different price rates depending on the time of day to encourage customers to shift the use of certain appliances, such as washing machines, to off peak hours when electricity price is cheaper. This approach contributes to the reduction of peak demand, however this implies active consumer involvement which can be difficult to manage. Relying on consumers to manage their energy consumption to off peak hours can work during an initial period, where they are motivated by the novelty and savings that can be achieved, however after this initial period they will start to revert to old habits. Using an automated system that takes into account user preferences, to manage the loads is a better solution since the system will automatically adapt by continuously evaluating the grid status and could also allow the utility to disconnect/connect loads in certain situations [18] [19] [22].

Since EVs are a significant load (around 3.6 kW during the charging cycle of the EV, which can last up to 6-8 hours), the use of an automated load management system can contribute to an automated demand response program controlled by the grid. This demand response system refers to the ability to reduce loads at peak times to lighten the need for peaking generation sources. These power plants are usually gas turbines that burn natural gas, due to their fast response, and since they only supply power occasionally, the price per kilowatt hour is much higher when compared with the price for base load power plants. The shift of these loads to off peak hours can also contribute to a reduction of GHG emissions due to an increasing in the efficiency of gas and coal power plants [24].

Loads equipped with communication and control capabilities can be aggregated and dispatched to help to manage the grid. This load aggregation can provide the same regulation as ancillary services, nowadays provided by power plants. This regulation is very valuable since it provides real time matching between load and generation. Without this equilibrium the grid frequency will drift up or down affecting the quality of service [20] [21] [25]. Despite the benefits for the network in terms of increased reliability, this service provided by EVs is also beneficial since it will have a financial revenue associated [22].

Nowadays this regulation is achieved by forecasting the load based on past data and dispatch of generation accordingly, however this load following approach becomes more difficult as the share of renewable generation increases. The intermittent nature of renewable energy sources, such as wind and solar, makes very difficult to predict with certainty their contribution to the total generation and can require more conventional generation sources used as backup to provide ancillary services and regulation to the grid.

The introducing in the market of vehicles with the capability to be plugged into the grid associated with a daily commute distance under 50 km (which requires up to 10 kWh of energy) for the majority of the users will make the EV one of the major energy consuming devices in a household. An EV charging, using a Level 2 charging station will draw 3.6 kW of power during around 3 hours per day for a 50 km commute. Based on the commute profile of the users, is reasonable to expect that EVs will be plugged in at least during 8 hours per day (or more if the EV is also plugged in at work and not necessarily charging during this period) which is more than the required time to restore the energy spent, resulting in a flexibility that also can be harnessed to provide grid services while ensuring the requirements of the user.

EVs could be an excellent demand dispatch resource given their potential for rapid response (can be turned on or off in a matter of seconds), the significant amount of power that they can draw during large periods of time and expected market penetration. It is possible, that in the future, a significant part of the ancillary services to provide regulation to the grid will rely on EVs.

3. SMARTplug System Architecture

This paper presents the development of a hardware and software architecture for demand response, where the main goal is to manage in real time the additional load introduced by EVs when charging at home, avoiding triggering the installation protections due to overload (Figure 1). This management also intends to flatten the load profile by shifting the peaks to the valleys based on user preferences, EV battery State of Charge SoC and local installation power capabilities. The system requires the following parameters from the user:

- Contracted power: Defines the maximum amount of power that can be used from the grid without tripping the installation protections. If at a given moment the present or foretasted power reaches 80% of this value, the electric vehicle is disconnected or the time slot is considered invalid for charge, respectively.
- Vehicle charger power: Specifies the amount of power that the electric vehicle will draw during the charge cycle (for a Level 2 charger this value is around 3.6 kW).
- Battery SoC required: Specifies the maximum state of charge for the electric vehicle.
- Unplug time: This time defines the deadline to achieve the required battery state of charge.
- Energy tariffs: Specifies the different costs of the consumed energy to different time periods. If several time slots are suitable to charge the electric vehicle, the chosen one will be the one with the lower tariff.

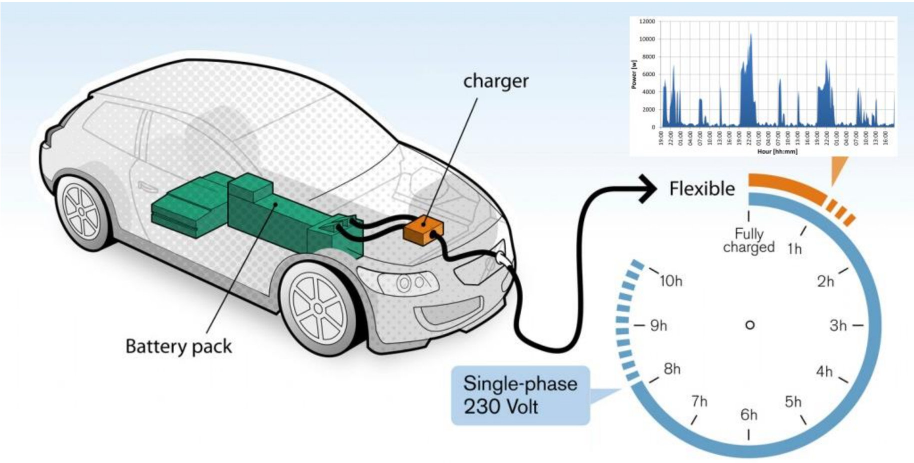

Figure 1: Scenario where is possible to implement the SMARTplug system. The system is aimed for a residential environment, with a single or multiple charge points.

Hardware Architecture

The system, described as SMARTplug, is composed by two main devices, an energy meter and a smart plug (Figure 2), both with communication, data storage and local processing capabilities. The energy meter is installed on the feed point of the infrastructure, to measure in real time the global energy consumption, while the smart plug will replace the standard plug used to charge the EV. The energy meter will also store the load diagram from at least the previous three weeks. Depending on the number of charging points for EVs, it is possible to have multiple intelligent plugs in the same infrastructure, but only one energy meter is required. For a single charging point it is possible to integrate these two devices into one to avoid complexity and reduce costs.

The stored data is used to forecast the load during the time when the electric vehicle is plugged in and to assign a time slot to charge the EVs. If the EV is plugged in eight hours and only requires two hours to achieve the desired SoC, the time slot chosen will be the one with the lower tariff, with the lower footprint and the lower impact on the load diagram in terms of peak power.

Both devices have a dedicated energy measurement unit that calculates all the relevant parameters (voltage, current, energy, power and power factor). The micro-controller communicates with the energy measurement unit through RS-485, and stores the power data each minute. The smart plug additionally has a solid state relay used to turn on and off the power. The communication between the two devices is currently done by RS-232, but another communication interfaces could be used.

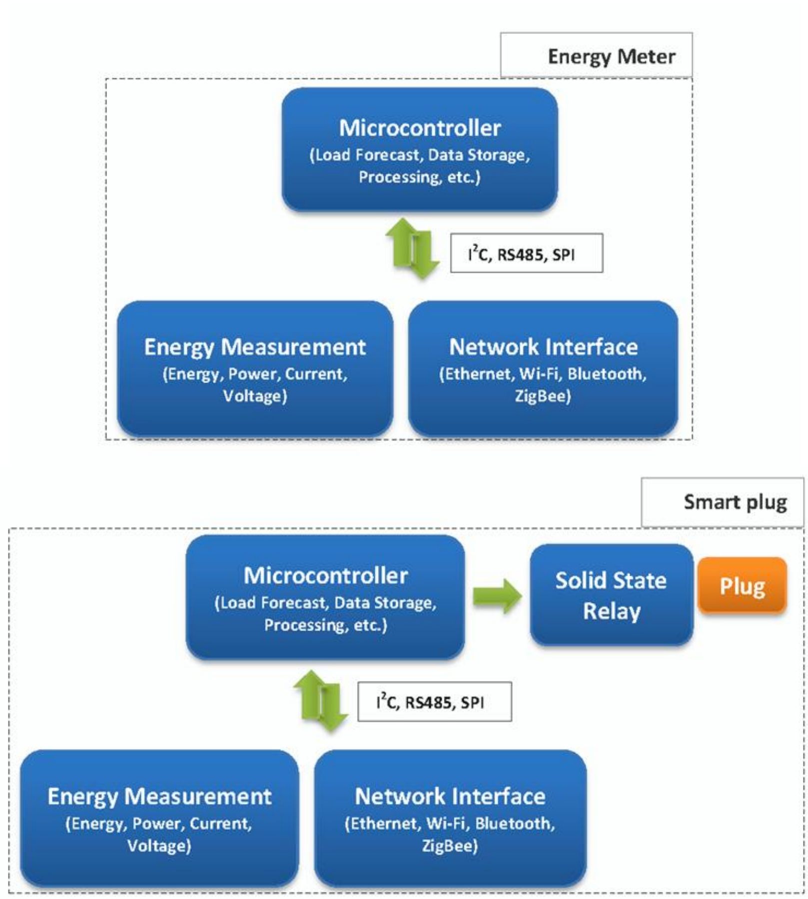

Figure 2: SMARTplug system architecture with the energy meter (top) and the smart plug (bottom).

Software Architecture

In terms of software architecture, the SMARTplug system has three main components: a load forecast module, a classifier module and a scheduler module. The Load Forecast module is responsible to forecast the load based on previous data. This module uses the power data stored by the energy meter, excluding the contribution from EVs charging stations, for the global power consumption. The forecast is performed by using the average previous data for the same time frame and taking into account if it is a weekday or weekend, since the load diagram varies significantly from weekday to weekend. The forecast is performed with a five minutes interval, despite the data being stored each minute.

The Classifier module (Figure 3) is responsible by the analyses of the time slots where the charge of the EV may occur and classify them as valid or invalid. This module will run when the EV is plugged in and based the load forecast, electricity price, contracted power and power draw by the vehicle will determine a set of valid time frames to charge. The load forecast for a given timeslot considers the past five identical timeslots (e.g. the load from the previous five days at 15:00 hours) and is calculated using Equation 1.

Equation 1 $$L_t = \sum_{n=1}^{5} \propto_n \cdot L_n$$

Where L_n is one of the past timeslots and $\propto_n$ the weight factor considered for that timeslot. A given time slot is only valid if the contracted power is higher than the load forecast plus the power draw by the vehicle. The availability of a time slot is calculated using Equation 2:

Equation 2 $$A_{vt} = P_{cont} - (F_{pt} + SM) - P_{ch}$$

Where P_{cont} is the contracted power, F_{pt} is power consumption forecast for time T, P_{ch} is the power of the EV charger (3.6 kW for Level 2) and SM is a safety margin (0.2 kW). From Figure 3 in the validation of availability, depending on the ratio between A_{vt} and P_{ch}. a grade is assigned. The values for the grade were chosen arbitrarily to penalize time slots with high energy tariffs and demand forecast.

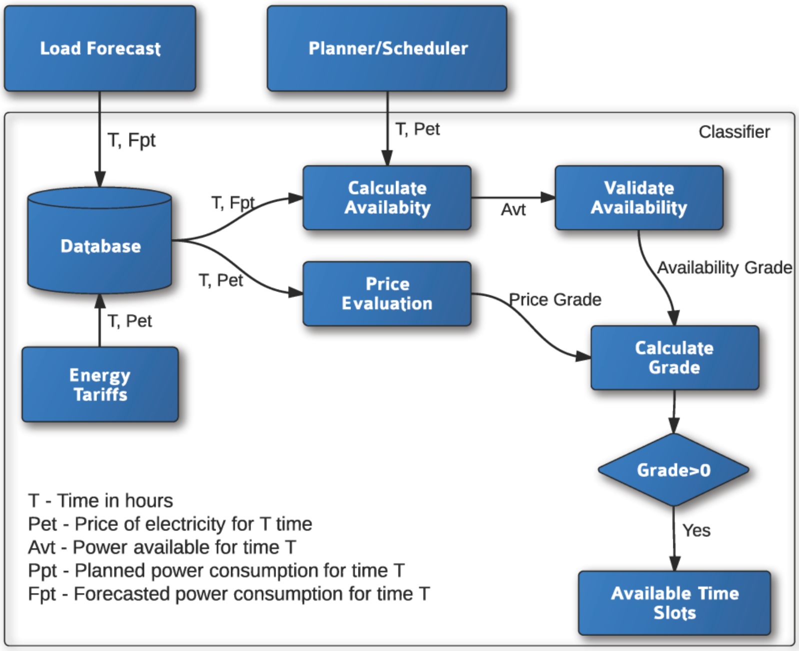

Figure 3: Diagram for the classifier implemented in the SMARTplug system. The classifier determines the valid time slots to charge the EV based on the load forecast, electricity price and planned power consumption.

The Scheduler module (Figure 4) is responsible by the generation of a charge plan. After the validation of the time slots, the planner will assign the best slot to charge the vehicle, based on load requirements (in this case the load is the EV).

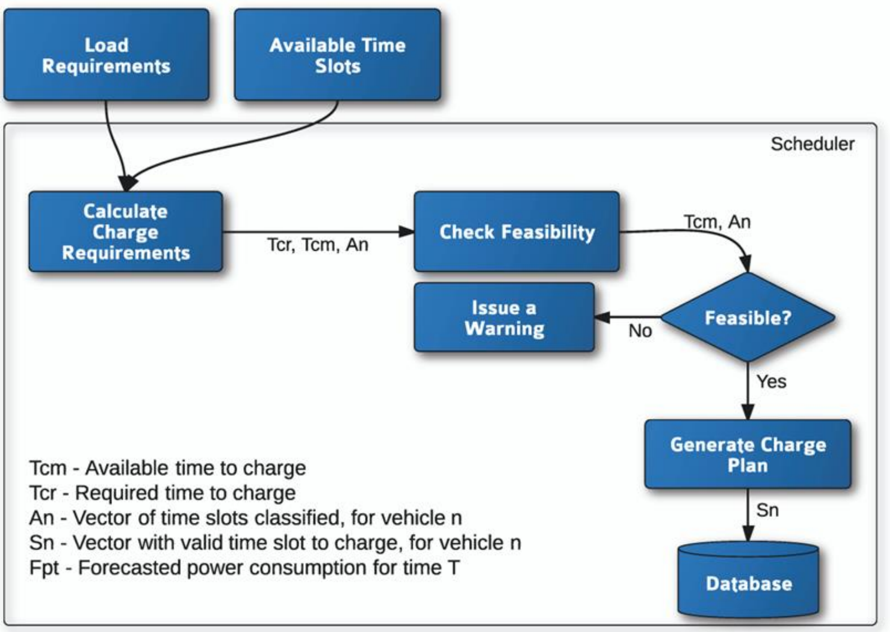

Figure 4: Diagram for the scheduler implemented in the SMARTplug system. The scheduler generates a charge plan based on the available time slots and load requirements.

The load requirements are the capacity of the battery, the SoC of the battery when the vehicle is plugged in, the required SoC and the time of unplug. Based on these parameters the charge requirements are calculated using Equation 3:

Equation 3

$$T_{cr} = \left(B_{cap} - B_{cap} \times \frac{SoC_{ini}}{100}\right) \Big/ P_{ch}$$

Where T_{cr} is the required time to charge in hours, SoC_{ini} is the initial SoC in % and B_{cap} in kWh is the useful battery capacity (on the Nissan Leaf from the 24 kWh only 20 kWh are useful). The feasibility is only validated if a set of available time slots required to charge the vehicle are less or equal than the ones available. If several sets of time slots are available to charge the vehicle, the chosen one will be the one with less impact in the load diagram.

Load Diagram Analyses

To understand the extent in which the management of the additional load introduced by EVs could be controlled by a system with minimal intervention by the user, it is important to have detailed information regarding the energy consumption during a large period of time. Figure 5 represents the load diagram for an average European household [23].

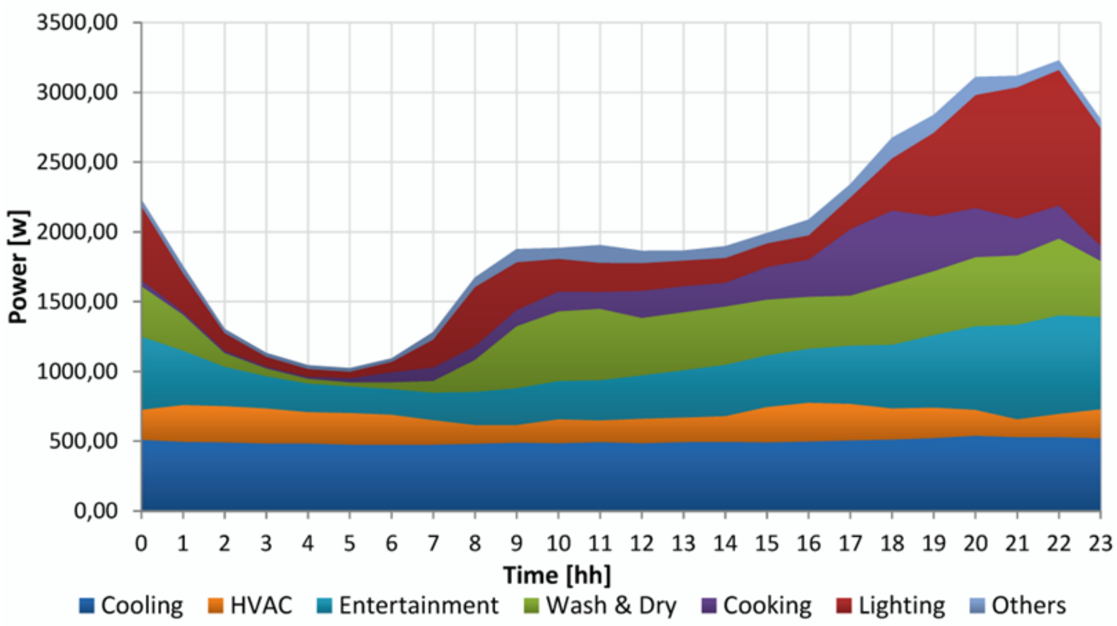

Figure 5: Load diagram, by type, for an average European residence during a day [23].

From Figure 5 it can be seen that the majority of the power consumption occurs between 17:00 and 00:00 and between 01:00 and 07:00 the consumption reaches its minimum. By analyzing the load diagram, is visible that the best time to charge an EV is between 01:00 and 07:00, however this implies that the user must plug in the vehicle or program it to charge during this period. Despite this being a valid solution, this implies active participation from the user, and as referenced before, cannot be guaranteed that the charging will occur at optimal times.

Figure 6 and Figure 7 show an extract of a load diagram for two residences that were monitored, A and B, for a weekend and three days of the week [23]. These load diagrams are only for the household loads, excluding EVs. By observing the load diagrams it is visible that the consumption is concentrated in specific points in time and is very similar from day to day. For a given residence the load diagram tends to be very stable for works days and weekends. Based on these facts and using consumption data gathered over time, the consumption for the next 12 hours can be predicted. Without access to this information it would be very difficult to the user to choose the ideal time to start charging the vehicle. The benefits of an automated system over the common approach, where the user is responsible for the process of start charging the vehicle, is that the system can choose the best time to charge the EV taking into account several variables.

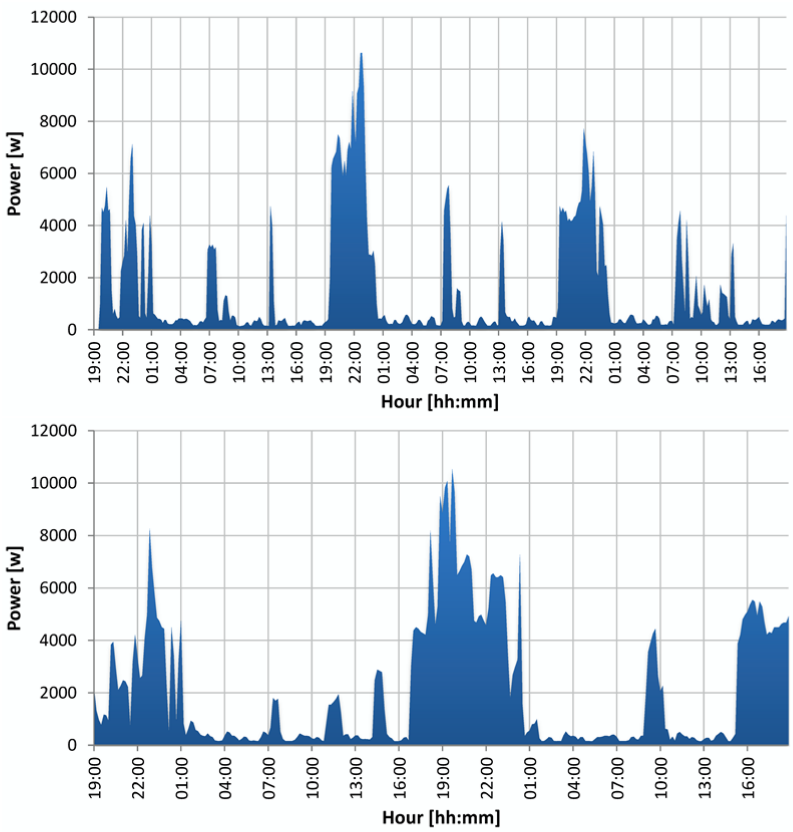

Figure 6: Load diagram for three weekdays (top) and for a weekend (bottom), for residence A.

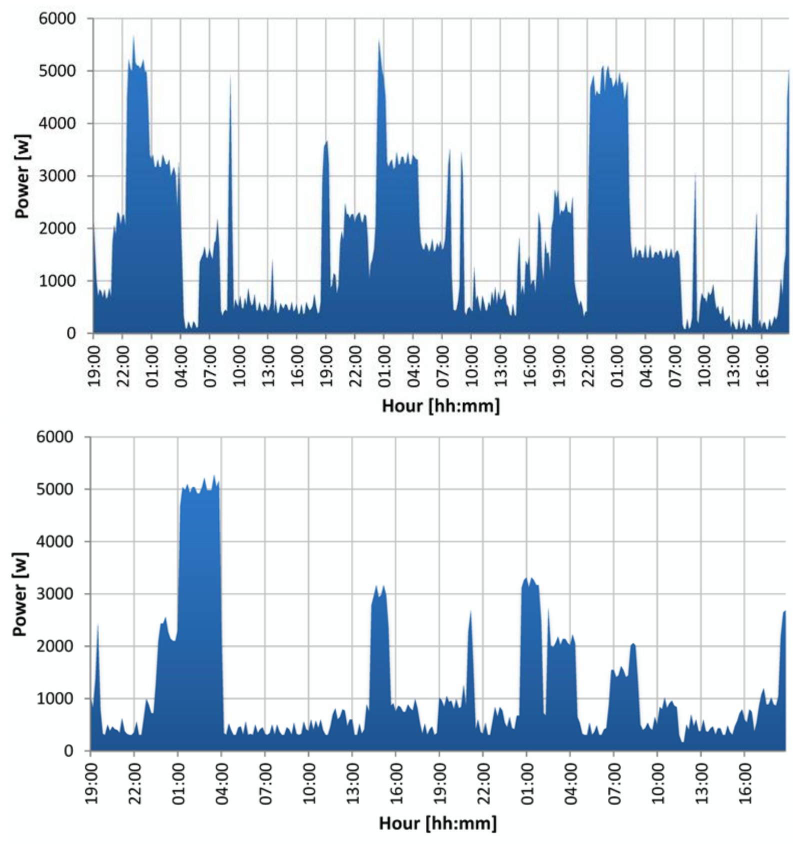

Figure 7: Load diagram for three weekdays (top) and for a weekend (bottom), for residence B.

To assess the impact that an EV can have in the energy and power consumption of a residence, the load profile during the charging cycle must be analyzed. Figure 8 presents the load profile of a Nissan Leaf for full charge and for a partial charge. The full charge absorbed 20.6 kWh of energy from the grid at an approximately constant rate of 3.6 kW during a period of five and a half hours. The profile of a partial charge is identical to the one of a full charge, except in the duration. This partial charge has absorbed 5.5 kWh during one and a half hour. For an EV with an energy consumption of 150 Wh/km, a charge of 20 kWh will provide a range of about 130 km, while a charge of 6 kWh will be suitable for 40 km.

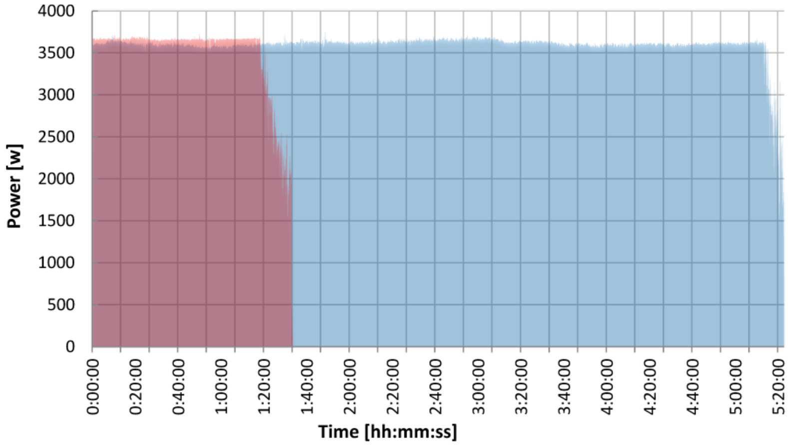

Figure 8: Charge profile for the Nissan Leaf over a full charge cycle (blue), with an energy consumption of 20 kWh over five and a half hours, and a partial charge cycle (red), with an energy consumption of 5.5 kWh over one hour and a half.

Figure 9 and Figure 10 present the impact of the additional load imposed by the EV in different scenarios, where the EV is plugged at 19:00 and must be fully charged at 08:00. The managed charge is based on the load forecast while the real load profile is presented for comparison. Figure 9 represents the impact of a partial unmanaged charge, where the vehicle starts charging when is plugged, and for a managed scenario, managed by the SMARTplug system.

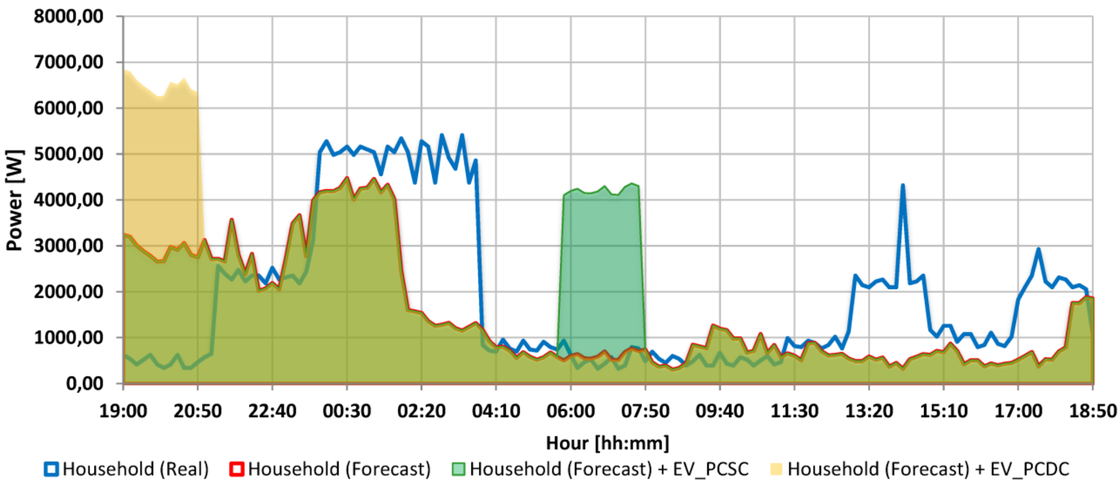

Figure 9: Load diagram (real and forecasted) for a household with an EV unmanaged (EV_PCDC) and managed (EV_PCSC) partial charge. The vehicle is plugged in at 19:00 hours and must be charged at 08:00. The charge takes two hours and consumes 7.2 kWh.

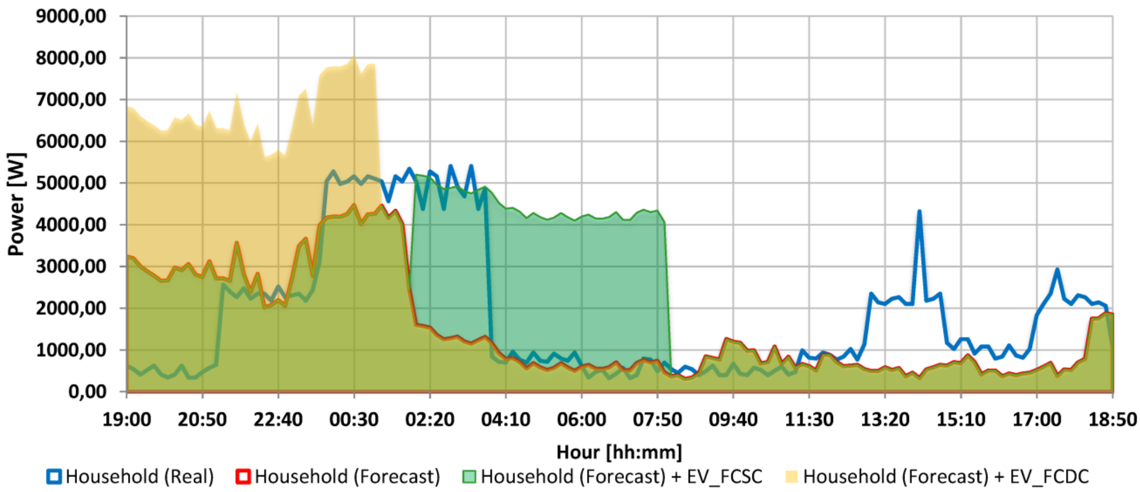

Figure 10: Load diagram (real and forecasted) for a household with an EV unmanaged (EV_PCDC) and managed (EV_PCSC) full charge. The vehicle is plugged in at 19:00 hours and must be charged at 08:00. The charge takes six hours and consumes around 21 kWh.

Observing Figure 9, it is noticeable that the managed charge has a better performance than the unmanaged charge since it will occur in the valley of the load diagram that take place during the night, when the energy is cheaper. The managed charge also reduces the peak power required to charge the vehicle, since it only tries to charge it when the forecasted power consumption for the household, in a given time period, is minimum. If the vehicle is plugged in only at 23:00 hours the peak power will be much higher and the household protections could be tripped due to overload. The benefit of a managed charge is more visible for full charge cycles where a large amount of power is drawn over a long period of time (Figure 10).

In this approach a simple forecast algorithm was used and by observing the load diagram from Figure 9 is noticeable that for given time periods the load forecast will not follow the real load accurately. This happens for periods where the load variation for a given time period is not very constant during the past days. Upgrading it to consider the different types of loads found in a household and include a model based on their use could improve the load forecast, however this approach would require a more extensive configuration of the system.

If multiple EVs are charge at the same time, the algorithm takes into account the charge plan of the remaining (their load is considered in the load forecast) vehicle. The system will give priority to the vehicles with tighter deadlines to achieve a pre-determined battery SoC. If a given vehicle cannot meet the user requirements, the user intervention is required to change the parameters.
